residues in the C*c*P variant with those responsible for binding Ca^{II}.[175] The success of conversion was confirmed by X-ray crystallography. In contrast to what was observed with the C*c*P variant containing K^+-binding site, the EPR signal and enzyme activity of the new variant are much more selective for Ca^{II} than for K^+.

B. Design by Inspection. While design through homology is effective in the design of new metal-binding sites, like protein redesign, it cannot address the roles of important residues that are common to both proteins. Metalloprotein design in proteins with little homology represents a new level of challenge. To meet the challenges, several methods have been applied, including design by inspection, through using automated computer search algorithms, and structural based design.

Design by inspection is the method of choice in early metalloprotein design without homology. It relies on the knowledge of both starting proteins and target metal-binding sites. In the simplest case, metal-binding sites were created by introducing a single amino acid, such as His and Cys, or a series of His residues. Then those conserved metal-binding motifs described in the metallopeptide section (Section 2.1) were inserted into a protein. Finally, an even higher level of metal-site design is apparent from work where two or more metal-chelation residues were introduced at specific locations. The work in introducing conserved metal-binding motifs into native protein scaffolds has been covered in Section 2.1 and Section 3.1. Here we focus mainly on incorporating two or more chelating residues in a special defined way. To create these metal-binding sites, more intricate design strategies were necessary. These sites were generally created either through a knowledge of secondary structure or by analyzing the three-dimensional structure of the target protein. Residues thought to be in close proximity and capable of binding were changed to histidine or cysteine and the success of the site was tested by experiments. In many cases it remained to be shown if all of the designed ligands actually coordinated to the metal ion. Despite this concern, the designed metal-binding sites have been used in a variety of applications such as elucidation of protein topology, increase in protein stability, aid in protein purification, regulation of enzyme activity and selectivity, and creation of new enzymatic activities.

To Elucidate Protein Topology. Numerous examples have been presented in the literature in which two His residues have been created at two different locations and then metal-binding used to identify helix position, orientation, or other types of protein topology.[23] For example, a transmembrane segment in the human dopamine transporter (hDAT) was probed with new metal-binding sites.[176] A bis-histidine site was created with a residue at position 375 plus neighboring residues. Inhibition of the transporter with Zn(II) coordination was observed only with histidine residues located at position 375 and those located at residue 371, 377, 378, or 379. The results from Zn(II) binding to the mutants suggested that the transmembrane segment was helical, ending at position 375 and then changing to another loop structure beyond there.

To Stabilize Proteins. Metal-binding sites were created between helices or domains in the same subunit, or between subunits of multimeric proteins to help stabilize their interactions. For example, a Leu58His mutation in one of the helices together with the naturally occurring His39 on a neighboring helix in iso-1-cytochrome *c* was used to chelate metal complexes, $[Ru(2,2'bipyridine)_2]^{2+}$,[177] or $[Cu(iminodiacetate)]^{2+}$,[178] which resulted in 16.5 and 5 °C increases in melting temperature, respectively, over the wild type protein.[177,178] Increase of thermal stability was also observed when a metal-binding site was incorporated between two domains of the serine protease trypsin.[179] Finally. cross-linking of the helices with Zn(II) sites were designed into the interface of two GFP variants, yellow (YFP) and cyan (CFP) fluorescent proteins to stabilize the heterodimer.[180]

To Aid in Protein Purification. In addition to the increase of protein stability, the His58/His39 chelating site of iso-1-cytochrome *c* later became an important part of a dual gene/protein system for the homologous expression and purification of nonfunctional cytochrome *c*.[181] Homologous expression of nonfunctional mutant proteins of iso-1-cytochrome *c* in yeast *Saccharomyces cerevisiae* lacking the wild type cytochrome *c* gene was not possible because the yeast cells lacking this essential electron transfer protein could not grow. A strategy was designed to overcome this problem by coexpressing both the nonfunctional cytochrome *c* variant and a functional cytochrome *c*.[181] To separate the two proteins of similar properties, a Leu58His mutation was made on the functional cytochrome *c* so that a bis-His site was formed with the His39 originally in the protein. The functional cytochrome *c* was then easily separated from the nonfunctional cytochrome *c* by a metal affinity column.

To Regulate Enzyme Activity and Substrate Selectivity. Engineered metal-binding sites have been used to control the activity and substrate specificity of enzymes.[23] For example, addition of Zn^{II} to the Arg96His variant of rat trypsin switched off enzyme catalysis, while subsequent addition of EDTA restored full activity.[182] The inhibition is due to Zn^{II}-binding to both the engineered His96 and the naturally existing His57, an important residue for catalysis. The metal-dependent stabilization of protein–protein interface is also used as a way to induce enzyme activation. For example, substitution of opposing residues at the dimer interface of glycogen phosphorylase to His allowed the use of a Ni^{II} ion to lock the enzyme in the dimeric form and activate the enzyme.[183] Furthermore, bis-His variants of trypsin were made around the substrate-binding pocket of trypsin to modulate substrate specificity by metal binding.[184–186]

To Create New Activities. Section 2.3.2 describes a few studies of using design by homology to create a Mn^{II}-binding site in cytochrome *c* peroxidase and lignin peroxidase that mimic a structurally homologous manganese peroxidase. A similar Mn^{II}-binding site has been created in myoglobin by inspection even though there is no homology between myoglobin and manganese peroxidase.[187] The Mn^{II}-site was created at the exposed heme edge of myoglobin through mutations of two Lys to Glu. The resulting protein exhibits increased manganese peroxidase activity.

C. Design using Automated Computer Search Algorithms. To help design new metal-binding sites in proteins with little structural homology between the starting and target proteins, a number of computer algorithms have been written. Among several of these reported algorithms, two programs called Metal-Search[188] and Dezymer[189] have been the most successful in guiding metalloprotein design. Both Metal-Search and Dezymer algorithms make predictions based on strict geometric principles.[190] They assume a fixed protein backbone and search for optimal locations of ligands using different amino acid side chain rotamers. In the Metal-Search program, the idealized metal positions at every residue, including its side chain and rotamer are precalculated and those substitutions that result in idealized metal positions near each other are then grouped and evaluated. The Dezymer program, on the other hand, starts with an anchor point of an amino acid substitution with a selected rotamer, and systematically searches for additional coordinating residues that can satisfy the desired geometry of the designed site. Once a site and its substitution are identified, other changes in the surrounding area may be needed to avoid steric conflicts and to optimize packing of the site. In its current form, the Metal-Search program is used mainly for design of tetrahedral metal-binding sites while the Dezymer program is more versatile in this regard. Discussed below are several successful examples.

Design of A Tetrahedral Zn^{II}-Binding Site Containing Cys and His. Using the Metal-Search program, a tetrahedral His_3Cys metal-binding site has been designed into the B1 domain of IgG-binding protein G.[191] Solvent-exposed residues were chosen as places to put ligands in order to avoid major perturbations to the overall structure of this small, 56-residue scaffold. In addition to the four metal ligands, additional mutation of a residue that was in a predicted steric conflict with one of the introduced histidines was also carried out. In a complementary approach, several tetrahedral Zn^{II}-binding sites have also been designed into the deeper hydrophobic core of thioredoxin using the Dezymer program.[192] Spectroscopic studies showed that the designed proteins by both programs bind metal ions in the predicted tetrahedral environment and prefer binding Zn^{II} over Co^{II} by 100- to 1000-fold. With estimated constants on the order of a few nanomolar, the strong binding affinity in both studies is remarkable for a designed protein.

The importance of the secondary coordination sphere in improving metal-binding affinity has been demonstrated in one of the designed proteins.[193] Inspired by the work of Christianson and Firke's groups on the study of zinc protein carbonic anhydrase,[8] Marino and Regan placed Glu, Gln, Asp, or Asn close to each of the three histidine ligands in the designed $Zn(II)His_3Cys$ tetrahedral site of the B1 domain so that they could form hydrogen-bonding interactions with the imidazole nitrogens of the histidine ligands. These mutations resulted in 1.5- to 6.4-fold enhancement of affinity. Double mutations in the secondary coordination sphere resulted in even further enhancement and the effects appeared additive. An intriguing find from the study is that the above mutant proteins with enhanced metal-binding affinity unexpectedly shared little secondary structure with the parent protein, probably because many of the mutations caused major perturbations of the protein scaffold.

Design of iron–sulfur clusters. The mononuclear $[Fe(Cys)_4]$ rubredoxin center has been designed into native protein scaffolds using both the Metal-Search[194] and Dezymer[195] programs. The Dezymer program was used to convert a disulfide bond in thioredoxin to a mononuclear $[Fe(Cys)_4]$ rubredoxin center (Figure 17a).[195] The protein was capable of undergoing several successive cycles of air oxidation and reduction by β-mercaptoethanol.[195] In another study, the Metal-Search program was used to design the same mononuclear $[Fe(Cys)_4]$ center into the B1 domain of the IgG-binding protein G.[194] From these studies, Farinas and Regan recognized a limitation of the Dezymer and Metal-Search programs. Both programs used the fixed backbone of protein coordinates from either X-ray or average NMR structures. Small backbone movements can occur in solution and are sometimes necessary to accommodate slight changes associated with introducing new amino acid ligands. Therefore, the authors decided to select at random six out of 60 calculated NMR structures to apply the Metal-Search program.[194] Indeed, they found that, while certain sites can be identified in both the average and the individual structures, some sites could only be found in the individual structures. Since this strategy does not change the program algorithms, it can be applied to protein design using other programs or computer modeling packages. More study using this strategy is needed to find out how useful it is in metalloprotein design.

Most of the design of metal-binding sites has been limited to mononuclear centers. The design of tetranuclear $[Fe_4S_4]$ clusters into proteins represents a new challenge. In this case the Dezymer program was used to search for backbone positions of thioredoxin to place Cys side chains to match the $[Fe_4S_4]$ structures of a HiPIP protein.[197] In addition, two cysteines in the native thioredoxin were removed to avoid their competing chelation. A final isosteric Asp-to-Leu mutation was also included to improve the stability of the designed protein. The successful design of the center in thioredoxin was supported by the optical and EPR studies that showed similar

spectral signatures as that in HiPIP proteins. Furthermore, the $[Fe_4S_4]$ cluster was much more stable in the designed protein than when it was free in solution.

Design of A Calcium-binding Protein. A Ca^{II}-binding site has been introduced into a noncalcium-binding protein, domain 1 of the rat cell surface adhesion receptor CD2 using the Dezymer program (Figure 17b).[196] A survey of a number of calcium-binding proteins indicate that, despite the great diversity in the composition of ligand residues and bond angles and lengths of calcium-binding sites, common local structural parameters can be used to identify and design calcium-binding proteins, the most common geometry being pentagonal bipyramidal.[198] The defined parameter was used to search for locations in CD2. The resulting candidates (~7000) from the program were further filtered by several known criteria for calcium-binding sites, such as solvent accessibility, side-chain steric conflict, hydrogen bonding, hydrophobic, and electrostatic environment around the designed site. The final designed protein selectively binds Ca^{II} over Mg^{II} with Ca^{II}-binding affinity comparable to that of natural extracellular calcium-binding proteins (K_d of 50 μM).[196]

Design of A Blue Copper Center. Design of a blue copper center in proteins represents a still further challenge in metalloprotein design. For most successful examples of metalloprotein designs described so far, construction of a geometrically correct, sterically compatible primary coordination sphere was sufficient to reproduce the dominant features of the structure and function of the desired centers. However, certain metal-binding sites in proteins are unique in that metal ions are not necessarily in their preferred state and, to design such sites correctly, special caution has to be taken to prevent many alternative reactivities and coordination geometries.[199] Type 1 blue copper centers are a primary example. These centers contain a mononuclear copper with $CysHis_2$ in a trigonal plane and another weak axial ligand, usually Met (Figure 15a). Since this geometry is not preferred by either Cu(I) or Cu(II), blue copper proteins display many unusual spectroscopic properties, such as an intense blue color and very small $A_{\parallel}$ in electron spin resonance spectroscopy. In addition to the challenge of designing a site that allows incorporation of copper ions into a geometry that is not preferred, the assembly of the designed protein has to overcome the alternative reactivity of disulfide bond formation between proteins. This competing reaction is especially efficient in the presence of redox active metal ions such as Cu(II). Despite these complications, the Dezymer program was used to carry out a series of four primary designs and 32 variants.[189,199,200] The most successful variant of the designed thioredoxin was able to mimic the type 1.5 copper center after a strong, exogenous ligand, azide, was introduced axially into the designed center. By using an iterative strategy of design, characterization, and evaluation, the author provided many valuable insights into the metalloprotein design process. These included the need to surround the designed primary coordination sphere with a hydrophobic shell to ensure the absence of potential alternative coordinating residues or even solvent (water) and the requirement of forming a strong Cu(II)-thiolate bond in order to destabilize disulfide bond formation. It demonstrated that negative design (i.e. destabilization of competing reactions and coordination) is a crucial aspect of the protein design process.

Design of Mononuclear Nonheme Iron Centers with Catalytic Activities. Perhaps the biggest challenge in protein design is the introduction of catalytic activity into proteins, which requires a careful design of open coordination sites for binding small molecules like O_2, as well as substrates. Using the X-ray structure of the trigonal bipyramidal iron site in iron superoxide dismutase (SOD) as a guide, Pinto *et al.*[201] used the Dezymer program to search thioredoxin and

identify positions to place one Asp and two His in a plane. Another His at the axial position was also chosen so that an open coordination site was created on the opposite end. Additional mutations were introduced to prevent competing chelation by two internal cysteines and one histidine and to improve packing for the designed site. The electronic absorption spectrum of the designed protein as well as its N_3^- and F^- adducts are similar to those of native iron SOD and the iron has a dissociation constant of less than 1 μM. More importantly, comparative studies with the unrelated *E. coli* iron SOD indicated that the designed protein can catalyze superoxide dismutation with a rate on the order of 10^5 $M^{-1}s^{-1}$. Even though the catalytic rate is still about 10^4 fold slower than the native SOD, the rate is quite impressive considering that many of the long-range structural features in the native SOD have not been introduced into the designed protein.

The above work was extended by Benson *et al.*,[202] who designed six mononuclear iron-binding sites with three histidines and at least one open site at three different locations of thioredoxin. Unfavorable steric clashes were eliminated through further mutations. In almost all cases, the designed proteins were found to bind one Fe(III) with a K_d less than 5–10 μM. Two of the designs exhibit SOD activities appreciably above the background, with one of them approaching 1% of native *E. coli* SOD activity. An apparent correlation between the SOD activity and the number of positive charges in the vicinity of the designed site was also noted. This observation confirms the importance of electrostatic interactions between the superoxide anion and protein side chains in SOD activity.

D. Design using a Combination of Strategies. So far we have discussed two approaches to designing new metal-binding sites in proteins with little structural homology. Design by inspection relies heavily on the knowledge of the designer while design using automated computer algorithms requires correct input of parameters to define unique metal-binding sites. Owing to lack of knowledge, a number of metal-binding sites, such as blue copper proteins and heteronuclear metal assemblies (e.g. heme-copper centers) remain difficult to define and application of the automated computer algorithms have not been successful. The third approach uses a combination of the two strategies, by combining visual inspection of proteins to find proper locations for creating new metal-binding sites, and computer program evaluation for the energetics of positioning appropriate amino acid residues. It is most suitable for creating new metal-binding sites where location of the site is fairly certain from previous knowledge or study. As in the design by inspection approach, this approach uses previous knowledge to locate the site and thus bypasses the exhaustive search process of theoretical approaches. At the same time, this approach uses similar rigorous methods for evaluation of energetics of positioning appropriate amino acid residues for the site formation.

Design and Creation of A New Metal-binding Site in Antibodies and Green Fluorescent Proteins. Both antibodies and green fluorescent proteins have found wide applications in biology. Engineering metal binding into either protein would be an interesting way of increasing their functional diversity. By examining the morphology of Zn^{II} sites in PDB structures of carbonic anhydrase and carboxypeptidase, and then the structure of the anti-fluorescein antibody 4-4-20, multiple potential Zn^{II} sites were identified.[203] Many of the designed proteins successfully bound Zn^{II} in addition to other divalent metal ions. It remains to be seen if the sites can successfully catalyze a reaction. One particular protein was also used as a metal-ion sensor.[204] Similarly, work towards using the green fluorescent protein (GFP) as a metal-ion sensor was accomplished by creating a metal-binding site on its surface.[205] The coordination of metal ions in these designed proteins resulted in quenching of the protein's fluorescence. The first round of design was a bis-histidine site that loosely bound Ni^{II}. The second round of design involved the addition of a third metal-coordinating residue, aspartate. This variant yielded an effective metal site for Cu^{II}, Ni^{II}, or Co^{II} with binding constants in the low micromolar range.

Design and Creation of a Cu_B Center in Myoglobin and Cytochrome c Peroxidase: Toward A Novel Heme-copper Oxidase. Heme-copper oxidases (HCO's) are a superfamily of terminal oxidases in the respiratory chains of both eukaryotic mitochondria and bacteria (*see* ***Cytochrome Oxidase***). At the heart of these enzymes is a dinuclear center consisting of a heme with a proximal histidine and a Cu(II) with three histidines (Figure 18). One major difference between heme-copper oxidases and other heme proteins is the presence of the Cu(II), called the Cu_B center. It would be quite interesting to find out how to design and engineer a Cu_B center into other heme proteins at a similar location with respect to the heme center, and whether the presence of the new Cu_B center can transform heme proteins such as globins and peroxidases into an oxidase. Toward this goal, the Cu_B-site

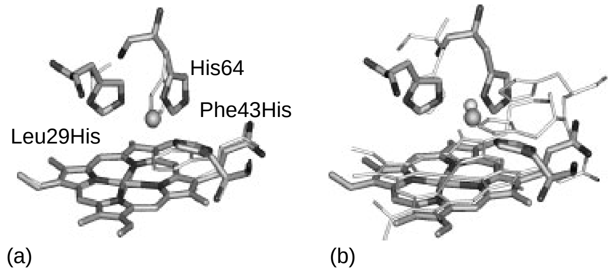

Figure 18 (a) Overlay of the crystal structure of WTMb (thin) and the a structural model of Cu_BMb based on computer modeling and energy minimization (thick); (b) Overlay of the crystal structure of heme-cooper center in C*c*O (thin) and the same structural model of Cu_BMb (thick) as in (a). (Reprinted with permission from Ref. 207. © 2000 the American Chemical Society)

has been designed into both cytochrome *c* peroxidase[206] and myoglobin.[207] It was accomplished through a careful overlay of the heme-copper center in cytochrome *c* oxidase (C*c*O) with the heme site in either C*c*P or Mb (Figure 18). Different orientations of the C*c*P/Mb active-sites were sampled until an appropriate match of residues in C*c*P/Mb to the histidine ligands of the Cu_B-site in C*c*O were found. The matched residues in C*c*P/Mb were then mutated to histidines and the energetic parameters after energy minimization of the resulting proteins were evaluated and compared with the parameters of wild type proteins. Spectroscopic studies confirm the creation of a single Cu(II)-binding site in both Mb and C*c*P. In addition, the study also revealed that the presence of Cu(II) and Ag(I) (as a Cu(I) mimic) increased the affinity of heme for diatomic ligands such as CN^- and O_2. More importantly, further studies showed that the Cu_B center plays a critical role in O_2 binding and reduction, and proton delivery during the O_2 reduction is important to avoid heme degradation and to promote the HCO reaction.[208]

3 RATIONAL DESIGN: MODULAR APPROACH

In addition to the consensus sequence/structure approach described above, the modular approach is also very effective in designing new metalloproteins. This approach involves transplanting a conserved structural unit from one protein into another. It is commonly used by Nature to create new structures and functions since gene shuffling and recombination is often observed in biological systems. Therefore learning this ‘trick’ is an important step in metalloprotein design and engineering.

3.1 Application to Metallopeptide Models

Zinc finger proteins (*see* ***Zinc: DNA-binding Proteins***) are a good example where the modular approach can be applied, since the proteins almost always contain two or more zinc finger domains, which have to work together to achieve high activity (i.e. DNA binding). It has been shown that one zinc finger domain interacts primarily with three base pairs of DNA; the identity of amino acids at the −1, 2, 3 and 6 positions (numbered relative to the start of helix) defines the specificity of the DNA base pairs they recognize. Three zinc finger domains can recognize nine base pairs. By swapping one zinc finger domain with another, the specific DNA sequences that the zinc finger proteins can recognize have been altered. A number of these designed zinc finger proteins have already been applied as artificial transcription factors for different DNA sequences.

Incorporating common structural motifs such as the His- and Cys-containing motifs and the zinc finger domain discussed above onto other proteins has resulted in new hybrid proteins with dual functionality. Two strategies have been used to achieve this goal. In the first strategy, the metal-binding motifs or domains are fused by a linker to either the N- or C-terminus of another protein. For example, the Ni^{II}·Xaa-Xaa-**His** peptide (see Section 2.1.1) has been fused onto the N-terminus of the DNA-binding domain of Hin recombinase and the resulting hybrid metalloenzyme can carry out sequence specific (due to Hin recombinase) oxidative cleavage (due to Ni^{II}·Xaa-Xaa-**His** peptide). The incorporation of a series of histidines (∼4–6 residues) at the N- or C- termini of proteins formed functional metal-binding sites. It is an efficient way of creating nonspecific metal sites of relatively high binding affinity. The histidine repeats, including histidine tags, are widely used in protein purification with the technique called immobilized metal affinity chromatography (IMAC),[209] to sense or remove metal ions, or to immobilize proteins to a surface for structure determination. Finally, site-specific DNA methylases or restriction enzymes have also been obtained when the zinc finger domains were combined in this way with *S*-adenosyl methionine-dependent methylase or the type IIS restriction enzyme *Fok*I, respectively.

In the second strategy, metal-binding structural motifs are crafted in the middle of another protein domain that shares similar structural homology. For example, an arginine-rich α-helix from HIV-1 Rev was engineered into the zinc finger framework by replacing the α-helix of the zinc finger protein while keeping the metal-binding histidine ligand (Figure 19a).[210] The new hybrid protein can now bind RNA (HIV-1 Rev response element) instead of DNA in a Zn^{II}-dependent manner. The His-X_3-His motif (Figure 1b) can be incorporated into proteins with only a few residue substitutions.[209,211] For example, the His-X_3-His motif was engineered into T4 lysozyme to aid the determination of distances between residues by measuring the EPR relaxation of a nitroxide spin label attached to a cysteine by a Cu^{II} ion

bound to the engineered His-X_3-His motif.[212] The His-X_3-His arrangement was also engineered into iso-1-cytochrome *c* through Lys4His/Thr8His mutations to create a more stable variant resistant to thermal and chemical denaturation,[178,213] and to aid in protein separation in the presence of metal ions.[214]

The EF-hand calcium-binding motif was engineered onto a loop in human lysozyme for increased stability,[216] or between two green fluorescent protein (GFP) variants to form an effective calcium sensor.[217,218] Interestingly it has been recognized that the EF-hand Ca^{II}-binding motif and a helix-turn-helix DNA-binding motif are almost superimposable (Figure 19b).[215] By crafting ligands to the Ca^{II} site into the helix-turn-helix motif and replacing Ca^{II} with lanthanide, a sequence-selective peptide nuclease has also been obtained.[210,215,219,220]

3.2 Application to Designing Metal-binding Site in De Novo Designed Proteins

A demonstration of the modular approach in de novo designed proteins appeared in 1996, in which a metallopeptide model of a ferredoxin-like [4Fe-4S] cluster (described in Section 2.1.2) has been incorporated into the loop region of a de novo designed di-heme protein (described in Section 2.2.1).[31] Normally the loop regions of the four-helix bundle proteins play a structural role. By replacing the loop of the de novo designed di-heme proteins with conserved loop derived from ferredoxins, a multicofactor metalloprotein containing [4Fe-4S] cluster at one end and a di-heme center in the middle was obtained. This approach has been extended to design bridged [Ni^{II}-(μ_2-S_{Cys})-Fe_4S_4]-containing assembly into the four-helix bundle.[221] In the design, the Fe_4S_4 ferredoxin motif [Cys-Ile-Ala-Cys-Gly-Ala-Cys] was used, with the fourth cysteine positioned to serve as the bridging ligand between the cluster and Ni^{II}. Three other binding residues (either N_3S (His_3Cys) or N_2S_2 (His_2Cys_2)) were incorporated in appropriate positions to constitute a binding site for Ni^{II}. Finally, the template-assisted assembly of metalloproteins described in Section 2.2.1 may also make the modular design possible. For example, the cyclic peptides containing four cysteines with different protection groups allow coupling of different peptides with different functional groups. In this way different metal-binding centers can be attached to different peptides.

3.3 Application to Designing Metal-binding Site in Native Protein Scaffolds

3.3.1 *Gene Shuffling and Recombination*

Gene shuffling and recombination has been used as a tool to engineer heme proteins. This research endeavor is aided by identification of exons and their corresponding protein structural units called modules.[222,223] For example, human hemoglobin contains two α- and two β-subunits. Amino acids associated with the $\alpha_1\beta_1$ interface are located in a single module. Replacing this module from the β-subunit with the module in the α-subunit resulted in a chimeric hemoglobin that binds preferentially to the β-subunit.[224] Furthermore, a heme-binding module was also identified. Substitution of the heme-binding module in myoglobin with that in α-subunit of hemoglobin makes the heme environment of the chimeric myoglobin resemble more of α-subunit of hemoglobin, including the orientation of proximal His.[225] These successes suggest small structural modules can be defined and used for design and engineering of metalloproteins.

3.3.2 *Loop-directed Mutagenesis*

On average, loops account for ~30% of globular protein structural elements. They are highly tolerant of amino acid replacement, insertion, and deletion; this feature makes it an ideal place to design different metal-binding sites without changing or disrupting the overall scaffolds of the proteins. Therefore a number of metal-binding sites are in between loops, and transplanting the active site in the loop from one protein into another can be a general approach of designing novel proteins. Analogous to site-directed mutagenesis, the replacement of one loop with another loop is termed loop-directed mutagenesis (LDM).

Grafting of Calcium-binding Loop to Increase Stability. In a complementary approach to using automated computer algorism to designing Ca^{II}-binding sites in domain 1 of the rat cell surface adhesion receptor CD2 (see section 'Creation of A New Mn(II)-binding Site in Peroxidases: Toward A New Manganese Peroxidase'), the EF-hand calcium-binding loop III from calmodulin was inserted with glycine linkers into the same protein and shown to bind Ca^{II}.[226] To increase protein stability, the Ca^{II}-binding ω loop containing 10 amino acids in thermophilic thermolysin was introduced into homologous mesophilic neutral protease to replace a seven-residue loop in the corresponding position.[227] While maintaining similar activity as the native enzyme, the designed neutral protease binds a new calcium ion with a K_d ~0.1 mM, and was 2-fold more stable than the native protein in the presence of Ca^{II}. Similarly, replacing a loop in mesophilic subtilisin BPN′ with the corresponding Ca^{II}-binding loop of a homologous thermophilic thermitase resulted in a new Ca^{II}-binding site with a K_d ~0.1 mM, and 10-fold more stability to irreversible inactivation at 60 °C.[228]

Introduction of Metal-binding Loop to Regulate Activity. In an extension of their work on metal-ion regulation of enzyme activity (see section 'Creation of A New Zn^{II}-binding Sites'), Halfon and Craik succeeded in regulating trypsin activity by introducing a metal-binding loop from its homologous protein called tonin.[229] Based on computer modeling, two histidines in the loop, together with the

catalytic histidine of trypsin, could complex metal ions. Addition of Cu^{II}, Ni^{II}, or Co^{II} ions to the engineered protein substantially inhibited the proteolytic activity of trypsin and the inhibition can be fully reversed by removal of the metal ions using EDTA. Significantly, LDM made it possible to create a tridentate histidine ligand set, resulting in much higher metal-binding affinity (~100 nM for Cu(II)) and tighter regulation of enzyme activity than the previously reported bidentate histidine ligand sets based on site-directed mutagenesis.

Incorporation of Metal-binding Loop to Create New Functionality. LDM can also be used to introduce new metal-binding sites and functionality into proteins. This principle has been demonstrated in several cases of protein design study based on the Greek key β-barrel scaffold. For example, it was recognized that subunit II of cytochrome *c* oxidase (C*c*OII) was structurally and functionally homologous to the CyoA subunit of cytochrome *o* quinol oxidase, and shared the same Greek key β-barrel fold. However, the CyoA did not contain the Cu_A center as in C*c*OII. A careful sequence alignment revealed that the amino acids capable of forming the Cu_A center were replaced by those that could not coordinate copper and those amino acids were clustered in a loop between two β strands F and G (called the FG loop) (Figure 20).[230] Replacing the whole loop sequence of CyoA with the corresponding loop sequence of C*c*OII restored the Cu_A center.[230]

Similar sequence alignments also revealed that C*c*OII shared similar structural homology with the mononuclear type 1 blue copper proteins and the main difference between the two families of proteins resided in the FG loop sequence (Figure 20).[230–233] The conversion of the blue copper center into a Cu_A center using LDM is more challenging because the blue copper protein had to accommodate not only the extra copper ion, but also the longer C*c*OII FG loop. The LDM was successfully carried out in azurin[233,234] and amicyanin[232,235] (Figure 20). The X-ray structures of the engineered Cu_A center in CyoA[236] and in azurin[237] indicated that, with the exception of the FG loop region, the protein backbones of the engineered proteins were superimposable on that of the wild type proteins. Azurin was able to accommodate the insertion of extra amino acids and the additional copper ion by a simple 'breathing' motion of ~3 Å.[237] These findings are encouraging because they suggest that protein scaffolds can be rigid enough to withstand large changes in the loop region, and at the same time are fluid enough to accommodate incorporation of new and very different metal-binding sites. Therefore, in addition to its value in protein design, LDM may be a general way to introduce metal-binding sites with known sequences but unknown structures into a well-characterized protein for facile spectroscopic and X-ray crystallographic study. Indeed, LDM was used to convert one blue copper protein into another blue copper protein with different spectroscopic and redox properties,[238] and from a Cu_A center in C*c*O to a blue copper protein.[239]

4 COMBINATORIAL DESIGN

While the rational design approach described above is an effective tool for optimizing and altering protein function, one drawback is that the structure and mechanism of the proteins to be designed must be understood. Unfortunately, the number of structures in the protein databases is increasing dramatically and our knowledge about protein structure and function is quite limited. Furthermore, it is extremely difficult to predict long-range effects of residues far from the active site on structure and function. More studies show that those long-range effects are important in protein design. Design

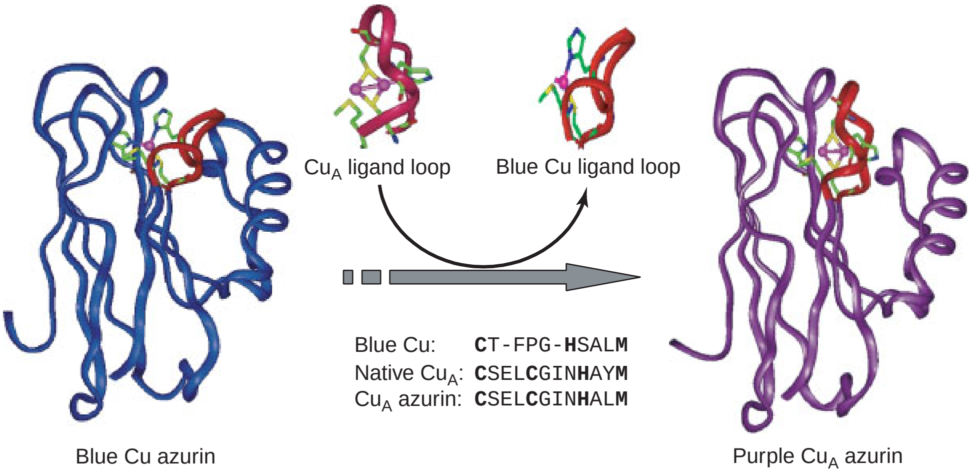

Figure 20 Schematic illustration of engineering the Cu_A center into azurin through loop-directed mutagenesis.

through combinatorial and evolution methods requires little prior knowledge of the protein structure.

4.1 Application to Metallopeptide Models

While rational designs have enjoyed much success on well-characterized proteins, it has been difficult to apply the same principles to proteins with unknown structure or function. For example, zinc finger peptides have been designed based on consensus sequence to recognize certain DNA sequences specifically. The modular approach has expanded the DNA sequences zinc finger proteins can bind by domain swapping (see Section 3.1). However, the range of DNA sequences that the designed protein can recognize is still limited as only a limited number of zinc finger proteins are known and key structural features responsible for binding a specific DNA sequence have been elucidated in only selected cases. In addition, even if new zinc finger proteins have been designed, the binding affinity and selectivity may not be optimal. Therefore, new zinc finger proteins have been obtained through a phage display method, where proteins of interest are presented on the surface of phage. By randomizing residues in contact with DNA and selecting those proteins with the highest affinity for a given DNA sequence, zinc finger proteins have been selected to recognize new DNA sequence with high affinity and selectivity.[28,240,241] The selected protein bound the target DNA with high affinity (nanomolar dissociation constants) and specificity (greater than 20 000-fold discrimination against nonspecific DNA). Interestingly, some of the selected zinc finger proteins have been tested in cell cultures and were shown to block DNA transcription.[242]

4.2 Application to Designing Metal-binding Site in De Novo Designed Proteins

The template-assembled synthetic protein based on cysteine-containing cyclic peptides was described in Section 2.2.1 as an effective approach for modular design of helical bundle proteins that bind heme and other cofactors. This system has also been used to generate combinatorial libraries of helical bundles to select for the most stable variants that bind heme[243] or copper.[244] Instead of varying every amino acid in every positions of the four helices, the authors restricted variation to only those hydrophobic amino acids of different sizes and a few polar ones (Gly, Ala, Val, Leu, Ile, Phe, Tyr, and Gln) and only at positions that form the hydrophobic core of the helix bundle. For the copper protein library, potential ligands of His residues and a single Cys residue were positioned next to each other in the hydrophobic core. In addition, residues adjacent to these ligands were also varied to optimize packing and prevent Cys oxidation. This combination of rational design principle with combinatorial protein assembly makes the libraries manageable (462 combinations of two of the four helices for the heme protein library and 96 combinations of three of the four helices for the copper protein library). Screening by UV-vis absorption spectra resulted in heme proteins with a more positive midpoint potential than that of the de novo designed heme proteins. The selection also resulted in stable copper-thiolate proteins with UV-vis and EPR spectra similar to the redesigned CuZnSOD when a Cys is introduced into the tetragonal copper center (see Section 2.3.1).[135,139]

While the above work was designed to bind metal cofactors specifically, work from the Hecht group has shown that it is possible to obtain heme proteins from libraries that were not explicitly designed to bind heme.[245] The group has demonstrated the design of libraries of helical proteins based on ‘binary patterning’ of polar and nonpolar amino acids, which create amphipathic segments of secondary structures with one face containing only polar residues and the other face containing only nonpolar residues. Surprisingly half of the 30 members of binary libraries could bind heme with a broad range of affinities and with spectroscopic features resembling those of natural cytochromes, even though no selection for binding was performed.[246] The library did include potential heme-binding ligands such as His and Met residues. More interestingly, the heme proteins from the library were shown to bind CO with kinetic association and dissociation rates similar to those of natural heme proteins.[247] Several of them exhibit peroxidase activities, the best of which had a catalytic turnover rate approaching that of horseradish peroxidase (only 3.5 times slower).[248]

4.3 Application to Designing Metal-binding Sites in Native Protein Scaffolds

Selection of Metalloproteins Through Phage display. Similar to selection of zinc finger peptides (see Section 4.1), variants of carbonic anhydrase containing random mutations in the hydrophobic residues surrounding the metal-binding site have been displayed on phage.[249] Those with high metal-binding affinity have been selected and enriched, and consensus residues at each position were identified. A correlation between the dissociation constant and catalytic activity of the variants and the volume of the amino acids at selected positions were noted.

Search for New Metallo-antibodies. In an approach that is complementary to the rational design of metal-binding sites in antibodies (see Section 2.3.2), preparing antibodies against metal complexes such as metalloporphyrins or the transition state analogs of the reactions they catalyze has resulted in new metalloproteins with catalytic functions. For example, monoclonal antibodies have been prepared using metalloporphyrin,[250,251] or transition state analogs of porphyrin metallation[252] as antigens. The antibodies isolated were found to bind the antigen metal complexes more tightly than other similar complexes.[250] More importantly, by choosing the porphyrin antigens carefully, several groups have

been able to obtain metalloporphyrin-containing antibodies that can catalyze a variety of reactions such as porphyrin metallation,[252] electron transfer,[253,254] peroxidation,[255–261] mono-[251,262,263] and dioxygenation.[264]

Directed Evolution of Heme Enzymes. Directed evolution of horse heart Mb has been carried out to select variants with enhanced peroxidase activity.[265] After subjecting the Mb gene to several cycles of PCR random mutagenesis, the expressed variants were selected against a low concentration of a common peroxidase substrate (2,2-azino-bis-(3-ethyl)-benzothiazoline-6-sulfonic acid (ABTS)). Among the selected variants, one variant contains four substitutions in the heme pocket and exhibits ~25-fold higher peroxidase activity than WTMb. In another study, directed evolution of cytochrome P450 was carried out to improve its hydroxylation reactivity by more than 20-fold over that of the native enzyme.[266] The investigators were able to efficiently screen for the improved variant P450s by coexpressing them with horseradish peroxidase, which converts the products of the P450 reaction into fluorescent compounds amenable to digital image screening.[267] In both studies, the mutations found in the selected variants with enhanced activities were not obvious and would have been difficult to uncover using a rational design approach.

5 DESIGN OF METALLOPROTEINS WITH STRUCTURES AND FUNCTIONS UNPRECEDENTED IN NATURE

As shown in the above sections, important progresses have been made in designing metalloproteins that closely mimic those in nature. However, natural metalloproteins use only 20 amino acids, only less than 10 of which are potential metal ligands. Furthermore, they employ only a small sub-set of metal ions listed in the periodic table and of metal-containing prosthetic groups synthesized by inorganic chemists. Therefore introducing unnatural amino acid and nonnative metal ions or metal-containing prosthetic groups into a designed protein can dramatically expand the repertoire of its functionalities and thus its range of applications.[268]

5.1 Introducing Unnatural Amino Acids into Metal-binding Sites of Designed Proteins

Since solid-state peptide synthesis is commonly used in both peptide models and de novo designed proteins, introducing unnatural amino acids is relatively straightforward, as one can replace the natural amino acids with unnatural ones in the synthesis. One nice example is replacing bis-His ligation with bis-pyridine ligation to heme in a de novo designed four-α-helix bundle, through incorporation of 4-β-(pyridyl)-L-alanines in place of His residues.[269] The ligation change resulted in 287 mV change in heme reduction potential.

Introducing unnatural amino acids into native proteins is more challenging when the proteins are used as scaffolds for metalloprotein design because of its size. A classic way is global replacement of one type of natural amino acids in the protein with an unnatural amino acid when growing cells lacking the particular amino acid (called auxotroph) and supplementing with an analog of the natural amino acids. For example, all of the Met residues in azurin[270] and cytochrome P450[271] have been replaced by selenoMet and Norleucine, respectively, using a Met auxotroph supplemented with the replacement amino acid. The approach is restricted by which amino acids can be replaced and by the analogs available. The location of replacement is also not specific as all of the natural amino acids of a given type will be replaced. A more specific way of introducing unnatural amino acids is by cavity complementation.[272] This approach involves replacing one of the metal-ion ligands with either Gly or Ala to create a cavity. Addition of exogenous ligands of the appropriate size and character complement the cavity created by the replacement. For example, different ligands have been introduced into a cavity created by replacing the promixal His ligand in both myoglobin[273] and cytochrome *c* peroxidase.[274] However, the cavity complementation approach is useful only when a cavity can be generated with enough rigidity and the added unnatural ligand has strong enough affinity to the cavity because the ligand is not covalently linked. If one wants to introduce unnatural amino acids covalently linked to other residues, one effective approach is to synthesize the proteins in smaller pieces, and then use the recently developed technique called native chemical ligation to join the peptides together forming a native peptide bond at the junction. This technique has been used by Low and coworkers to probe the roles of aromatic residues in rubredoxin,[275] the backbone amide-ligand interactions in High-Potential Iron Proteins,[276] and heme axial ligand in cytochrome b_{562}.[277] For large proteins, chemical synthesis of peptides can be quite expensive and low yielding. Another high cost and low yield system is the use of tRNA molecules charged with unnatural amino acids during in vitro translation.[278] Extension of the system in vivo has resulted in significant saving in cost and increase in yield.[279] However, only certain analogs of natural amino acids can be incorporated using the method. Therefore few applications of such methods in metalloproteins have been reported.

Semi-synthesis where a bacterially expressed peptide is coupled with a synthetic peptide containing the unnatural amino acids is a nice balance between the costs and efficiency because large quantities of large peptides are expressed in bacteria at low cost.[91,92] Recent progress with the expressed protein ligation (EPL) method, enables the coupling without the requirement of protecting groups thus increasing overall yields.[280] The only limitation is the requirement of a cysteine residue at the union of the

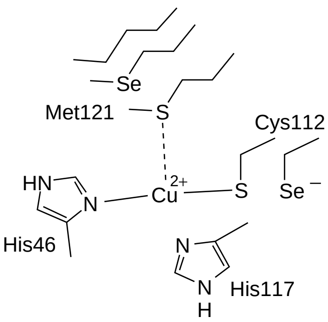

Figure 21 Introducing unnatural amino acids into type 1 blue copper azurin to fine-tune the properties with minimal structural perturbation

expressed protein and the synthetic peptide containing the unnatural amino acid. This limitation may be removed with innovative methods developed recently.[277,281] Using this method, both Cys and Met ligands in type 1 blue copper Azurin have been replaced specifically with selenoCys[282] and selenoMet/norleucine,[283] respectively (Figure 21). This allowed fine-tuning of the structural and functional properties (such as reduction potentials) of the proteins. Similarly, introducing citrulline into the recognition helix of a zinc finger protein by EPL demonstrated the use of unnatural amino acids to tailor the protein to recognize a broad range of DNA sites.[284]

5.2 Introducing Nonnative Metal Ions or Metal-Containing Prosthetic Groups into Designed Proteins

Like unnatural amino acid introduction described above, it is relatively straightforward to incorporate nonnative metal ions or metal-containing prosthetic groups into de novo designed metallopeptides and proteins. For example, a ruthenium complex has been used as a template to assemble helical bundle proteins (see Section 2.2.1). To introduce nonnative metal-containing prosthetic groups into native proteins, one way is to replace natural prosthetic groups with artificially synthesized ones. A nice example is replacing heme in myoglobin with metalloporphyrins such as protoporphyrin IX modified at the two propionate groups that created effective binding domains for protein−protein and protein-small molecule recognition and electron transfer (Figure 22a).[25] Furthermore, when the heme is replaced with iron porphycene[285] or modified by flavin at one of the propionate groups,[286] dramatically enhanced O_2-binding affinity or O_2 activation activities have been observed, respectively.

Covalent attachment of ligand or the whole metal complex to a specific site through bioconjugation to either Cys or Lys is another effective strategy. For example, 1,10-*o*-phenanthroline-copper, an effective DNA cleavage agent, has been attached to several DNA-binding proteins.[289] The combination of high cleavage activity of the metal complex with specific DNA recognition selectivity makes the artificial metalloproteins very effective nucleases. Fe-EDTA has been incorporated into proteins for the same reason.[290] Another remarkable achievement is the incorporation of copper-phenanthroline and rhodium-diphosphine complexes into proteins that turns the proteins into highly efficient asymmetric catalysts.[291,292]

To design artificial enzymes with asymmetric catalytic activities, one has to control chemo- and enantioselectivity. Since the native protein scaffolds have not evolved to tightly bind artificial metal complexes in a single conformation, three approaches have been used to design proteins with high enantioselective selectivity. In the noncovalent approach (Figure 22b), structure-based design of the protein and modification of the metal complexes has been shown to be important.[287,293–295] In the single point covalent attachment approach (Figure 22c), carefully selecting a protein host so that the metal complex can bury deep into a substrate accessible pocket is shown to be effective.[291,292] In the two-point covalent attachment approach (Figure 22d), careful positioning of the two attachment points limited the number of conformational states available to the metallocomplex inside the protein and by so doing significantly improved both rate of reaction and enantioselectivity.[288]

6 SUMMARY AND OUTLOOK

6.1 Summary

This review covers recent advances in metalloprotein design, with focus on different approaches to the design. Impressive progress has been made in designing metal-binding sites in peptides, de novo designed proteins, and native protein scaffolds. The approach can be rational or combinatorial. Under rational design, redesigning an existing metal-binding site to a new site with dramatically different structure and function complements well the design of new metal-binding sites by revealing the role of specific residues responsible for a particular structural or functional feature of the metal-binding site of interest. To create a new metal-binding site, several approaches have been used, including design based on structural homology, by inspection, using automated computer search algorithms, or combination of above approaches. In addition, the modular approach in which a conserved structural unit is transplanted from one protein into another has also been shown to be effective. Design through combinatorial and evolution methods has also been successful as it requires little prior knowledge of the protein structure. Finally introducing unnatural amino acids or nonnative metal ions/prosthetic groups to expand the repertoires of metalloproteins have been demonstrated. So which systems should one choose to work on and which approaches should one use? The answer depends on the goals of the design and experience and knowledge of the designers.

6.1.1 System Choice

Metallopeptide design represents the minimalist design in its purest sense. If a small metallopeptide can replicate large metalloproteins, it is the best approach to reveal essential features of the metal-binding sites and to be used for practical applications because of its small size. It is more likely to be successful if all the ligands in the native proteins are in a short segment of peptide and if metal binding directs the folding of the peptides and formation of the sites. However, a number of ligands span a large distance in the peptide chain and the rigid protein scaffolds play an important role in formation of many metal-binding sites, for example, enforcing distorted geometry that the metal ion may not prefer. Therefore designing metal-binding sites in protein scaffolds may be a preferred choice for designing those metalloproteins.

To design metal-binding sites into protein scaffolds, one can choose de novo designed proteins or native proteins. Designing metal-binding sites in de novo designed proteins represents the most fundamental and challenging endeavor. It is the ultimate goal of metalloprotein design and its success is the measure of progress in the field. However, the number of de novo designed scaffolds is quite limited when compared with large number of available native protein scaffolds. More importantly, nature has been shown to use the same native scaffold for many different metalloproteins. Therefore designing metal-binding sites in native scaffolds is part of metalloprotein design endeavor.

When designing metal-binding sites in native protein scaffolds, one can design new metal-binding sites or redesign the existing metal-binding sites. Designing new metal-binding sites should be a preferred choice. However, owing to lack

of knowledge, some metal-binding sites, such as type 1 blue copper center, are simply difficult to design. In those cases, redesign offers a better chance of success and offers equally important insights, although redesign often misses common factors existing between the starting and target proteins.

6.1.2 Approach Choice

The rational approach is the best at testing our knowledge. Both success and failure from the rational design may offer deep insight. Rational design using automated computer search algorithms has clear advantages for efficient crafting of metal centers and judicious choice of the best amino acid side chains for the formation of the metal-binding sites. It is best used for creation of new metal-binding sites in proteins where neither site location nor side chain choice can be determined based on the investigator's knowledge or protein homology. It is especially useful for designing metal-binding sites where construction of a geometrically correct, sterically compatible primary coordination sphere is sufficient to reproduce the dominant features of the structure and function of the desired center. Tetrahedral Zn(II) centers, iron–sulfur clusters, and mononuclear nonheme iron centers are primary examples of the successful designs.

For many other metal centers, such as blue copper and purple Cu_A centers, construction of a geometrically correct, sterically compatible primary coordination may not be sufficient to result in the desired metal-binding sites because their formation may be opposed by several alternative reactivities and geometries. Most metal-binding sites in proteins are not in idealized geometries as in their small metal complex counterparts. For example, the geometry of the blue copper center is preferred by neither Cu(II) nor Cu(I). Without a careful design that includes secondary coordination sphere or even longer range interactions, the amino acid side chains may be flexible enough to accommodate the geometry of the free metal ions and ruin the computer program design. Until now few effective programs are known to overcome these problems and much iteration, mostly based on knowledge and inspection, are needed for a successful design. Moreover, structural features responsible for protein selectivity of one metal ion over the other still remains to be fully understood. Thus, it is difficult to write programs capable of designing metal-binding sites selectively. In this regard, protein redesign, rational design by homology or modular approach may offer a better chance of success by gaining insight into the structure and function of the centers one (or a few) residue(s) at a time. This advantage is demonstrated by the successful redesign of a type 2 copper protein CuZnSOD into a type 1 blue copper protein (see Section 2.3.1)[135–138] or transformation of type 1 blue copper proteins into purple Cu_A proteins by loop-directed mutagenesis (see Section 3.3.2).[230,232–235]

Another equally attractive empirical approach is the design of new metal-binding sites based on protein homology. This approach depends strongly on the degree of sequence or structural homology. Generally speaking, higher homology often leads to a better chance of success. At the same time, factors that are common to both template protein and the target protein cannot be revealed from the design exercise. This problem also applies to the protein redesign approach. Despite these limitations, both approaches are extremely useful at elucidating the role of specific structural features in protein design and function, and at revealing principles of protein design.

Design of metal-binding sites by inspection is one of the early forms of protein design. Although it appears less elegant than other methods, design by inspection has produced proteins with many practical applications, such as proteins with a His-X_3-His chelating site on the surface and with poly-His tags for protein purification. The designed metal-binding sites also resulted in proteins with increased stability, altered activities, altered selectivity, new functions, and elucidated protein topologies. It can be an effective approach for creating metal-binding sites with more complexity if the investigators are armed with a thorough understanding of the structure and function of both the target and the template proteins, and have a reasonably good idea where the metal site can be created. This approach can be enhanced further if it can utilize computer programs to help evaluate and modify the initial design through energy minimization. This is the basis of the combined approach. On one hand, the combined approach is similar to design by inspection in that it relies on the investigator's knowledge to pinpoint the location of the metal-binding site. On the other hand, the approach resembles the automated computer algorithm approach in that it uses rigorous computer programs to evaluate the initial design and to suggest better designs with better energetic terms.

All the rational methods described above rely heavily on our knowledge of principles governing the structure and function of metal-binding sites. However, despite much progress made so far, our knowledge is still quite limited. For example, the high affinity and selectivity of many metal-binding sites remains to be elucidated. Fascinating new metal centers are being discovered. To fill the gap of our knowledge and to keep pace with the rapid development of the field, combinatorial design of metal-binding sites is of great value. However, this approach requires a clear and convenient selection scheme.

Modular approaches may bridge the gap between rational design and combinatorial engineering. It allows easier rational generation of a site by swapping structural elements, such as a loop, that are important for the formation of the metal-binding site. At the same time, it is easier to search combinatorially for optimal sequences since the search is narrowly focused on the region of difference and its surrounding areas.

6.2 Outlook

Given this vast and rapidly developing field, it is very difficult to predict the future. All one can do is to offer the best possible path to the future based on what we have

learned. One focus for future research should be on design of geometrically strained metal-binding sites, such as the blue copper center, and multinuclear (particularly heteronuclear) metal centers. It is a test of our knowledge and ability. One way to improve success is to combine the advantages of two or more approaches. For example, rational approaches can be used to create a new metal-binding site and combinatorial searches can then be used to fine-tune the metal-binding affinity, selectivity, or in the case of catalytic sites, the substrate-binding pocket. Furthermore, automated computer programs can be used to design or redesign geometrically strained metal-binding sites, such as the blue copper center, in proteins with high homology to these proteins. This strategy offers a higher chance of success. Study of the designed protein may help improve the programs.

Another focus of future research should be the role of the secondary coordination sphere in metalloprotein design. With few exceptions, most designed metal-binding sites have a binding affinity that is orders of magnitude weaker than that in the native proteins. The role of secondary coordination sphere in tuning the properties of metal-binding sites has been well recognized.[8] Recent work has strongly suggested the importance of negative design, for example, to avoid steric conflict, to prevent solvent exposure and to inhibit ligand oxidation. Positive interactions such as hydrogen bonding and electrostatic interactions are also very important.[106,109,111,193] Introducing those positive design elements has been shown to be essential for successful metalloprotein design.[106,109,111]

The importance of three-dimensional structural characterization of the designed proteins should also be recognized. Spectroscopy has been the main tool to demonstrate the success of the design. However, the spectroscopic signatures can indicate only part of the designed metal-binding sites. Three-dimensional structures of the designed protein, whether confirming the design or revealing surprises, will be quite valuable for further design.

Finally, in addition to structurally defined metal-binding sites, designing catalytically active metal centers will be another exciting area of research. It is the best way to realize the potentials of metalloprotein design.

1 INTRODUCTION

Most known multiheme cytochromes and enzymes belong to the family of cytochromes *c* (*see* ***Iron: Heme Proteins & Electron Transport***), which contain Fe-protoporphyrin IX covalently attached to the polypeptide chain by two thioether bonds, formed by addition of two cysteinyl residues to the vinyl side-chains of the porphyrin ring. The two cysteines form a characteristic amino acid sequence motif CXXCH, usually indicative of heme *c* ligation, and where the histidine is the axial fifth ligand to the iron. For some cytochromes (see Section 2), the number of residues between the two cysteines can be three or four. The heme redox potentials in cytochromes *c* cover a wide range and are tuned by several factors, usually dominated by the type of axial ligation and the extent of solvent exposure of the heme.[1,2]

Bacterial cytochromes *c* are either periplasmic or attached to the periplasmic side of the membrane, and this led to the suggestion by Wood that the covalent attachment of heme evolved as a way of preventing its loss from periplasmic proteins to the external medium.[3] However, there are some observations that go against this idea, namely, the fact that there are both extracellular and periplasmic proteins that contain noncovalently bound hemes. It has been argued that there are a number of reasons that justify the advantage of having heme covalently attached to the polypeptide.[4,5] Studies, in which a *c*-type cytochrome was converted to a *b*-type, or a *b*-type to a *c*-type, show that covalent attachment of the heme confers increased stability to a cytochrome. Furthermore, covalent attachment enables a tight binding of heme with much less polypeptide required, and permits the clustering of spatially very close hemes in well defined arrangements. Such dense packing of hemes, as observed in multiheme proteins, probably allows for extremely fast electron transfer between them.[6]

The biogenesis of cytochromes *c* involves quite complex assembly systems that differ between organisms. The simplest one is found in mitochondria of fungal, vertebrate, and invertebrate cells, but is unrelated to both the bacterial system I (the *ccm* system), found in some gram-negative bacteria, and to system II (the *ccs* system) found in other classes of gram-negative bacteria, gram-positive bacteria, cyanobacteria, and in plant and algal chloroplasts.[7–9] These systems are involved in the transport of apocytochrome and heme across the membrane, maintaining the cysteine residues of the heme-binding motif in a reduced state, and in covalent attachment of heme catalyzed by a heme lyase.

The most widely known protein containing a heme *c* is the mitochondrial cytochrome *c* (*see* ***Iron: Heme Proteins & Electron Transport***) that, together with similar bacterial cytochromes, form the family of monoheme cytochromes *c*. These are characterized by histidine-methionine coordination, and a low solvent exposure of the heme, resulting in positive redox potentials. Their fold can be found as a domain of more complex proteins like the cytochrome cd_1 nitrite reductase, caa_3 and cbb_3-type oxidases (*see* ***Cytochrome Oxidase***), and several diheme cytochromes such as cytochrome *c* peroxidases, cytochrome c_4 from *Pseudomonas stutzeri*, and the cytochrome subunit of the flavocytochrome *c* sulfide dehydrogenase from *Allochromatium vinosum*. An interesting protein related to this family is SoxAX, a heterodimeric *c*-type cytochrome involved in the oxidation of thiosulfate.[10] The two hemes of the SoxA subunit constitute the first example of hemes *c* with histidine/cysteine ligation, and the catalytic heme 2 (the heme numbering used throughout this text follows the order of the heme-binding site in the polypeptide sequence from the N-terminus) is further unusual in that its cysteinyl ligand suffers a posttranslational modification to form cysteinyl persulfide.

Multiheme *c* cytochromes and enzymes form distinct families from the monoheme *c* cytochromes. They are characterized by a low amino acid residues to heme ratio (resulting in significant exposure of heme to the solvent) and bis-histidinyl coordination, with few known exceptions. These two characteristics are responsible for the low heme redox potentials of this family. In some cases, the multiheme

c domain is part of more complex proteins. The hemes may be six coordinated and low spin or pentacoordinated and high spin, and it is generally assumed that the low-spin hemes have an electron transfer function, whereas the high-spin hemes have a catalytic function, owing to the possibility of binding a substrate. However, there are two examples of proteins containing one high-spin heme, the high molecular mass cytochrome c_3 (see Section 2.3) and cytochrome c_{554} (see Section 3.2), for which a purely electron transfer function is proposed and no enzymatic activity has, so far, been detected.

A striking feature apparent from the structures of multiheme proteins described to date, is that the hemes are found clustered in structural arrangements that are quite conserved among, otherwise, totally unrelated proteins in amino acid sequence or polypeptide fold. Indeed, most hemes in these proteins are part of diheme packing motifs where the two heme planes are found either parallel but offset ('heme stacking motif') or perpendicular to each other ('diheme elbow motif') (Figure 1).[11] In the parallel motif the interheme iron distances are around 10 Å and the heme planes are separated by a distance of less than 4 Å. In the perpendicular motif, the heme iron distances are around 12 Å. Furthermore, these diheme motifs may form larger structural heme motifs (superheme motifs) that are almost superimposable, and the similarity may also extend to the folding of the polypeptide chain surrounding the hemes.[4,12] The functional significance of these heme structural arrangements is not yet understood, and they possibly reflect favorable arrangements to tune heme–heme redox potential interactions and/or warrant very fast electron transfer.

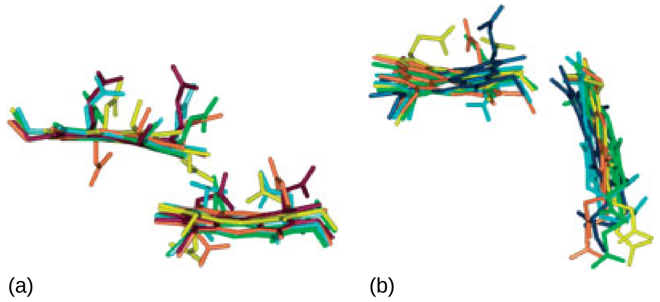

Figure 1 (a) Superposition of heme pairs displaying the parallel heme stacking motif. The hemes shown are from the *D. desulfuricans* ATCC 27774 Split-Soret cytochrome (PDB code 1DCC, hemes 1 and 2, magenta), *N*. europaea HAO (PDB code 1FGJ, hemes 3 and 5, yellow), *W. succinogenes* NrfA (PDB code 1FS7, hemes 3 and 4, green), *N*. europaea cytochrome c_{554} (PDB code 1FT5, hemes 1 and 3, orange) and *S. oneidensis* MR-1 Stc (PDB code 1M1Q, hemes 2 and 3, light blue). (b) Superposition of heme pairs displaying the perpendicular diheme elbow motif. The hemes shown are from the *D. vulgaris* Hildenborough 4HCc_3TpI (PDB code 2CHT, hemes 1 and 3, dark blue), *N. europaea* HAO (PDB code 1FGJ, hemes 7 and 8, yellow), *W. succinogenes* NrfA (PDB code 1FS7, hemes 2 and 3, green), *N. europaea* cytochrome c_{554} (PDB code 1FT5, hemes 3 and 5, orange) and *S. oneidensis* MR-1 Stc (PDB code 1M1Q, hemes 3 and 4, light blue)

Most multiheme *c* proteins for which the structure has been determined can be divided into two families of similar superheme motifs. The first one is the cytochrome c_3 family, which includes proteins containing one or more tetraheme arrangements (see Section 2). In this tight and closely spaced arrangement, the perpendicular motif is predominant, since both of the most distant hemes, 1 and 4 (almost parallel to each other) are perpendicular to both hemes 2 and 3 (Figure 2). This heme core architecture is found in other members of the family like the nine-heme cytochrome c_3 (9HCc_3), the sixteen-heme high molecular mass cytochrome c_3 (16HCc_3), and even the three-heme cytochrome c_7 (3HCc_3). Since the larger proteins of this family are assemblies of cytochrome c_3-like heme motifs, they are here also named as cytochromes c_3.

The second family is more diverse and includes proteins like the eight-heme hydroxylamine oxidoreductase (HAO), its redox partner the tetraheme cytochrome c_{554}, the five-heme NrfA nitrite reductase, the tetraheme domain of the flavocytochrome *c* fumarate reductase (Ffr), and the small tetraheme cytochrome *c* (Stc) of *Shewanella* sp. Several of the hemes of each protein have almost identical orientation to groups of hemes in the other proteins. Taking HAO as a reference, the four hemes of cytochrome c_{554} are superimposable on hemes 3–6 of HAO, the five hemes of the NrfA are superimposable on hemes 4–8 of HAO, the four hemes of the Stc are superimposable on hemes 5–8 of HAO and hemes 1–3 of the Ffr are superimposable on hemes 5–7 of HAO (Figure 3). This family includes both stacked and perpendicular diheme motifs with the interesting feature that the two motifs alternate.

In the two following sections, several proteins belonging to each family are discussed. In the third section, a brief overview of other multiheme *c* proteins is presented.

2 THE CYTOCHROME c_3 FAMILY

A very high cellular content of multiheme cytochromes *c* is a characteristic of a specialized group of gram-negative δ-proteobacteria that use sulfate as terminal electron acceptor. *Desulfovibrio* (*D*.), from which the first known multiheme cytochrome was isolated, is the best studied genus. Most of these cytochromes are related in terms of sequence and structure forming a family that is characterized by a low polypeptide to heme ratio, low redox potentials, and a tetraheme globular arrangement where the perpendicular motif is predominant.[13] The prototype of this family is the Type I cytochrome c_3 (4HCc_3TpI), which was the third cytochrome *c* to be identified and is the most studied member of the family.

2.1 Type I Cytochrome c_3

The 4HCc_3TpI is a periplasmic cytochrome that is highly abundant in all *Desulfovibrio* species described so far,[13] and is

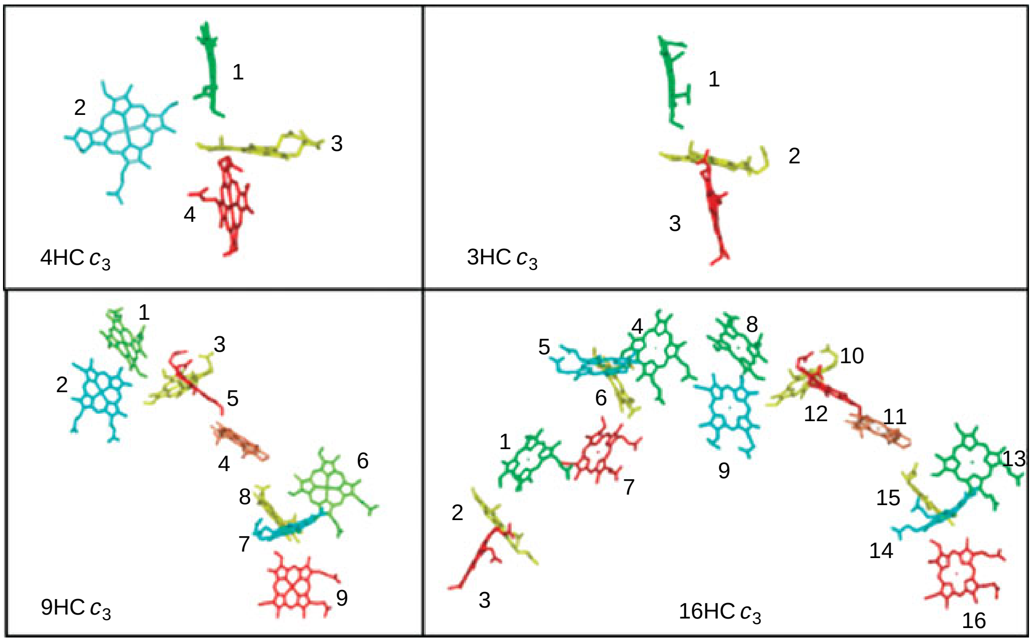

Figure 2 Heme structures of multiheme *c* proteins belonging to the cytochrome c_3 family: *D. vulgaris* Hildenborough 4HCc_3TpI (PDB code 2CHT), *Dsm. acetoxidans* 3HCc_3 (PDB code 1HH5), *D. desulfuricans* ATCC 27774 9HCc_3 (PDB code 19HC) and *D. vulgaris* Hildenborough 16HCc_3 (PDB code 1H29). The hemes are colored according to the corresponding heme in the 4HCc_3TpI (heme 1 green, heme 2 blue, heme 3 yellow, heme 4 red). Hemes 4 in 9HCc_3 and 11 in 16HCc_3 are not part of tetraheme arrangements and are colored orange

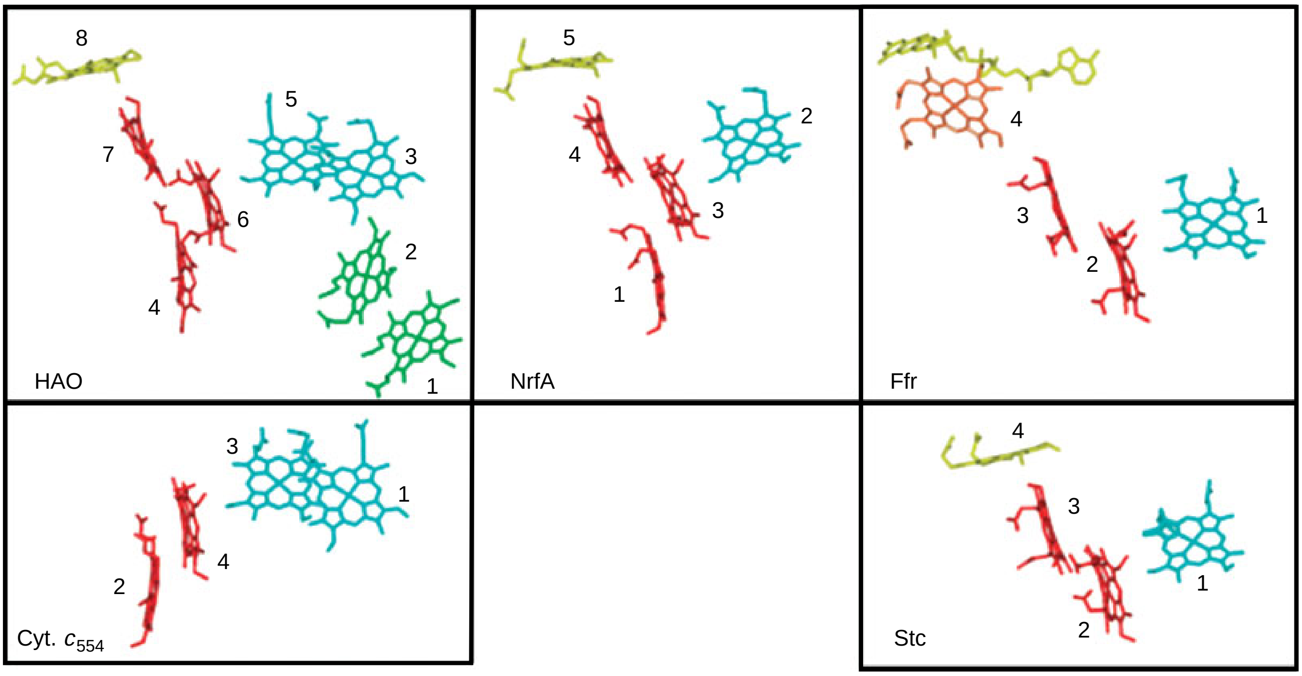

Figure 3 Heme structures of multiheme *c* proteins belonging to the HAO family: *N. europaea* HAO (PDB code 1FGJ), *W. succinogenes* NrfA (PDB code 1FS7), *S. frigidimarina* NCIMB400 Ffr (PDB code 1QJD), *N. europaea* cytochrome c_{554} (PDB code 1FT5) and *S. oneidensis* MR-1 Stc (PDB code 1M1Q). The hemes are colored according to the four-heme clusters of HAO. Hemes in the same color are superimposable. Heme 4 of Ffr is colored orange, since it shows a considerable deviation from heme 8 in HAO. The flavin group of Ffr is shown in yellow

also present in other sulfate-reducing bacteria such as *Desulfomicrobium*, *Desulfobulbus*, and *Thermodesulfobacterium*. The designation of Type I stems from the fact that recently a second type of tetraheme cytochrome c_3 was identified (see Section 2.3). The 4HCc_3TpI has a central role in the bioenergetic metabolism of *Desulfovibrio* sp., working as a coupling protein between hydrogenase (H_2ase) and one of several possible transmembrane electron transfer complexes (TETC), which transport electrons from the periplasm to the reduction of sulfate in the cytoplasm (see Section 2.3). It is a small (~14 kDa), monomeric protein containing four hemes *c* with bis-histidinyl coordination. The four hemes are quite exposed to the solvent and have low redox potentials in the range of −200 to −400 mV. The 4HCc_3TpI is a very stable protein that has been studied by a wide range of techniques, making it one of the most well-characterized electron transfer proteins in terms of structure-function relationship. The detailed characterization of some 4HCc_3TpIs includes: (1) thorough microscopic thermodynamic characterization of their relevant redox and protolytic centers, including their pairwise homotropic (heme–heme redox potential) and heterotropic (heme redox potential and p*K*a of specific groups, known as redox-Bohr effect, rB) cooperativities; (2) X-ray crystal and/or solution nuclear magnetic resonance (NMR) structures in different redox and/or protonation states; and (3) elucidation of the molecular bases that govern the functional cooperativities.[14] These studies indicate that the 4HCc_3TpI has two characteristics that are fundamental for its function: it performs a two-electron step and is capable of electron-to-proton energy transduction.

The 3D-structure of the 4HCc_3TpIs shows no similarity to other known tetraheme cytochromes *c* like cytochrome c_{554} (see Section 3.2), the *Shewanella* small tetraheme cytochrome (which was initially also referred to as a cytochrome c_3) (see Section 3.4), or the tetraheme cytochrome of the photosynthetic reaction center.[15] The structure of 4HCc_3TpI is very compact, displays little secondary structure and is dominated by the characteristic heme arrangement where all the closest hemes are perpendicular to each other (Figure 4). Remarkably, 4HCc_3TpIs have a small number of conserved residues, with approximately 20% sequence identity. Nevertheless, they form a very conserved structural family, having an almost identical polypeptide fold and heme core architecture. This is due to the fact that the conserved residues include the 16 that constitute the four hemes binding motifs (2 His and 2 Cys per heme), and the order of these residues in the polypeptide chain is crucial in determining the globular structure of the protein. One of the most important characteristics of cytochromes c_3 is its folding: although it has only few and small secondary structure elements it comprises two domains of approximately the same length (Figure 5). Interestingly, the N-terminal domain has all the ligands of heme 1 and the C-terminal all those of heme 4. Hemes 2 and 3 have ligands from both domains and are nestled in the interdomain region. The resulting tight globular folding is largely controlled by the interwound positioning of the histidinyl ligands in the polypeptide sequence. Another interesting characteristic feature of 4HCc_3TpIs is the presence of the conserved motif CX_2CHH where the two consecutive histidines are axial ligands to hemes 1 and 2, respectively. In addition, two heme-binding sites in 4HCc_3TpIs are unusual in that they have four residues between the two cysteines that bind hemes 2 and 4. However, this is not important for the tetraheme structural motif, since it is not observed in some members of the cytochrome c_3 family (see Section 2.3). A further conserved feature of 4HCc_3TpIs is the presence of a positive surface region surrounding heme 4 that is proposed to be the site of interaction with a negative region of hydrogenase.[16,17]

The 4HCc_3TpI from *D. vulgaris* Hildenborough captures both electrons and protons resulting from the oxidation of

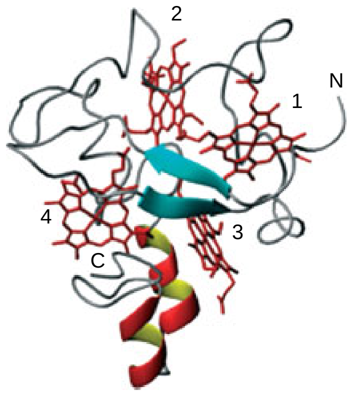

Figure 4 Structure of *D. vulgaris* Hildenborough 4HCc_3TpI (PDB code 2CHT)[18]

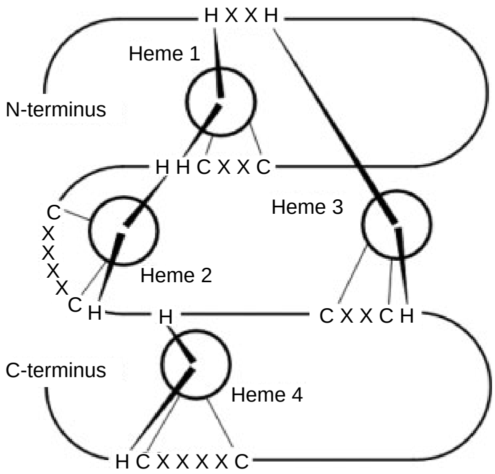

Figure 5 Schematic representation of 4HCc_3TpI, depicting the N- and C-terminal domains, each embedding one of hemes 1 and 4, respectively. The other two hemes are in the groove between the two domains

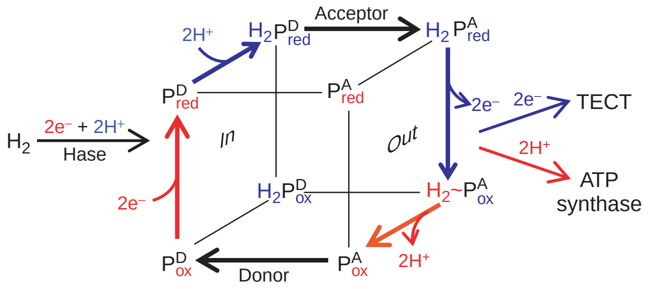

Figure 6 Mechanism proposed for the energy transducing role of 4HCc_3TpI that leads to energy conservation.[14] The cube paradigm, generally accepted to describe this type of activity, is adapted so that the In and Out faces represent the stepwise recognition of the energy transducer protein (P) by the donor (D) and acceptor (A) proteins. These specific recognitions must be redox/protonation state specific in order to avoid short circuits, and warrant vectoriality to the process. Blue (deenergized) and red (energized) are used for comparative purposes

H_2 by hydrogenase,[19] and the heterotropic cooperativities between redox and protic centers, are essential for the electron-to-proton energy transduction role of 4HCc_3TpI (Figure 6).[14] This crucial function involves the electrons and protons produced by oxidation of hydrogen and subsequently given to the cytochrome:: $H_2 \rightarrow 2e^{-*} + 2H^+ \rightarrow 2e^- + 2H^{+*}$, where the asterisks represent energized electrons (i.e. in centers with low redox potential) and energized protons (i.e. bound to protic groups with low pK_a). Thus, acidified protic groups are obtained, as high reducing energy originating from oxidation of hydrogen is transferred via the cytochrome to deenergized redox centers of the acceptor (TETC) (see Section 2.3). Concomitantly, a protic rB center is energized (i.e. acidified). Thus, working as an electro-protonic energy transducer, 4HCc_3TpI performs a ‘proton thrusting’ mechanism that can activate ATP synthase and lead to energy conservation.[19]

Both *D. vulgaris* and *D. gigas* 4HCc_3TpIs receive the two electrons produced by the oxidation of H_2 in a concerted two-electron step, which results from a positive homotropic redox cooperativity between two hemes. Thus, there is a stabilization of the protein states with these two hemes in the same oxidation state and a concerted binding (release) of two electrons. This process cannot be explained by direct electrostatic considerations (Coulomb’s law) that imply a repulsive effect between charges of the same sign. Consequently, this cooperative effect must involve a redox-linked structural modification, such that reduction of one center induces a structural modification, resulting in an overall anti-Coulomb effect.[14] It should be stressed that the structural rearrangement that stabilizes the new conformation need not involve large structural modifications.[20]

Like other low redox potential cytochromes, the 4HCc_3TpIs can catalyze the reduction of several molecules such as sulfur, polysulfides, Fe^{III}, Cr^{VI}, U^{VI}, and other metal oxides. This has been suggested to be a nonspecific property driven by the difference in reduction potential and high exposure of the heme groups in these cytochromes. Moreover, other proteins with redox centers of low potential, like hydrogenase, display the same property,[21] and even hemin has been shown to reduce chromate.[22] However, an NMR study revealed that the binding of the negatively charged $CrO_4{}^{2-}$ to cytochrome c_7 (see Section 2.4) is not unspecific, but occurs close to heme 4, probably due to the positive surface area surrounding this heme.[23] Interestingly, this is the same heme that is proposed to be involved in electron transfer from hydrogenase.

2.2 Dimeric Cytochrome c_3

A dimeric cytochrome c_3 (Di4HCc_3), containing two tetraheme subunits, is also present in some sulfate-reducers, having been isolated from *D. gigas*, *D. africanus*, and *Desulfomicrobium norvegicum*. It is also named as cytochrome c_3 (M_r 26 000) and was previously known as cytochrome cc_3.[24] This cytochrome is a periplasmic homodimer of two 13 500 Da tetraheme subunits, both in *Dsm. norvegicum* and in *D. gigas*. In this last case the two subunits are linked by two disulphide bridges. The reduction potentials of the *Dsm. baculatum* Di4HCc_3 hemes are as low as those of 4HCc_3TpI, in agreement with the bis-histidinyl coordination for the four hemes.

The crystal structures of the Di4HCc_3 from *Dsm. baculatum* and *D. gigas* have been obtained.[25,26] The two structures are very similar and show that each monomer has a polypeptide fold and heme arrangement identical to that observed for 4HCc_3TpIs. The dimer interface is formed by the surface region around heme 1 of each monomer. As in the case of 4HCc_3TpIs the exposed heme 4 is surrounded by a positive surface region.

The physiological role of Di4HCc_3 has not been extensively investigated. However, it has been shown that it can be reduced by the main hydrogenase isolated from the organism (a [NiFe] hydrogenase for *D. gigas* and a [NiFeSe] hydrogenase for *D. africanus* and *Dsm. norvegicum*) in a similar way to 4HCc_3TpI. The *D. gigas* Di4HCc_3 was shown to stimulate the reduction of thiosulfate by a partially purified extract, using H_2/hydrogenase as electron donor, but strangely this was not observed with purified thiosulfate reductase. In the case of *Dsm. norvegicum*, reduction of the Di4HCc_3 by the [NiFeSe] was slower than reduction of the 4HCc_3TpI, indicating that 4HCc_3TpI is the preferred electron acceptor for this hydrogenase. Furthermore, the rate of reduction of the Di4HCc_3 is increased in the presence of small amounts of the 4HCc_3TpI.[27] However, in *D. africanus* the [NiFeSe] hydrogenase displays a lower K_m for reduction of Di4HCc_3 than for reduction of 4HCc_3TpI.[28] Interestingly, analysis of the preliminary genome data available for *D. vulgaris* Hildenborough and *Desulfovibrio desulfuricans* G20 shows that the gene for a Di4HCc_3 homolog is encoded in the same transcription unit as a second [NiFe] hydrogenase isoenzyme. This suggests that in these organisms the Di4HCc_3 is the

physiological partner for this hydrogenase. In *D. vulgaris* Hildenborough, the [NiFe] hydrogenase isoenzyme 1 has been well characterized and its physiological partner is the 4HCc_3TpI. The [NiFe] hydrogenase isoenzyme 2 and the Di4HCc_3 have so far not been detected in this organism, suggesting they will be expressed under different conditions to the [NiFe] hydrogenase isoenzyme 1 and the 4HCc_3TpI.

2.3 Membrane-associated Cytochromes

Several multiheme cytochromes of the cytochrome c_3 family are associated with membrane–bound redox complexes. These cytochromes are targeted to the periplasmic side of the membrane as indicated by the presence of signal peptide sequences in the corresponding genes. The strength of their association with the membrane is variable since some can be isolated from the soluble periplasmic fraction. The members of this subgroup are a tetraheme cytochrome known as Type II cytochrome c_3 (4HCc_3TpII), a nine-heme cytochrome c_3 (9HCc_3) and a 16-heme cytochrome c_3 (16HCc_3). The last two cytochromes are composed of tetraheme-like domains with the typical heme arrangement of the cytochrome c_3 family. This suggests they originated from gene duplication events and/or that the tetraheme arrangement found in this family is a structural module with a specialized function shared by the whole family. However, the results so far do not support the latter idea, but rather indicate that the membrane-associated cytochromes do not have the same functional properties as the 4HCc_3TpI and form a separate group that evolved to perform a different function (see below).

The Type II Tetraheme Cytochrome. Type II cytochromes c_3 (4HCc_3TpII) are a second group of tetraheme cytochromes c_3 that have structural, genetic, and reactivity features that distinguish them from the previously characterized 4HCc_3TpIs.[29] *D. africanus* was the first *Desulfovibrio* sp. reported to contain a 4HCc_3TpII, and was referred to as 'acidic cytochrome c_3'.[28,30] A homolog of this cytochrome was later characterized from *D. vulgaris* Hildenborough, and a 4HCc_3TpII is also encoded in the genome of *D. desulfuricans* G20. The nomenclature of 'acidic' and 'basic' cytochromes c_3 is not appropriate, since 4HCc_3TpIs can have low pIs (e.g. 4HCc_3TpI from *D. gigas*) and 4HCc_3TpIIs may be not very acidic.

The macroscopic reduction potentials of the *D. vulgaris* Hildenborough 4HCc_3TpII hemes (−170, −235, −260, and −325 mV) are similar to those commonly observed for the 4HCc_3TpIs. In the case of the *D. africanus* 4HCc_3TpII, the four reduction potentials obtained by cyclic voltammetry were quite close (−210, −240, −260, and −270 mV).

Comparison of the crystal structure of the *D. africanus* 4HCc_3TpII[31] with a theoretical model for the structure of the *D. vulgaris* Hildenborough cytochrome shows that, although its four-heme arrangement is identical, and the overall protein fold is similar to 4HCc_3TpI, it displays some localized differences that can affect the heme's reactivity, reflecting a different physiological role. The 4HCc_3TpII cytochromes lack the characteristic positive surface region around heme 4, proposed to be the site of interaction and electron exchange with a negatively charged region of the redox partner hydrogenase. In addition, 4HCc_3TpIIs have a more exposed heme 1 that is surrounded by a negative surface region, indicating that this may be the heme involved in electron transfer with the physiological partner. In fact, the rate of reduction of the 4HCc_3TpIIs by hydrogenase is stimulated by catalytic amounts of 4HCc_3TpI. Thus, although the four-heme structural motif is conserved in both the 4HCc_3TpI and 4HCc_3TpII, they have different properties that are the result of only small structural differences, and have evolved to perform different physiological functions. All of the heme-binding sites present in the 4HCc_3TpII display the typical motif CXXCH, whereas a characteristic of 4HCc_3TpIs is the presence of one or more heme-binding sites with four residues between the two cysteines (CX_4CH).

The gene coding for the *D. vulgaris* Hildenborough 4HCc_3TpII is part of an operon with genes coding for two other proteins that are related to predicted proteins of the 9HCc_3 and 16HCc_3 operons. One of them is an integral membrane protein that belongs to the family of heme *b*-containing subunits of respiratory complexes, which are involved in electron transfer with the membrane quinone pool. The other is a hydrophilic protein, probably located in the cytoplasmic face of the membrane that is related to the catalytic subunits of heterodisulfide reductases present in methanogenic archaea. It contains two [4Fe4S] centers and a conserved five-cysteine motif that has been proposed to bind another iron–sulfur center, responsible for reduction of the heterodisulfide of CoM and CoB to the corresponding thiols.[32] Thus, this operon encodes a transmembrane protein complex with redox centers in the periplasm, membrane, and cytoplasm, which is likely to have a role in the respiratory electron transfer (Figure 7). Such a complex is also encoded in the genome of *D. desulfuricans* G20, and in the case of *D. africanus* the partial sequence available reveals an incomplete open reading frame upstream of the TpII-c_3 gene encoding a FeS protein homologous to the one found in the *D. vulgaris* Hildenborough genome. The *D. vulgaris* Hildenborough 4HCc_3TpII cannot be detected in the soluble fraction indicating it has a strong association with the membrane complex, in contrast to the corresponding cytochrome from *D. africanus*, which was isolated as a soluble protein. Nevertheless, *D. vulgaris* Hildenborough 4HCc_3TpII is also a hydrophilic protein with no membrane-associated domains, that remains soluble after the detergent is removed.

The Nine-heme Cytochrome c_3. The nine-heme cytochrome c_3 (9HCc_3), originally reported to contain 12 hemes, was referred to as the dodecaheme cytochrome *c*.[34] Only when its structure became available was the correct number of hemes established as nine.[35] This cytochrome of 37.8 kDa has been isolated from *D. desulfuricans* strains ATCC 27774

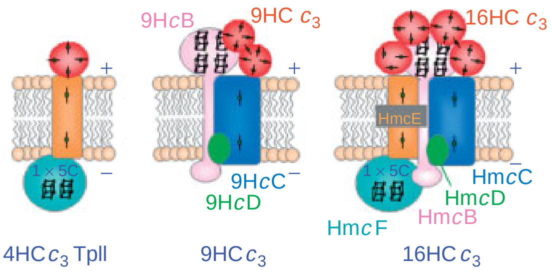

Figure 7 Schematic representation of the membrane-bound complexes associated with 4HCc_3TpII, 9HCc_3, and 16HCc_3 as deduced from sequence data.[33] Related subunits are in similar colors

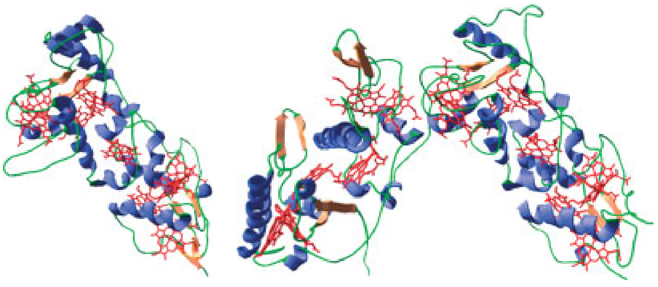
and Essex, which are sulfate-reducing bacteria that can also use nitrate as electron acceptor.[36] The structure shows that this cytochrome has two tetraheme motifs similar to those of cytochrome c_3, with an extra heme located between the two (Figures 2 and 8). The N-terminal motif contains hemes 1, 2, 3, and 5 and heme 4 is the isolated heme. The two tetraheme regions display some of the characteristics of the 4HCc_3TpII cytochrome, including all of the heme-binding sites of the form CXXCH, an exposed first heme surrounded by a negative surface charge, and a heme that corresponds to 4HCc_3TpI heme 4 in the C-terminal domain (heme 9), that lacks the positive surface charge. The structure of the reduced form shows significant changes surrounding hemes 1 and 4, and thermodynamic simulations indicate that the hemes belonging to the N-terminal domain have, in general, a lower redox potential than those found in the C-terminal domain, suggesting electrons will flow from the former to the latter.[37]

Like the 4HCc_3TpII, 9HCc_3 from *D. desulfuricans* 27774 can be reduced by hydrogenase but this reduction is faster in the presence of catalytic amounts of 4HCc_3TpI. Modeling studies indicate a specific interaction between the negative 9HCc_3 N-terminal region surrounding hemes 1 and 2 and the positive heme 4 region of 4HCc_3TpI.[38]

The 9HCc_3 sequence is similar to the C-terminal region of the high molecular mass cytochrome c_3 16HCc_3 (see below), and the 9HCc_3 gene is the first of an operon (*9hc*) encoding three other proteins that have a strong similarity to predicted proteins of the 16HCc_3 operon.[39] They are an integral transmembrane subunit possibly containing hemes *b* (similar to HmcC), a small membrane subunit (similar to HmcD) and a periplasmic subunit with binding sites for four [4Fe4S] clusters (similar to HmcB) (Figure 7). Thus, the *9hc* operon encodes a membrane-bound redox complex and given the similarity between 9HCc_3 and the two C-terminal domains of 16HCc_3 it is likely that the 9Hc complex replaces the Hmc complex in *D. desulfuricans* 27774, as also suggested by the fact that the 16HCc_3 is not detected in this organism. Expression of the *9hc* operon in *D. desulfuricans* 27774 is higher on sulfate than on nitrate, in agreement with a possible role of this complex as a substitute for the Hmc complex in electron transport to the reduction of sulfate. The 9HCc_3 cytochrome can be found both in the soluble and in the membrane fraction indicating that it may dissociate from the 9Hc complex.



(a) (b)

Figure 8 (a) Structure of 9HCc_3 from *D. desulfuricans* ATCC 27774 (PDB code 19HC).[35] (b) Structure of 16HCc_3 from *D. vulgaris* Hildenborough (PDB code 1H29)[33]

The Sixteen-heme Cytochrome c_3. The high molecular mass cytochrome c_3 (16HCc_3) is the largest in the cytochrome c_3 family, containing 16 hemes *c* and a mass of around 65 kDa. It is the cytochrome with the highest number of hemes in a single polypeptide known so far. 16HCc_3 may be isolated as a soluble protein from *D. vulgaris* Hildenborough, *D. vulgaris* Miyazaki, and *D. gigas*, but it is found in higher amounts in the membrane fraction. The presence of high-spin heme(s) in both oxidized and reduced form of 16HCc_3 was detected by visible, EPR, and Mössbauer spectroscopies.[40] In *D. vulgaris* 16HCc_3, the reduction potentials of the 16 hemes span a large range and can be roughly divided into three groups: 4 to 5 hemes have redox potentials of −30 to −100 mV, 3 to 4 hemes around −170 mV and 7 to 8 hemes −250 to −280 mV. Several of these reduction potentials are strongly pH dependent. The 16HCc_3 cytochrome is only very slowly reduced by the hydrogenases but, like the other membrane-associated cytochromes 4HCc_3TpII and 9HCc_3, its rate of reduction is stimulated by addition of catalytic amounts of 4HCc_3TpI.

The structure of the *D. vulgaris* Hildenborough 16HCc_3 is organized in four tetraheme cytochrome c_3-like heme motifs (Figures 2 and 8).[33,41] The first motif is incomplete and contains only three hemes, and the final two, including an isolated heme connecting them, show great similarity to the 9HCc_3 from *D. desulfuricans*. The four motifs are spatially arranged in two different regions: an N-terminal region that comprises the first two cytochrome c_3-like motifs, and a C-terminal region that is similar to 9HCc_3. These two elongated regions are at an angle thus giving the 16HCc_3 molecule the shape of a stretched 'V'. An interesting aspect of 16HCc_3 is that the heme groups of the N-terminal region are not positioned according to their order in the sequence. Thus, the N-terminus and heme 1 are not present at one extremity of the molecule, but in the region between the first two motifs,

and heme 4 (the first heme of the second motif) is placed between the second and third tetraheme motifs, whereas it is heme 7 that is closest to the first motif (Figure 2). This situation is not found in the C-terminal 9HCc_3-like region in which the hemes are found according to their order in the sequence (with the exception of the isolated heme 11) with heme 16 located at the C-terminus extremity. This peculiar heme arrangement of the 16HCc_3 N-terminal region results in a symmetry between the two regions, with hemes equivalent to cytochrome c_3 heme 4 (16HCc_3 hemes 3 and 16) at each extremity of the molecule and with hemes equivalent to cytochrome c_3 heme 1 (16HCc_3 hemes 4 and 8) at the V-angle. The four-heme cytochrome c_3-like regions of 16HCc_3 have more similarities with 4HCc_3TpII than with 4HCc_3TpI, and all of the heme-binding sites are of the CXXCH form. The first heme motif is missing heme 2 of tetraheme cytochromes c_3, and for this reason has been considered to be similar to cytochrome c_7 (3HCc_3) (see Section 2.4). However, this first motif is considerably larger than 3HCc_3 and indeed resembles more the tetraheme cytochrome c_3 fold, particularly that of 4HCc_3TpII than that of the triheme cytochrome (which is not surprising considering that 3HCc_3 is present in phylogenetically more distant bacteria). The C-terminal region is strikingly similar to the 9HCc_3 structure, including the isolated heme between the two tetraheme domains, heme 11 in 16HCc_3. The main difference is that heme 15 (heme 8 of 9HCc_3) is only coordinated by one axial ligand and is the high-spin heme of 16HCc_3. The histidine that binds heme 8 in 9HCc_3 is replaced by an isoleucine, which is positioned in van der Waals contact distance to the heme iron. The presence of a high-spin heme is suggestive of a substrate-binding site and an enzymatic activity. However, no enzymatic activity has yet been found for 16HCc_3. Furthermore, binding of a substrate would require a considerable conformational change to expose the free iron coordination site. The fact that 9HCc_3 has no high-spin heme also argues against an enzymatic activity of 16HCc_3 and it is possible that heme 15 may have lost its His ligand without affecting the physiological function. The presence of such a high-spin heme in a cytochrome is also observed in cytochrome c_{554} (see Section 3.2).

The gene for 16HCc_3, named *hmcA*, was cloned in *D. vulgaris* Hildenborough and found to be part of a large operon (the *hmc* operon) encoding a transmembrane complex of six proteins, having redox centers in the periplasm, membrane, and cytoplasm (Figure 7).[42] The 16HCc_3 is a periplasmic hydrophilic cytochrome with no transmembrane helices and its association with the membrane probably occurs *via* interaction with the other proteins in the complex. The gene *hmcB* encodes a transmembrane protein with a periplasmic hydrophilic N-terminal domain containing four [4Fe4S] cluster binding motifs and a cytoplasmic C-terminal tail; *hmcC*, *hmcD*, and *hmcE* encode integral membrane proteins, of which HmcC and HmcE may bind hemes *b*, and *hmcF* encodes a cytoplasmic protein having two [4Fe4S] cluster binding motifs, that is related to the catalytic subunits of heterodisulfide reductases. This complex has been proposed to be an important component in the sulfate respiratory chain by performing the electron transfer between periplasmic hydrogen oxidation and cytoplasmic sulfate reduction. Evidence for such a role of the Hmc complex could be found in the case where hydrogen is used as sole energy source. Indeed, expression of the *hmc* operon increases when hydrogen is used as electron donor when compared to either lactate or pyruvate.[43,44] In *D. vulgaris* Hildenborough, the *hmc* operon is adjacent to two genes (*rrf1* and *rrf2*) encoding expression regulating proteins. A mutant containing a deletion of the *rrf1* and *rrf2* genes overexpresses the *hmc* operon three times, and grows faster than the wild type on hydrogen but slower on lactate.[43] A second mutant, in which the *hmc* operon is deleted, grows normally with either lactate or pyruvate as electron donor, and can still grow with hydrogen as sole energy source, but with a slower rate than the wild type.[45] These results implicate the Hmc complex in the metabolism of hydrogen but not of lactate, and support the proposal that it is involved in the transfer of electrons from periplasmic hydrogen oxidation to the cytoplasmic reduction of sulfate. The fact that deletion of the *hmc* operon in *D. vulgaris* Hildenborough does not prevent growth on hydrogen indicates that there are other proteins that can fulfill the same role, and a likely candidate is the complex associated with the 4HCc_3TpII.

2.4 Cytochrome c_7

Cytochrome c_7 (3HCc_3) is the only member of the cytochrome c_3 family that is not present in sulfate-reducing bacteria. It is found in members of the *Geobacteraceae* like the marine *Desulfuromonas acetoxidans*, *Geobacter metallireducens*, and *Geobacter sulfurreducens*, all of which perform dissimilatory Fe^{III} reduction.[46,47] It is a periplasmic cytochrome of about 9 kDa containing three hemes *c*, with bis-histidinyl coordination and redox potentials of −140, −210, and −240 mV. The structure of the *D. acetoxidans* 3HCc_3 has been obtained both by NMR[48] and X-ray crystallography.[49] The overall protein fold and heme arrangement of this cytochrome is similar to cytochromes c_3, but it lacks the heme corresponding to heme 2 in these cytochromes (Figure 2). As in 4HCc_3TpIs, there is a region of positive surface charge surrounding heme 4, suggesting a similar mode of reactivity involving this heme. 3HCc_3 can be reduced by a recently identified hydrogenase from *D. acetoxidans*,[50] and also by *Desulfovibrio* hydrogenases. However, this cytochrome has different kinetic and thermodynamic properties from 4HCc_3TpIs, and does not present a redox-Bohr effect or perform a concerted two-electron step.[51]

The physiological function of 3HCc_3 is not completely established. The cytochrome from *D. acetoxidans*, has a high polysulfide reductase activity and was therefore proposed to act as the terminal reductase when this bacterium is growing with elemental sulfur as electron acceptor.[52] It also displays high activity in the reduction of several metal oxides

(see Section 2.1), suggesting a possible direct role in the dissimilatory reduction of metals, although the periplasmic location of 3HCc_3 precludes such a role in the case of insoluble metal oxides. In *G. sulfurreducens* a knockout mutant of the 3HCc_3 homolog (designated by PpcA) is affected in the reduction of Fe^{III}, U^{VI}, and anthraquinone 2,6-disulfonate (a humic acid analog) with acetate, but not with hydrogen, as the electron donor.[53] The acetate-dependent reduction of fumarate is also not affected. The results indicate that the triheme cytochrome is involved in electron transfer across the periplasm to the reduction of Fe^{III} by proteins in the outer membrane, but may be directly involved in periplasmic reduction of U^{VI} and antraquinone 2,6-disulfonate. The periplasmic location of hydrogenase overcomes the need for electron transfer across the periplasm, explaining why the PpcA mutant is not affected in growth with hydrogen.

3 THE HYDROXYLAMINE OXIDOREDUCTASE FAMILY

HAO is the largest member of the family of multiheme *c* proteins that share a similar superheme structural motif characterized by stacked diheme pairs generally interconnected by perpendicular heme arrangements. The members of this family show no apparent sequence identity or overall structural similarity, but there is local similarity in the polypeptide fold surrounding the hemes. This group includes both enzymes and electron transfer proteins, and the cases that have been more thoroughly investigated and for which there is structural information available will be discussed in particular. For two of the cases presented, the catalytic subunit is actually a multiheme *c* protein: HAO and cytochrome *c* nitrite reductase, which, interestingly, both act on nitrogen oxide compounds. In the two cases the electron donor/acceptor is also a multiheme *c* protein. There are also several examples of enzymes in which the catalytic subunit does not contain hemes *c*, but these are found in an electron transferring subunit, as in NapB subunit of the periplasmic nitrate reductase. In other cases, the multiheme *c* domain is actually fused to the catalytic domain, as in the case of the flavocytochrome *c* fumarate reductase.

3.1 Hydroxylamine Oxidoreductase

HAO catalyzes the four-electron oxidation of hydroxylamine to nitrite.[54] It is present in autotrophic nitrifying bacteria, like *Nitrosomonas*, which are obligate chemolithotrophs that use the oxidation of ammonia as their sole energy source.[55] For each cycle of hydroxylamine oxidation, two electrons are returned for the initial step of ammonia oxidation and the other two are either transferred to the terminal oxidase *via* the components of the respiratory chain, or used to generate NADH by reverse electron transport.

HAO from *Nitrosomonas europaea* is a homotrimer of 64 kDa subunits that is located in the periplasm. Each subunit contains eight hemes *c*, bound by typical CXXCH motifs. The catalytic heme has a third covalent bond to the protein between the 5-meso carbon of the porphyrin and the Cε1 ring carbon of tyrosine467 from a different subunit, thus providing the cross-link covalent attachment of the three subunits.[56,57] This heme has a Soret band at 463 nm in the reduced form, and is designated by heme P460.

The gene coding for HAO is expressed as a monocistronic transcript. There are three widely separated copies of this gene in the *N. europaea* genome, which are identical except for one nucleotide difference in one gene copy.[55] Mutants with any one copy of *hao* disrupted, or double mutants, show no growth differences to the wild type.[58] The nucleotide sequences of the two hao_1 and hao_2 gene copies are nearly identical for 160 bp upstream of the start codon, which includes the transcription start sites. The nucleotide sequence of the hao_3 gene copy diverges from the other two 15 bp upstream of the start codon.

The crystal structure of HAO has been determined.[57] The three subunits form a conical structure at the bottom of which a cavity is formed. There is also a cleft between the subunits that is negatively charged, and is proposed to be the docking site for the electron acceptor, cytochrome c_{554}, which is positively charged. Each subunit has three domains: the N-terminal domain contains hemes 1–3 and 5; the central domain is dominated by long α-helices and includes heme 8, while hemes P460 (heme 4), 6 and 7 are located in a pocket between these first two domains; the C-terminal domain is flexible and is not resolved in the electron density map. All *c*-type hemes have bis-histidinyl coordination, and heme P460 is five coordinate. The 24 hemes of the HAO trimer are in close contact to each other (Fe–Fe distances less than 12.8 Å) forming a circular structure. The three P460 hemes are located above a ring formed by 18 *c* hemes (all except the three hemes 1, which are not part of the ring). The hemes in each subunit are organized in three clusters showing parallel arrangements and an isolated heme (heme 8). In the triheme cluster formed by hemes P460, 6 and 7, hemes 6 and 7 form a typical parallel stacking motif, whereas hemes P460 and 6 are antiparallel (Figure 3). The two other clusters, formed by the diheme pairs 1/2 and 3/5, present also a parallel stacking motif. An interesting feature of HAO, observed in other multiheme proteins like the NrfA nitrite reductase or the small tetraheme cytochrome of *Shewanella* sp. is that the parallel motifs are connected by perpendicular motifs (see Section 1), formed by the heme pairs 2/3, 5/6, and 7/8 (Figure 3).

The peculiar heme arrangement of HAO is proposed to be linked to the two two-electron oxidation steps of hydroxylamine (NH_2OH) with HNO as an enzyme-bound intermediate.[54] The cross-linkage of heme P460 with Tyr467 may allow these two components to remove two electrons from NH_2OH, which will be transferred to the 6/7 heme pair and successively to the pairs 5/3 and 2/1. Heme 1 is exposed to the solvent at the negatively charged cleft where cytochrome

c_{554} is proposed to bind, and may thus be the electron exit heme. Cytochrome c_{554} also has two coplanar diheme pairs, which may indicate that it can also accept two electrons simultaneously. This cytochrome then transfers electrons to the membrane-bound tetraheme cytochrome c_{m552} (see Section 4), which is a good candidate to reduce the membrane ubiquinone pool, from where electrons are partitioned between the ammonia monooxygenase reaction, the aerobic respiratory chain, and reverse electron transport.[59]

The redox and spectroscopic properties of HAO have been closely investigated.[54] The EPR spectrum of HAO displays three types of signals, and show that four of the hemes are magnetically isolated and noninteracting, two hemes are weakly spin-coupled, and the remaining pair of hemes (which includes the high-spin heme P460) are exchange-coupled and give an integer-spin resonance. The EPR signals have been attributed to the hemes in the structure, with the pair P460/6 originating the strongly exchange-coupled signal, the pair 3/5 the weakly spin-coupled signal, and the hemes 1, 2, 7, and 8 the magnetically isolated heme signal.[60] Thus, magnetic heme interactions are only observed for the parallel heme pairs and not the perpendicular ones. Apparently the pair 1/2 does not present an exchange interaction, although it has a parallel arrangement similar to the pair 3/5. However, it may have an isotropic exchange coupling, in which case the signal is indistinguishable from the mononuclear species. The observed exchange interactions are probably derived from direct electronic overlap of the porphyrin orbitals in the stacked hemes. Interestingly, heme coupling in HAO is weaker than that observed for both cytochrome c_{554} and the NrfA nitrite reductase, although all the hemes in these two proteins can be spatially overlaid to equivalent ones of HAO (Figure 3).

3.2 Cytochrome c_{554}

The periplasmic cytochrome c_{554} is the electron acceptor for HAO. It is a monomeric protein of 25 kDa that binds four *c*-type hemes.[61] Its crystal structure is mainly α-helical, and has been determined for both oxidation states.[11,12] Three of the hemes have bis-histidinyl coordination (hemes 1, 3, and 4) and heme 2 is five coordinate and high spin. Heme 1 is unusual since it is the first example of a heme iron coordinated by the N_δ atom of a histidine. The macroscopic redox potentials of hemes 1 to 4 are +47, +47, −147, and −276 mV, respectively.[62] The four hemes of cytochrome c_{554} have a structural arrangement identical to hemes 3–6 of HAO, and hemes 2–4 of cytochrome c_{554} are equivalent to hemes 1–3 of NrfA (Figure 3). This similarity is also extended to the polypeptide chain surrounding the hemes, despite no obvious sequence similarity between these proteins. The four hemes are organized in two diheme pairs with a stacked parallel arrangement (hemes 1/3 and 2/4) perpendicular to each other. As observed for HAO, the hemes in each parallel pair are spin-coupled but there is no detectable magnetic interaction between the perpendicular hemes.[62] Treatment of cytochrome c_{554} with HAO and hydroxylamine results in reduction of two hemes,[63] supporting the idea that these two proteins perform two-electron transfer steps.

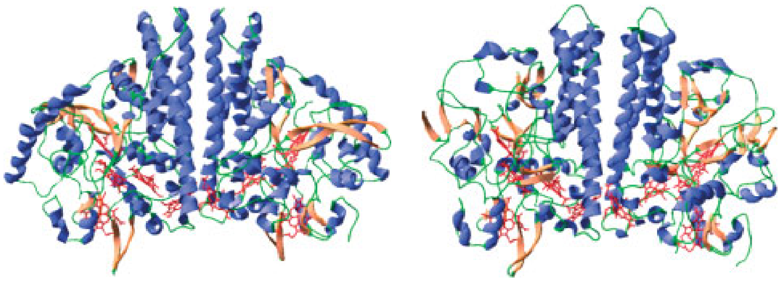
The presence of a high-spin heme in cytochrome c_{554} suggests the possibility of a catalytic function for this protein. However, this heme does not bind small ligands such as CN^-, F^-, CO, or NO in a pH range of 4–10,[62] and there is no evidence for a catalytic activity for this cytochrome. The crystal structure shows that the vacant coordination position of heme 2 is shielded from binding an exogenous ligand by the presence of three residues, Thr154, Pro155, and Phe156. The unusual presence of a high-spin heme in an electron transfer protein is also observed in the case of the sixteen-heme high molecular mass cytochrome from *Desulfovibrio* spp. (see Section 2.3).

There are three copies of the *hcy* (or *cyc*) gene coding for cytochrome c_{554}, each located 1,162-bp downstream of each copy of *hao*.[55] Two of the copies have been sequenced and are identical. The membrane-bound cytochrome c_{m552} (see Section 4) is encoded by genes contiguous with two of the three copies of *hcy*, but this does not happen for the third copy. It is likely that cytochrome c_{m552} is cotranscribed with cytochrome c_{554} and acts as its electron acceptor.

3.3 Cytochrome *c* Nitrite Reductase

There are four different types of nitrite reductases: the copper-containing protein ***Copper Enzymes in Denitrification*** and cytochrome cd_1 perform a one-electron reduction of nitrite to nitric oxide, and are involved in denitrification;[64–67] the siroheme-containing protein and the cytochrome *c* nitrite reductase (*c*NiR)[68,69] both perform the complete, six-electron reduction, of nitrite to ammonia. The *c*NiR is present in the γ, δ or ε-subclasses of proteobacteria, and is encoded by the *nrf* operon (*n*itrite *r*eduction with *f*ormate), which has different gene composition in the different classes of bacteria,[68] having in common only the gene for the catalytic subunit, *nrfA*.

In the γ-proteobacteria (like *E. coli* or *Haemophilus influenzae*), the *nrf* operon has the structure *nrfABCDEFG*, where NrfB is a periplasmic pentaheme cytochrome that probably acts as electron donor to NrfA, and NrfC a periplasmic iron–sulfur protein that together with the membrane-bound NrfD acts as a quinol oxidase to transfer electrons to NrfB.[70] The products of the *nrfEFG* genes form a NrfA-specific heme lyase required for attachment of a heme group to the active site.[71] In the ε-proteobacteria (e.g. *Wolinella succinogenes* or *Sulfurospirillum deleyianum*), the *nrf* operon includes *nrfHAIJ*, in which NrfH is a membrane-anchored tetraheme cytochrome that transfers electrons directly from the quinol pool to NrfA,[72] and NrfHI are involved in the heme attachment to the active site.[73] In the δ-proteobacteria (e.g. *D. vulgaris* or *G. sulfurreducens*), no accessory genes are present in the operon that is formed only by *nrfAH*.



(a) (b)

Figure 9 Structure of NrfA dimer from (a) *Wolinella* succinogenes (PDB code 1FS7)[76] and (b) *D. desulfuricans* ATCC27774 (PDB code 1OAH)[78]

NrfA is a 55–65 kDa protein that for a long time was considered to bind six hemes *c*: There are a great deal of spectroscopic data on this protein interpreted on the basis of this assumption! When the sequence of the *E. coli* enzyme became available, it revealed the presence of four typical heme *c* binding sites (CXXCH),[74] and an unconventional motif with a lysine replacing the histidine (CXXCK), later shown to bind a fifth heme.[71] NrfA is thus a pentaheme cytochrome and the unusual lysine-bound heme is the high-spin catalytic site. There are now several crystal structures available for NrfA from several organisms,[75–78] all of which show a very conserved arrangement of the five hemes. In all cases, the protein crystallizes as a homodimer, and the hemes in each monomer are in close contact allowing electron transfer between the monomers. The dimer is stabilized by the presence of long α-helices that interact across the dimer interface (Figure 9a). Despite a relatively low sequence identity, the polypeptide fold of the *S. deleyianum*, *W. succinogenes*, and *E. coli* NrfA are very similar, whereas that for *D. desulfuricans* ATCC 27774 shows more differences (Figure 9b). In all structures, hemes 2–5 are bis-histidinyl coordinated, and heme 1 is coordinated by a lysine with the other site being available to bind an external ligand. There are two conserved calcium ions, one near the active site and a second one coordinated by the propionates of hemes 3 and 4, and it has been shown that calcium is required for maximal activity of NrfA.[79] Another common feature of all the structures is the presence of two channels that lead from the surface to the active-site heme: a positively charged channel that is a putative inlet pathway for nitrite, and a negatively charged one that is a putative exit pathway for ammonia.

The five-heme groups in the NrfA monomer are tightly packed together on one side of the molecule with Fe–Fe distances of less than 12.8 Å. All the hemes are involved in the heme pair arrangements found in other multiheme proteins. The hemes 1, 3, and 4 are in parallel planes, forming two pairs of stacked hemes (1/3 and 3/4). The pairs 2/3 and 4/5 form diheme elbow motifs where the heme planes are almost perpendicular to each other. All of the hemes in NrfA can be superimposed on hemes 4 to 8 of HAO, including the two high-spin catalytic hemes (1 in NrfA and 4 in HAO) (Figure 3).

The solvent-exposed heme 2 is surrounded by a surface area of positive electrostatic potential, proposed as the site of interaction of the *S. deleyianum*, *W. succinogenes*, and *D. desulfuricans* NrfA with the physiological partner NrfH. In *E. coli*, NrfA has a different physiological partner, NrfB, and this correlates with some differences observed in the area around heme 2, that is, a more acidic surface region and a seven-residue insertion, only observed in the sequence of NrfA from organisms that have a *nrfB* rather than a *nrfH* gene in the *nrf* operon.

The NrfA protein is isolated in distinct forms from different groups of proteobacteria. In the γ-proteobacteria (like *E. coli*), NrfA is purified as a single protein either from the periplasm or from the membrane fraction and there is no evidence for the formation of a stable complex with its electron donor NrfB. In the ε-proteobacteria, such as *W. succinogenes* and *S. deleyianum*, NrfA can be isolated either as a soluble protein from the periplasm, or in the form of a complex with NrfH from the membrane fraction. In the δ-proteobacteria, such as *D. desulfuricans* and *D. vulgaris*, it can only be isolated from the membranes in the form of a tight complex with NrfH, which can only be dissociated in the two subunits in the presence of denaturing agents.[80,81]

The *c*NiR has been extensively investigated by spectroscopic techniques, including EPR, MCD, and Mössbauer. This enzyme has quite interesting spectroscopic features owing to the presence of magnetic interactions between the hemes. However, many of these studies are hampered by the fact that their interpretation was performed before it was known that NrfA contains five hemes and/or that NrfA is present in a complex with the tetraheme cytochrome NrfH. Recent analysis of the NrfA spectroscopic properties have overcome these problems.[77,81]

NrfA catalyzes the final step of the respiratory chain in dissimilatory nitrite ammonification. Proteoliposomes containing the formate dehydrogenase, menaquinone, and NrfAH complex from *W. succinogenes* catalyze electron transport from formate to nitrite, which is associated with the development of an electrochemical proton potential across the

membrane.[72] However, oxidation of a menaquinol analog by nitrite does not generate a membrane potential, indicating that the site of energy conservation is the formate dehydrogenase. Further than the six-electron reduction of nitrite to ammonia, NrfA also catalyzes the five-electron reduction of nitric oxide and the two-electron reduction of hydroxylamine, both of which are possible intermediates in the reduction of nitrite, as well as the six-electron reduction of sulfite to sulfide.[82] A detailed mechanism has been proposed for the reduction of nitrite,[83] and the reduction of both nitrite and hydroxylamine have been probed by protein film voltammetry.[84] Interestingly, the ability of NrfA to reduce nitric oxide may have an important role in the survival of several enteric pathogenic bacteria to this toxic agent.[85] There is also evidence that in these bacteria the *c*NiR works in coordination with the periplasmic nitrate reductase, Nap, which is responsible for the reduction of nitrate when low levels of nitrate are available, for example, in body fluids.[66] The two systems (*c*Nir and Nap) have similar transcriptional regulation and may form a multimeric complex in the periplasm.

The *c*NiR has also been proposed to have a role in the detoxification of nitrite, since it is present in organisms that cannot use this compound for growth, but where it has a role in preventing growth inhibition by nitrite.[80,86]

3.4 Flavocytochrome *c* Fumarate Reductase and *Shewanella* Small Tetraheme Cytochrome

Flavocytochrome Fumarate Reductase. The flavocytochrome fumarate reductase (Ffr) is a soluble periplasmic protein from *Shewanella* spp. that reduces fumarate but does not oxidize succinate, in contrast to the membrane-bound fumarate reductases that are related to succinate dehydrogenases, and transfer electrons from quinol to fumarate. It is a monomeric protein of 63.8 kDa that is composed of three domains. The N-terminal domain contains four *c*-type hemes, and the flavin domain contains noncovalently bound FAD and is related to flavoprotein subunits of membrane-bound fumarate reductases and succinate dehydrogenases. There is also a third domain in the flavocytochromes that has considerable flexibility and may be involved in controlling access of substrate to the active site. The macroscopic redox potentials of the four hemes of Ffr are −102, −146, −196, and −238 mV, while that of FAD is −152 mV.[87] The low redox potential of FAD in Ffr compared to that in membrane-bound fumarate reductase (−55 mV)[88] may explain why it is unable to oxidize succinate.

The physiological electron donor of Ffr is likely to be the membrane-anchored tetraheme cytochrome CymA (see Section 4), since a soluble form of this cytochrome can transfer electrons efficiently to Ffr.[89] In *S. frigidimarina* (formerly *S. putrefaciens* NCIMB400), the Ffr gene is expressed under microaerobic and all anaerobic growth conditions. A null mutant lacking this enzyme is unable to grow anaerobically with fumarate, indicating that this protein is the physiological fumarate reductase.[90] However, a second tetraheme cytochrome similar to Ffr is induced during growth of this bacterium in the presence of Fe^{III}, and was named Ifc for iron-induced flavocytochrome.[91] Although Ifc does have a high fumarate reductase activity it is not expressed during growth with fumarate, during microaerobic growth or anaerobic growth with electron acceptors other than Fe^{III}. The physiological role of Ifc is proposed to be the electron transport to soluble Fe^{III} compounds. A mutant strain deficient in this cytochrome can still grow with Fe^{III} but this leads to overexpression of soluble and membrane-bound *c*-type cytochromes.

The crystal structures of Ffr from two *Shewanella* spp. and Ifc have been determined and are very similar to each other.[92–94] The FAD domain of these flavocytochromes has significant structural similarity to other FAD-binding proteins. The heme-binding domain shows very little secondary structure. All of the hemes are coordinated by two histidines and are in close distance to each other. Hemes 1 and 2 are positioned in a perpendicular motif, whereas hemes 2 and 3 are in a parallel stacked motif. These three hemes can be superimposed to hemes 5–7 of HAO and 2–4 of NrfA (Figure 3). Heme 4 of Ffr is deviated from the corresponding heme 8 position in HAO, because it is oriented toward the FAD group.

The structural similarity of the flavin domain and the conservation of a few residues of the active site in soluble and membrane-bound fumarate reductases suggest a common catalytic mechanism for these enzymes.[93] A series of studies involving site-directed mutagenesis have helped to elucidate this mechanism (for a recent reference see Ref. 95). A key arginine residue acts as the active-site catalyst by acting both as a Lewis acid (stabilizing a negative charge in the transition state) and a Brønsted acid (delivering a proton to the substrate).[96,97]

Shewanella Small Tetraheme Cytochrome. The small tetraheme cytochrome (Stc) isolated from *Shewanella* spp. has this designation owing to the fact that it is the smallest tetraheme cytochrome *c* known to date, having only 86 residues and a molecular mass of 11.8 kDa. This cytochrome was initially designated as a cytochrome c_3, but determination of the elongated heme core architecture by NMR revealed that it is completely different from the globular one found in the cytochrome c_3 family, as expected from a primary sequence alignment that depicts quite different motifs for the residues that bind hemes 2 and 3, which are essential for the globular folding of cytochrome c_3 (Figure 5).[98] The Stc is encoded by the monocistronic gene *cctA*, and is involved in periplasmic electron transfer of the respiratory chain when Fe^{III} is the terminal electron acceptor. A mutant strain lacking this cytochrome shows no difference relative to the wild type in aerobic growth, or anaerobic growth in the presence of other electron acceptors, but respiration with Fe^{III} as electron acceptor is severely, although not completely, impaired.[99]

The crystal structure of *Shewanella oneidensis* MR-1 Stc has been determined, both in oxidized and reduced forms.[100] The heme structural arrangement is similar, but not identical, to that observed in *Shewanella* Ffr, with the main difference being heme 4, which is oriented toward the FAD group in Ffr (Figure 3). The hemes in Stc show the typical diheme arrangement of this family, with the pairs 1/2 and 3/4 in a perpendicular orientation and the pair 2/3 in a parallel stacked motif. Hemes 1 to 4 of the Stc can be superimposed on hemes 5–8 of HAO and 2–5 of NrfA. Reduction induces small changes in the position of several residues, resulting in decreased solvent exposure of the hemes and removal of the single positive charge from the molecular surface. The surface charge of *S. oneidensis* MR-1 Stc is mainly negative but homogeneous, with no obvious binding sites for redox partners. In the *S. frigidimarina* Stc, the pH dependence of the microscopic heme redox potentials is small.[101]

3.5 Split-Soret Cytochrome and NapB

Split-Soret Cytochrome. The split-Soret cytochrome (Ssc) and NapB proteins have no relationship except the fact that both contain a single stacked parallel diheme motif. Ssc is a dimer of two identical 26.3 kDa subunits, which has so far been isolated only from the *D. desulfuricans* ATCC 27774, a species that can use sulfate or nitrate as terminal electron acceptors. Each monomer contains two *c*-type hemes with bis-histidinyl coordination and redox potentials of −168 and −330 mV. The name of this cytochrome derives from the fact that the reduced form displays a split-Soret band with maxima at 420 nm and a shoulder at 415 nm.

A model of the three-dimensional structure of Ssc shows that this protein has unique features, and does not belong to the cytochrome c_3 family.[102] The heme groups are attached at a C-terminal domain of the molecule and exposed to the solvent, in a parallel stacked motif. In the Ssc dimer, the four hemes are very close together, and the sixth histidinyl ligand of heme 1 is provided by the chain of the other monomer, indicating that the dimer is the functional unit of Ssc. This cytochrome also contains an α-helical N-terminal domain where four cysteines are positioned at an open surface pocket of the protein suggesting the binding of a FeS center. Indeed, the presence of a [2Fe2S] cluster in Ssc had been proposed on the basis of Mössbauer data,[103] and it could be confirmed by EPR spectroscopy of anaerobically purified Ssc.[104] This cluster is very oxygen-labile as indicated by nonheme iron quantification of aerobically and anaerobically prepared Ssc, and the fact that it is not observed in the structure of the aerobically purified Ssc. Modeling of the [2Fe2S] center suggests a possible unusual coordination by only three of the available cysteines, leaving one free coordination position in one of the irons that is accessible from the outside of the molecule and thus pointing to a not yet found enzymatic activity.

The physiological function of Ssc has not been elucidated. Cloning and sequencing of the *D. desulfuricans* ATCC 27774 Ssc gene revealed that the cytochrome is encoded by a monocistronic operon, and contains a signal peptide sequence indicating that the protein is periplasmic. Transcriptional analysis revealed that sulfate-grown cells contained only 9% of the Ssc mRNA levels of nitrate-grown cells.[104] A homolog of the Ssc cytochrome gene is found in the genomes of *D. desulfuricans* G20, *S. oneidensis*, *Desulfitobacterium hafniense* but not *D. vulgaris* Hildenborough. In the genome of the sulfate-reducing archaeon, *Archaeoglobus fulgidus*, a putative homolog of Ssc is encoded, which contains only the N-terminal domain that binds the FeS cluster, but not the C-terminal heme *c* domain.

NapB. NapB is a subunit of the heterodimeric periplasmic nitrate reductase (NapAB) and transfers electrons to the catalytic NapA molybdoprotein. Nap systems are found in a number of bacteria, including enterobacteria, aerobic denitrifiers, and nonsulfur purple photosynthetic bacteria.[66,105] Their physiological function is different in these groups of bacteria and includes redox balancing using nitrate as an electron sink to dispose of excess reductant, aerobic denitrification, and nitrate scavenging in nitrate-limited environments.

NapB is a 13–19 kDa diheme cytochrome *c*, usually isolated in a strong complex with NapA, although in some cases it is possible to separate the two subunits. The redox potentials of the hemes vary in different bacterial species, probably reflecting the diverse physiological roles. NapB is essential for Nap activity since deletion mutants in *E. coli* and *Rhodobacter sphaeroides* have very low nitrate reductase activity. It receives electrons from the quinol pool *via* the membrane-anchored tetraheme cytochrome NapC. The crystal structure of a proteolyzed form of recombinant NapB from *H. influenzae* was determined[106] and, more recently, that of the NapAB complex from *Rb. sphaeroides* was also obtained.[107] The two hemes in NapB are bis-His coordinated, and display the typical diheme stacked arrangement. The structure of *H. influenzae* NapAB shows that NapB has extensive interactions with NapA, explaining the high affinity of this complex. The two proteins are bound such that heme II of NapB is in close contact to the iron–sulfur cluster of NapA, whereas heme I is exposed to the solvent, and is thus the heme likely to receive electrons from NapC. A comparison of the cofactors redox potentials in the bound and isolated subunits shows that there is a strong effect of complex formation on the redox potential of the [4Fe4S] cluster (a change of +180 mV), and a smaller, but significant, change for heme 2 (+40 mV). The increase in the redox potentials are due to the decrease in solvent exposure of the cofactors, and lead to favorable electron transfer steps between the cofactors.

4 OTHER MULTIHEME *c* CYTOCHROMES

An important family of multiheme proteins are the tetra or pentaheme *c*-type cytochromes that are bound to the membrane by an N-terminal hydrophobic anchor, usually referred to as the NapC family of cytochromes, since this was the first one to be recognized.[108,109] These cytochromes act as quinol dehydrogenases, transferring electrons from the quinone pool to periplasmic proteins involved in the reduction of various electron acceptors like nitrate, nitrite, fumarate, Fe^{III}, trimethylamine N-oxide, and dimethylsulfoxide. Phylogenetic analyses show these novel quinol dehydrogenases are more widely distributed among the *Proteobacteria* than the bc_1 complex. Examples include: NapC, which is involved in reduction of the periplasmic nitrate reductase NapAB; NirT, which is thought to donate electrons to the periplasmic cd_1 nitrite reductase; NrfH, the electron donor of the NrfA nitrite reductase; TorC, which is involved in the reduction of trimethylamine N-oxide reductase; DmsC and DorC, which are likely electron donors to dimethylsulfoxide reductases; and FccC, which is suggested to transfer electrons to a periplasmic methacrylate reductase. Two further interesting members of this family are the CymA from *Shewanella* spp. and cytochrome c_{m552} of *N. europea*. CymA is not specific for any one reductase, since it is involved in reduction of nitrate, nitrite, fumarate, DMSO, Fe^{III}, and Mn^{IV}, thus having to interact with a range of redox partners.[89,110] Cytochrome c_{m552} (or CycB) of *N. europea* probably operates in reverse of the rest of the family by reducing the quinone pool with electrons derived from the periplasmic oxidation of hydroxylamine.[59] Despite the importance of this family of cytochromes in electron transfer chains, no structure has yet been determined.

The common feature of these proteins is the presence of a tetraheme periplasmic domain that is attached to the membrane through a single α-helical anchor. In TorC and DorC, there is an additional C-terminal monoheme domain.[111] The four hemes have bis-histidinyl coordination and low redox potentials, whereas the monoheme has a high redox potential. There is evidence to indicate that the tetraheme globular domain is formed by two diheme domains, which show sequence similarity to each other, and may be related to the diheme binding segments of cytochromes of the HAO family (see Section 3).[108] In the case of CymA and NapC, the membrane anchor is apparently not necessary for interaction of the heme domain with quinols.

Multiheme cytochromes *c* play an important role in bacterial iron respiration.[47,112] In this process, soluble Fe^{III} chelates or insoluble Fe^{III} oxides serve as terminal electron acceptors of the anaerobic respiratory chain. In *Shewanella* and *Geobacter* spp., the two most studied Fe^{III}-reducing organisms, a great increase in cellular multiheme *c*-type cytochromes is observed upon growth by iron respiration. In the case of the genus *Shewanella,* electron transport to Fe^{III} involves CymA in the cytoplasmic membrane, and several periplasmic and outer membrane cytochromes. These include the products of the *mtrDEF-omcA-mtrCAB* gene cluster, which encodes two periplasmic decaheme cytochromes *c* (MtrA and MtrD), two putative outer membrane β-barrel proteins (MtrB and MtrE) and three outer membrane decaheme cytochromes *c* (OmcA, MtrC, which is also designated by OmcB, and MtrF).[113,114] In addition, the periplasmic Stc and Ifc proteins (see Section 3.4) may also play a role in Fe^{III} reduction. The periplasmic cytochromes may be involved in direct reduction of soluble Fe^{III} chelates that may enter the periplasm, or in electron transport between CymA and the outer membrane cytochromes that are most likely responsible for reduction of the insoluble Fe^{III} oxides. The outer membrane cytochrome OmcA was purified from *S. frigidimarina* cells and shown to bind 10 bis-His ligated hemes, with redox potentials centered at -243 and -324 mV.[115] A mutant deleted in OmcA is affected in its ability to reduce MnO_2, but not Fe^{III}.[113] Its paralog, MtrC (OmcB), seems to play a more significant role in Fe^{III} reduction, as is the case for the periplasmic cytochrome MtrA and the outer membrane MtrB.[114] MtrB is required for incorporation of cytochromes in the outer membrane.[116] A recombinant form of the periplasmic MtrA cytochrome has been characterized.[117] It is a 32 kDa cytochrome containing 10 bis-His coordinated hemes *c* that reduce over the potential range of -100 to -400 mV. Sequence analysis of MtrA suggests that six of the hemes may be organized in parallel diheme pair motifs similar to hemes 2/3 of Stc. MtrA can reduce several Fe^{III} chelates and transfer electrons to the *E. coli* host NrfA and NapAB. This indicates that, as in Stc, the surface-exposed hemes may be involved in nonspecific electron transfer, which is probably a general property for cytochromes with a low amino acid to heme ratio.

In *G. sulfurreducens,* two outer membrane cytochromes, designated as OmcB and OmcC, are also implicated in Fe^{III} reduction.[118] They are 79% identical and both contain 12 hemes *c*. OmcB is about twofold more abundant than OmcC, and an OmcB-deficient mutant is greatly impaired in its ability to reduce Fe^{III}, which is not observed for the OmcC-deficient mutant. The periplasmic triheme cytochrome *c* PpcA is also involved in electron transfer across the periplasm to the reduction of Fe^{III} (see Section 2.4). A great number of genes coding for multiheme cytochromes are present in the *G. sulfurreducens* genome. Several of these are high molecular mass cytochromes with an astonishing number of hemes per polypeptide (e.g. 18, 24, 27, and 33 hemes!). This reveals there are still a number of multiheme *c* proteins to be investigated, the study of which may bring new insights to this group of proteins.

1 INTRODUCTION

An important parameter of a semiconductor material is the width of the energy gap that separates the conduction from the valence energy bands (Figure 1(a), left). In semiconductors of macroscopic sizes, the width of this gap is a fixed parameter, which is determined by the material's identity. However, the situation changes in the case of nanoscale semiconductor particles with sizes smaller than ∼10 nm (Figure 1(a), right). This size range corresponds to the regime of quantum confinement for which electronic excitations 'feel' the presence of the particle boundaries and respond to changes in the particle size by adjusting their energy spectra. This phenomenon is known as the *quantum size effect*, while nanoscale particles that exhibit it are often referred to as quantum dots (QDs).

As the QD size decreases, the energy gap increases, leading, in particular, to a blue shift of the emission wavelength. In the first approximation, this effect can be described using a simple 'quantum box' model. For a spherical QD with radius R, this model predicts that the size-dependent contribution to the energy gap is simply proportional to 1/R[1] (Figure 1(b)). In addition to increasing energy gap, quantum confinement leads to a collapse of the continuous energy bands of the bulk material into discrete, 'atomic' energy levels. These well-separated QD states can be labeled using atomic-like notations (1S, 1P, 1D, etc.), as illustrated in Figure 1(a). The discrete structure of energy states leads to the discrete absorption spectrum of QDs (schematically shown by vertical bars in Figure 1(c)), which is in contrast to the continuous absorption spectrum of a bulk semiconductor (Figure 1(c)).

Semiconductor QDs bridge the gap between cluster molecules and bulk materials. The boundaries between molecular, QD, and bulk regimes are not well defined and are strongly material dependent. However, a range from ∼100 to ∼10 000 atoms per particle can be considered as a crude estimate of sizes for which the nanocrystal regime occurs. The lower limit of this range is determined by the stability of the bulk crystalline structure with respect to isomerization into molecular structures. The upper limit corresponds to sizes for which the energy level spacing is approaching the thermal energy kT, meaning that carriers become mobile inside the QD.

Semiconductor QDs have been prepared by a variety of 'physical' and 'chemical' methods. Some examples of physical processes, characterized by high-energy input, include molecular beam epitaxy (MBE) and metalorganic-chemical-vapor-deposition (MOCVD) approaches to quantum dots[1–3] and vapor-liquid solid (VLS) approaches to quantum wires.[4,5] High-temperature methods have also been applied to chemical routes, including particle growth in glasses.[6,7] Here, however, we emphasize 'soft' (low-energy-input) colloidal chemical synthesis of crystalline semiconductor nanoparticles that we will refer to as nanocrystal quantum dots (NQDs). NQDs comprise an inorganic core overcoated with a layer of organic ligand molecules. The organic capping provides electronic and chemical passivation of surface dangling bonds, prevents uncontrolled growth and agglomeration of the nanoparticles, and allows NQDs to be chemically manipulated like large molecules with solubility and reactivity determined by the identity of the surface ligand. In contrast to substrate-bound epitaxial QDs, NQDs are 'freestanding.' In this discussion, we concentrate on the most successful synthesis methods, where success is determined by high crystallinity, adequate surface passivation, solubility in nonpolar or polar solvents, and good size monodispersity. Size monodispersity permits the study and, ultimately, the use of materials-size-effects to define novel materials properties. Monodispersity in terms of colloidal nanoparticles (1–15 nm size range) requires a sample standard deviation of $\sigma \leq 5\%$, which corresponds to ± one lattice constant.[8] Because colloidal monodispersity in this strict sense remains relatively uncommon, preparations are included in this chapter that achieve approximately $\sigma \leq 20\%$, in particular where other attributes, such as novel compositions or shape control, are relevant. In addition, we discuss 'soft' approaches to NQD chemical and structural modification.

2 COLLOIDAL NANOSYNTHESIS

The most successful NQD preparations with respect to nanocrystal quality and monodispersity entail pyrolysis of metal-organic precursors in hot coordinating solvents (120–360 °C). Understood in terms of La Mer and Dinegar's studies of colloidal particle nucleation and growth,[8,9] these preparative routes involve a temporally discrete nucleation event followed by relatively rapid growth from solution-phase monomers and finally slower growth by Ostwald

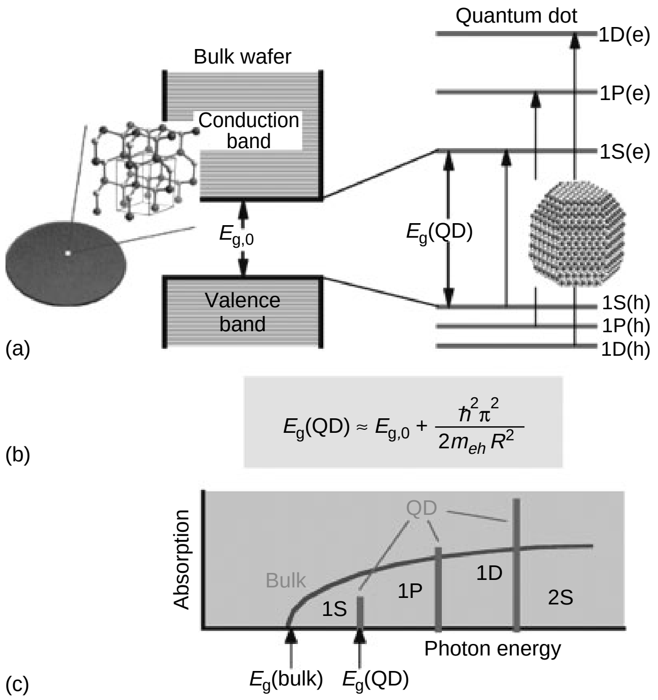

Figure 1 (a) A bulk semiconductor has continuous conduction and valence energy bands separated by a 'fixed' energy gap, E_{g0} (left), while a QD is characterized by discrete atomic-like states with energies that are determined by the QD radius R (right). (b) The expression for the size-dependent separation between the lowest electron [1S(e)] and hole [1S(h)] QD states (QD energy gap) obtained using the 'quantum box' model [$m_{eh} = m_e m_h/(m_e + m_h)$, where m_e and m_h are effective masses of electrons and holes, respectively]. (c) Schematic of the continuous absorption spectrum of a bulk semiconductor (curved line), compared to the discrete absorption spectrum of a QD (vertical bars)

ripening (referred to as recrystallization or aging) (Figure 2). Nucleation is achieved by quick injection of precursor into the hot coordinating solvents, resulting in thermal decomposition of the precursor reagents and supersaturation of the formed 'monomers' that is partially relieved by particle generation. Growth then proceeds by addition of monomer from solution to the NQD nuclei. Monomer concentrations are below the critical concentration for nucleation, and, thus, these species only add to existing particles, rather than form new nuclei.[10] Once monomer concentrations are sufficiently depleted, growth can proceed by Ostwald ripening. Here, sacrificial dissolution of smaller (higher-surface-energy) particles results in growth of larger particles and, thereby, fewer particles in the system.[8]

Alternatively, supersaturation and nucleation can be triggered by a *slow* ramping of the reaction temperature. Precursors are mixed at low temperature and slowly brought to the temperature at which precursor reaction and decomposition occur sufficiently quickly to result in supersaturation.[11] Supersaturation is again relieved by a 'nucleation burst', after which temperature is controlled to avoid additional nucleation events, allowing monomer addition to existing nuclei to occur more rapidly than new nuclei formation. Thus, nucleation does not need to be instantaneous, but it should be a single, temporally discreet event to provide for the desired nucleation-controlled narrow size dispersions.[10]

2.1 Tuning Particle Size and Maintaining Size Monodispersity

Size and size dispersion can be controlled during the reaction, as well as post-preparatively. In general, time is a key

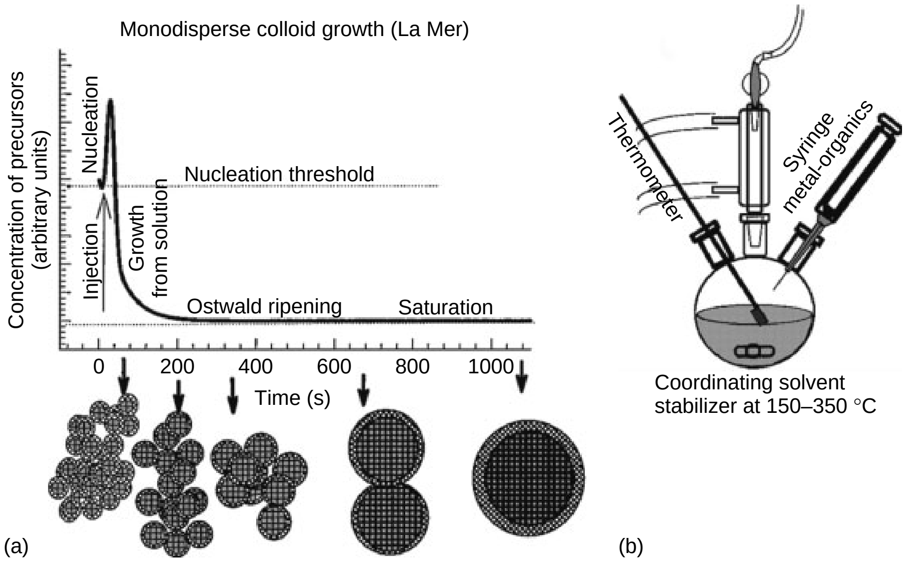

Figure 2 (a) Schematic illustrating La Mer's model for the stages of nucleation and growth for monodisperse colloidal particles. variable; longer reaction times yield larger average particle size. Nucleation and growth temperatures play contrasting roles. *Lower* nucleation temperatures support lower monomer concentrations and can yield larger-size nuclei. Whereas, *higher* growth temperatures can generate larger particles as the rate of monomer addition to existing particles is enhanced. Also, Ostwald ripening occurs more readily at higher temperatures. Precursor concentration can influence both the nucleation and the growth processes, and its effect is dependent upon the surfactant/precursor-concentration ratio and the identity of the surfactants (i.e. the strength of interaction between the surfactant and the NQD or between the surfactant and the monomer species). All else being equal, higher precursor concentrations promote the formation of fewer, larger nuclei and, thus, larger NQD particle size. Similarly, low stabilizer:precursor ratios yield larger particles. Also, weak stabilizer-NQD binding supports growth of large particles and, if too weakly coordinating, agglomeration of particles into insoluble aggregates.[10] Stabilizer-monomer interactions may influence growth processes, as well. Ligands that bind strongly to monomer species may permit unusually high monomer concentrations that are required for very fast growth (see Section 4),[12] or they may promote reductive elimination of the metal species (see below).[13]

The steric bulk of the coordinating ligands can impact the rate of growth subsequent to nucleation. Coordinating solvents typically comprise alkylphosphines, alkylphosphine oxides, alkylamines, alkylphosphates, alkylphosphites, alkylphosphonic acids, alkylphosphoramide, alkylthiols, fatty acids, and so on of various alkyl chain lengths and degrees of branching. The polar head group coordinates to the surface of the NQD, and the hydrophobic tail is exposed to the external solvent/matrix. This interaction permits solubility in common nonpolar solvents and hinders aggregation of individual nanocrystals by shielding the van der Waals attractive forces between NQD cores that would otherwise lead to aggregation and flocculation. The NQD-surfactant connection is dynamic, and monomers can add or subtract relatively unhindered to the crystallite surface. The ability of component atoms to reversibly come on and off of the NQD surface provides a necessary condition for high crystallinity – particles can anneal while particle aggregation is avoided. Relative growth rates can be influenced by the steric bulk of the coordinating ligand. For example, during growth, bulky surfactants can impose a comparatively high steric hindrance to approaching monomers, effectively reducing growth rates by decreasing diffusion rates to the particle surface.[10]

The two stages of growth (the relatively rapid first stage and Ostwald ripening) differ in their impact on size dispersity. During the first stage of growth, size distributions remain relatively narrow (dependent upon the nucleation event) or can become more focused. In contrast, sizes tend to defocus during Ostwald ripening as smaller particles begin to shrink and eventually dissolve in favor of growth of larger particles.[14] The benchmark preparation for CdS, CdSe, and CdTe NQDs,[15] which dramatically improved the overall quality of the nanoparticles prepared until that point, relied on Ostwald ripening to generate size series of II–VI NQDs. For example, CdSe NQDs from 1.2–11.5 nm in diameter were prepared.[15] Size dispersions of 10–15% were achieved for the larger-size particles and had to be subsequently narrowed by size-selective precipitation. The size-selective process simply involves first titrating the NQDs with a polar 'nonsolvent,' typically methanol, to the first sign of precipitation plus a small excess, resulting in precipitation of a small fraction of the NQDs. Such controlled precipitation preferentially removes the largest dots from the starting solution, as these become unstable to solvation before the smaller particles do. The precipitate is then collected by centrifugation, separated from the liquids, redissolved, and precipitated again. This iterative process separates larger from smaller NQDs and can generate the desired size dispersion of $\leq$5%.

More recently, preparations for II–VI semiconductors have been developed that specifically avoid the Ostwald-ripening growth regime. In one such method, the regime of relatively fast growth (the 'size-focusing' regime) is maintained by the addition of precursor monomer to the reaction solution after nucleation has occurred but before Ostwald growth has begun. The additional monomer is not sufficient to nucleate more particles, that is, not sufficient to again surpass the nucleation threshold. Instead, monomers add to existing particles and promote relatively rapid particle growth. Sizes focus as the monomer preferentially adds to smaller particles rather than to larger ones.[14] High monodispersity is evident in transmission electron micrograph (TEM) images (Figure 3). A slowly reacting precursor can provide a similar effect. For example, in the preparation of PbSe from lead oleate and trioctylphosphine selenide (see Section 2.3), the initial nucleation event consumes only a small fraction of the lead precursor. The lead oleate is relatively stable in phenyl ether, a reaction solvent. The unspent precursor present in solution

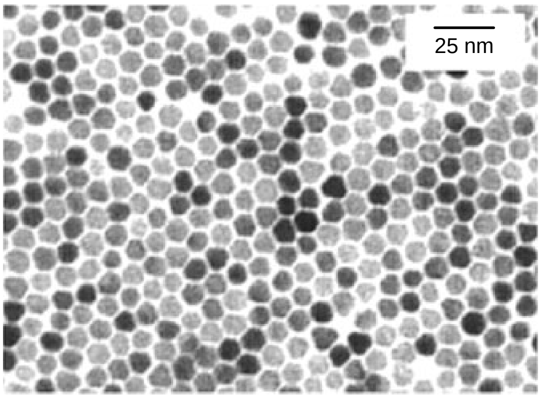

Figure 3 TEM of 8.5-nm diameter CdSe nanocrystals demonstrating the high degree of size monodispersity achieved by the 'size-focusing' synthesis method. (Reprinted with permission from Ref. 14. © 1998 American Chemical Society)

is sufficient to maintain growth in the size-focusing regime until particle sizes are reached that are several times those obtained in the initial stage of nucleation and growth ($\sim$3 nm to $\sim$12 nm). Alternatively, growth can simply be stopped during the fast-growth stage (by removing the heat source), and sizes are limited to those relatively close to the initial nucleation size. Because nucleation size can be manipulated by changing precursor concentration or reaction injection temperature, narrow size dispersions of controlled average particle size can be obtained by this method, as well.

2.2 CdSe NQDs – the ‘Model’ System

Owing to the ease with which high-quality samples can be prepared, the II–VI compound, CdSe, has comprised the ‘model’ NQD system and been the subject of much basic research into the electronic and optical properties of NQDs. CdSe NQDs can be reliably prepared from pyrolysis of a variety of cadmium precursors, including alkyl cadmium compounds (e.g. dimethylcadmium)[15] and various cadmium salts (cadmium oxide, cadmium acetate, and cadmium carbonate),[16] combined with a selenium precursor prepared simply from Se powder dissolved in trioctylphosphine (TOP) or tributylphosphine (TBP). Initially, the surfactant-solvent combination, technical-grade trioctylphosphine oxide (tech-TOPO) and TOP, was used, where tech-TOPO performance was batch specific owing to the relatively random presence of adventitious impurities.[15] More recently, tech-TOPO has been replaced with ‘pure’ TOPO to which phosphonic acids have been added to controllably mimic the presence of the technical-grade impurities.[17] In addition, TOPO has been replaced with various fatty acids, such as stearic and lauric acid. The fatty-acid systems are compatible with the full range of cadmium precursors, but are most suited for growth of larger NQDs (>6 nm in diameter), compared to the TOPO/TOP system, since growth proceeds relatively more quickly.[16] Further, the choice of fatty acid can influence particle growth, as shorter alkyl chain lengths yield relatively faster growth (likely improving monomer access to particle surfaces). The cadmium precursor is typically dissolved in the fatty acid at moderate temperatures, converting the Cd compound to cadmium stearate, for example. Alkyl amines were also successfully employed as CdSe growth media.[16] Incompatible systems are those that contain the anion of a strong acid (present as the surfactant ligand or as the cadmium precursor) and thiol-based systems.[16] Perhaps the most successful system, in terms of producing high quantum yields (QYs) in emission and monodisperse samples, uses a complex mixture of surfactants: stearic acid, TOPO, hexadecylamine, TBP, and dioctylamine.[18]

2.3 Optimizing Photoluminescence

High QYs are indicative of a well-passivated surface. NQD emission can suffer from the presence of unsaturated, ‘dangling’ bonds at the particle surface that act as surface traps for charge carriers. Recombination of trapped carriers leads to a characteristic emission band (‘deep-trap’ emission) on the low-energy side of the ‘band-edge’ photoluminescence (PL) band. Band-edge emission is associated with recombination of carriers in NQD ‘interior’ quantized states. Coordinating ligands help to passivate surface trap sites, enhancing the relative intensity of band-edge emission compared to the deep-trap emission. The complex mixed-solvent system, described above, has been used to generate NQDs having QYs as high as 70 – 80%. These remarkably high PL efficiencies are comparable to the best achieved by inorganic epitaxial-shell surface-passivation techniques (see Section 3). They are attributed to the presence of a primary amine ligand, as well as to the use of excess selenium in the precursor mixture (ratio Cd:Se of 1:10). The former alone (i.e. coupled with a ‘traditional’ Cd:Se ratio of 2:1 or 1:1) yields PL QYs that are higher than those typically achieved by organic passivation (40–50% compared to 5–15%). The significance of the latter likely results from the unequal reactivities of the cadmium and selenium precursors. Accounting for the relative precursor reactivities by using such concentration-biased mixed precursors may permit improved crystalline growth and, hence, improved PL QYs.[18] Further, in order to achieve the very high QYs, reactions must be conducted over limited time spans from 5–30 min. PL efficiencies reach a maximum in the first half of the reaction and decline thereafter (Figure 4). Optimized preparations yield rather large NQDs, emitting in the orange–red. However, high-QY NQDs representing a variety of particle sizes are possible. By controlling precursor identity, total precursor concentrations, the identity of the solvent system, the nucleation and growth temperatures, and the growth time, NQDs emitting with >30% efficiency from $\sim$510 nm to 650 nm can be prepared.[18] Finally, the important influence of the primary amine ligands may result from their ability to pack more efficiently on the NQD surfaces. Compared to TOPO and TOP, primary amines are less sterically hindered and may simply allow for a higher capping density.[19] However, the amine-CdSe NQD linkage is not as stable as for other more strongly bound CdSe ligands.[20] Thus, growth solutions prepared from this procedure are highly luminescent but washing or processing into a new liquid or solid matrix can dramatically impact the QY. Multidentate amines may provide both the desired high PL efficiencies and the necessary chemical stabilities.[18]

High-quality NQDs are no longer limited to cadmium-based II–VI compounds. Preparations for III-V semiconductor NQDs are also well developed (see Section 3). Exclusively band-edge UV to blue emitting ZnSe NQDs ($\sigma = 10\%$) exhibiting QYs from 20 – 50% have been prepared by pyrolysis of diethylzinc and TOPSe at high temperatures (nucleation: 310 °C; growth: 270 °C). Successful reactions employed hexadecylamine (HDA)/TOP as the solvent system (elemental analysis indicating that bound surface ligands comprised two-thirds HDA and one-third TOP), while the

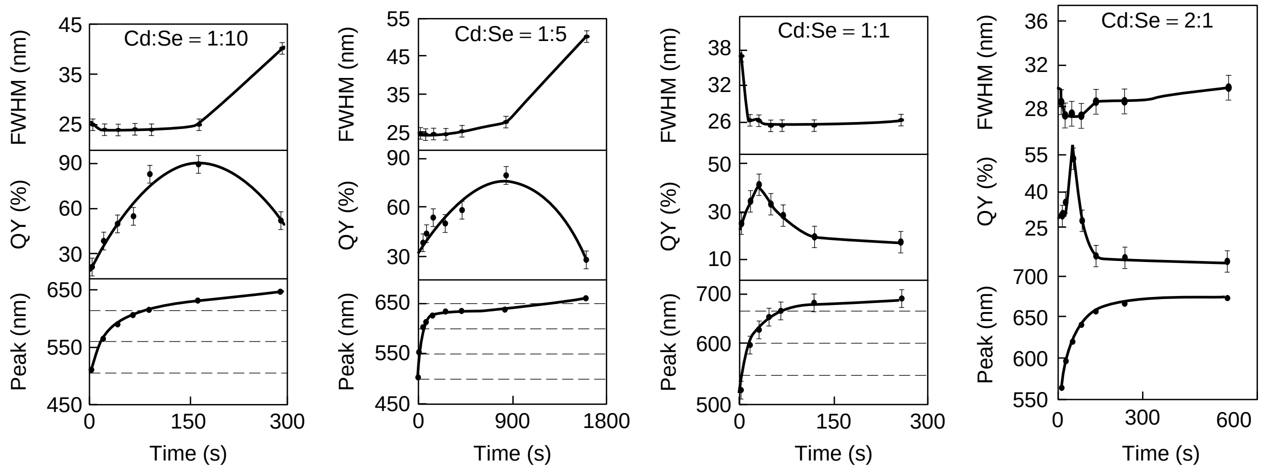

Figure 4 Temporal evolution of the full-width-at-half-maximum (FWHM) of the PL band, the PL QY, and the PL peak position for identical reactions differing only with respect to their initial Cd:Se precursor ratios (see top boxes). (Reprinted with permission from Ref. 18. © 2002 American Chemical Society)

TOPO/TOP combination did not work for this material. Indeed, the nature of the reaction product was very sensitive to the TOPO/TOP ratio. Too much TOPO, which binds strongly to Zn, generated particles so small that they could not be precipitated from solution by addition of a nonsolvent. Too much TOP, which binds very weakly to Zn, yielded particles that formed insoluble aggregates. As somewhat weaker bases compared to phosphine oxides, primary amines constitute ligands of intermediate strength, and, in addition, may provide enhanced capping density (as discussed earlier).[19] HDA, in contrast with shorter-chain primary amines (octylamine and dodecylamine), provided good solubility properties and permitted sufficiently high growth temperatures for reasonably rapid growth of highly crystalline ZnSe NQDs.[19]

High-quality NQDs absorbing and emitting in the infrared have also been prepared by way of a surfactant-stabilized pyrolysis reaction. PbSe colloidal quantum dots can be synthesized from the precursors: lead oleate (prepared *in situ* from lead(II)acetate trihydrate and oleic acid)[21] and TOPSe.[10,21] TOP and oleic acid are present as the coordinating solvents, while phenyl ether, a noncoordinating solvent, provides the balance of the reaction solution. Injection and growth temperatures are varied (injection: 180–210 °C; growth: 110–130 °C) to control particle size from ~3.5 nm–~9 nm in diameter.[21] The particles respond to 'traditional' size-selection precipitation methods, allowing the narrow as-prepared size dispersions ($\sigma \leq 10\%$) to be further refined ($\sigma = 5\%$) if desired.[10] Oleic acid provides excellent capping properties as photoluminescence (PL) quantum efficiencies, relative to IR dye no. 26, are ~85%.[21] PbSe NQDs afford an important alternative to their organic-dye counterparts, which suffer from low QYs in PL (<0.5%) and poor photostability. NQD emission is not limited to the near IR. By preparing large-size PbSe NQDs (>10 nm) (Figure 5), we recently achieved efficient emission in the mid-infrared (to 4 µm) (Figure 6), obtaining several-percent quantum efficiencies at this very red wavelength.[22]

2.4 Aqueous-based Synthetic Routes and the Inverse-micelle Approach

In addition to the moderate (~150 °C) and high-temperature (>200 °C) preparations discussed above, many room-temperature reactions have been developed. The two most prevalent schemes entail thiol-stabilized aqueous-phase growth and inverse-micelle methods. We will briefly consider these approaches here, and the former is discussed in some detail in Section 3 as it pertains to core/shell nanoparticle growth. In general, the low-temperature methods suffer from relatively poor size dispersions ($\sigma > 20\%$) and often exhibit significant, if not exclusively, trap-state PL. The latter is inherently weak and broad compared to band-edge PL, and it is less sensitive to quantum-size effects and particle-size control. Further, low-T aqueous preparations are limited in their applicability to relatively ionic materials. Higher temperatures are required to prepare *crystalline* covalent compounds (barring reaction conditions that may reduce the energetic barriers to crystalline growth, for example, catalysts and templating structures). Thus, II–VI compounds, which are more ionic compared to III–V compounds, have been successfully prepared at low temperatures (room T or less), while III-V compound semiconductors have not.[23]

The processes of nucleation and growth in aqueous systems are conceptually similar to those observed in their higher-temperature counterparts. Typically, the metal perchlorate salt is dissolved in water, and the thiol stabilizer is added (commonly, 1-thioglycerol). After the pH is adjusted to >11 (or from 5–6 if ligand is a mercaptoamine[24]) and the solution is deaerated, the chalcogenide is added as the hydrogen

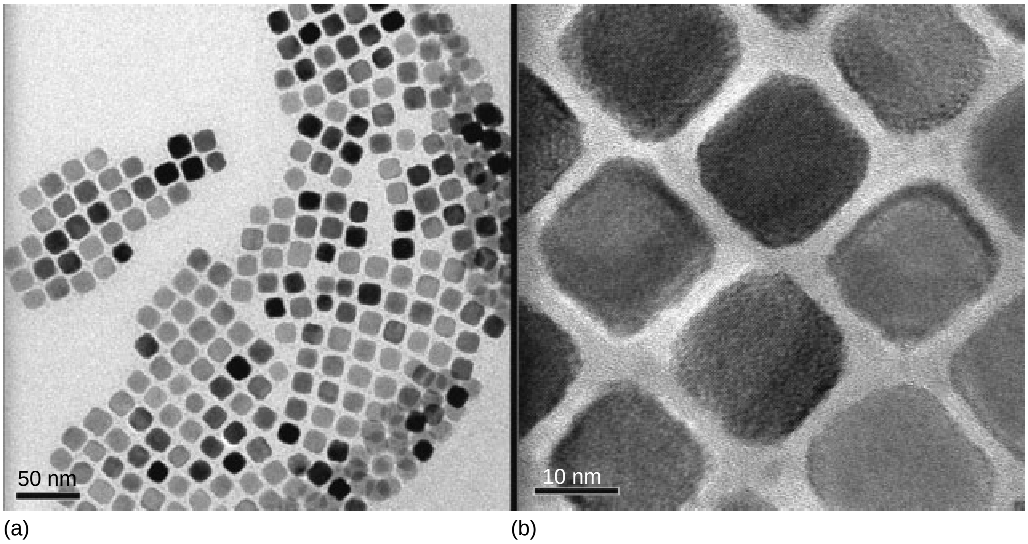

Figure 5 (a) Lower-magnification TEM imaging reveals the nearly uniform size and shape of the large-size PbSe NQDs (here, 17 nm). (b) High-resolution (HR) TEM of the PbSe NQDs, where the internal crystal lattice is evident for several of the particles

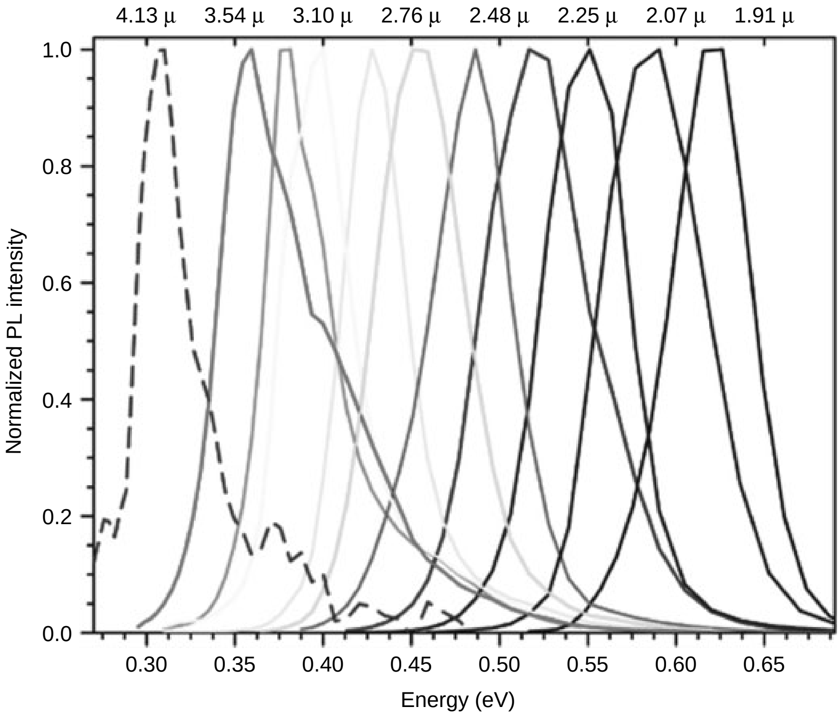

Figure 6 With large-size PbSe QDs (>8 nm in diameter) we demonstrated efficient PL in the mid-IR: Normalized spectra of a size series of PbSe QDs at RT, showing excellent tunability and narrow size distributions ($\sigma \sim 10\%$). The dashed spectrum was collected at 77 K from a sample with a peak at 0.34 eV at RT, exhibiting a red shift and narrowing

chalcogenide gas.[23,25,26] Addition of the chalcogenide induces particle nucleation. The nucleation process appears not to be an ideal, temporally discrete event, as the initial particle-size dispersion is large, as evidenced, for example, in broad PL spectra. Growth, or 'ripening', is allowed to proceed over several days, after which a redshift in the PL spectrum is observed, and the spectrum is still broad.[23] For example, fractional precipitation of an aged CdTe growth solution yields a size series exhibiting emission spectra centered from 540 nm to 695 nm, where the full width at half maximum (FWHM)

of the size-selected samples are at best 50 nm,[23] compared to ~25 nm for the best high-temperature reactions. In Cd-based systems, the ripening process can be accelerated by warming the solution; however, in Hg-based systems heating the solution results in particle instability and degradation.[23] Initial particle size can be roughly 'tuned' by changing the identity of the thiol ligand. The thiol binds to metal ions in solution prior to particle nucleation, and extended X-ray absorption fine structure (EXAFS) studies have demonstrated that the thiol stabilizer binds exclusively to metal surface sites in the formed particles.[27] By changing the strength of this metal–thiol interaction, larger or smaller particle sizes can be obtained. For example, decreasing the bond strength by introducing an electron withdrawing group adjacent to the sulfur atom leads to larger particles.[24,27]

The advantage of room-temperature, aqueous-based reactions lies in their ability to produce nanocrystal compositions that are, as yet, unattainable by higher-temperature pyrolysis methods. Of the II–VI compounds, Hg-based materials are thus far restricted to the temperature/ligand combination afforded by the aqueous thiol-stabilized preparations. The nucleation and growth of mercury chalcogenides have proven difficult to control in higher-temperature, nonaqueous reactions. Relatively weak ligands, fatty acids and amines (stability constant $K < 10^{17}$), yield fast growth and precipitation of the mercury chalcogenide, while stronger ligands, polyamines, phosphines, phosphine oxides, and thiols (stability constant $K > 10^{17}$), promote reductive elimination of metallic mercury at elevated temperatures.[13] Very high PL efficiencies (up to 50%) are reported for HgTe NQDs prepared in water.[26] However, the as-prepared samples yield approximately featureless absorption spectra and broad PL spectra. Further, the PL QYs for NQDs that emit at >1 µm have been determined in comparison with Rhodamine 6G, which has a PL maximum at ~550 nm. Typically, spectral overlap between the NQD emission signal and the reference organic dye is required to ensure reasonable QY values by taking into account the spectral response of the detector.

An alternative low-temperature approach that has been applied to a variety of systems, including mercury chalcogenides, is the inverse-micelle method. In general, the reversed-micelle approach entails preparation of a surfactant/polar-solvent/nonpolar-solvent microemulsion, where the content of the spontaneously generated spherical micelles is the polar-solvent fraction and that of the external matrix is the nonpolar solvent. The surfactant is commonly dioctyl sulfosuccinate, sodium salt (AOT). Precursor cations and anions are added and enter the polar phase. Precipitation follows, and particle size is controlled by the size of the inverse-micelle 'nanoreactors', as determined by the water content, W, where $W = [H_2O]/[AOT]$. For example, in an early preparation, AOT was mixed with water and heptane, forming the microemulsion. Cd^{2+}, as $Cd(ClO_4)_2{\cdot}6H_2O$, was stirred into the microemulsion allowing it to become incorporated into the interior of the reverse micelles. The selenium precursor was subsequently added and, upon mixing with cadmium, nucleated colloidal CdSe. Untreated solutions were observed to flocculate within hours, yielding insoluble aggregated nanoparticles. Addition of excess water quickened this process. However, promptly evaporating the solutions to dryness, removing micellar water, yielded surfactant-encased colloids that could be redissolved in hydrocarbon solvents. Alternatively, surface passivation could be provided by first growing a cadmium shell via further addition of Cd^{2+} precursor to the microemulsion followed by addition of phenyl(trimethylsilyl)selenium (PhSeTMS). PhSe-surface passivation prompted precipitation of the colloids from the microemulsion. The colloids could then be collected by centrifugation or filtering and redissolved in pyridine.[28]

More recently, the inverse-micelle technique has been applied to mercury-chalcogenides as a means to control the fast growth rates characteristic of this system (see above).[13] The process employed is similar to traditional micelle approaches; however, the metal and chalcogenide precursors are phase segregated. The mercury precursor (e.g. mercury(II)acetate) is transferred to the aqueous phase, while the sulfur precursor [bis (trimethylsilyl) sulfide $(TMS)_2S$] is introduced to the nonpolar phase. Additional control over growth rates is provided by the strong mercury ligand, thioglycerol, similar to thiol-stabilized aqueous-based preparations. Growth is arrested by replacing the sulfur solution with aqueous or organometallic cadmium or zinc solutions. The Cd or Zn add to the surface of the growing particles and sufficiently alter surface reactivity to effectively halt growth. Interestingly, addition of the *organometallic* metal sources results in a significant increase in PL QY to 5–6%, whereas, no observable increase accompanies passivation with the aqueous sources. Wide size dispersions are reported ($\sigma = 20$–30%). Nevertheless, absorption spectra are sufficiently well developed to clearly demonstrate that associated PL spectra, red-shifted with respect to the absorption band edge, derive from band-edge luminescence and not deep-trap-state emission. Finally, ligand exchange with thiophenol permits isolation as aprotic-polar-soluble NQDs, while exchange with long-chain thiols or amines permits isolation as nonpolar-soluble NQDs.[13]

The inverse-micelle approach may also offer a generalized scheme for the preparation of monodisperse metal-oxide nanoparticles.[29] The reported materials are ferroelectric oxides and, thus, stray from our emphasis on optically active semiconductor NQDs. Nevertheless, the method demonstrates an intriguing and useful approach: the combination of sol-gel techniques with inverse-micelle nanoparticle synthesis (with *moderate*-temperature nucleation and growth). Monodisperse barium titanate, $BaTiO_3$, nanocrystals, with diameters controlled in the range from 6–12 nm, were prepared. In addition, proof-of-principle preparations were successfully conducted for TiO_2 and $PbTiO_3$. *Single-source* alkoxide precursors are used to ensure proper stoichiometry in the preparation of complex oxides (e.g. bimetallic oxides) and are commercially available for a variety of systems. The

precursor is injected into a stabilizer-containing solvent (oleic acid in diphenyl ether; 'moderate' injection temperature: 140 °C). The hydrolysis-sensitive precursor is, up to this point, protected from water. The solution temperature is then reduced to 100 °C (growth temperature), and 30 wt% hydrogen peroxide solution (H_2O/H_2O_2) is added. Addition of the H_2O/H_2O_2 solution generates the microemulsion state and prompts a vigorous exothermic reaction. Control over particle size is exercised either by changing the precursor/stabilizer ratio or the amount of H_2O/H_2O_2 solution that is added. Increasing either results in an increased particle size, while decreasing the precursor/stabilizer ratio leads to a decrease in particle size. Following growth over 48 h, the particles are extracted into nonpolar solvents such as hexane. The extreme monodispersity of these relatively unique nano-oxides was evident following preparation of highly ordered superlattices, exhibiting periodicity over several microns, by slow precipitation from hexane (polydisperse samples yield disordered 2-D and 3-D arrays).[29]

3 INORGANIC SURFACE MODIFICATION

Surfaces play an increasing role in determining nanocrystal structural and optical properties as particle size is reduced. For example, owing to an increasing surface-to-volume ratio with diminishing particle size, surface trap states exert an enhanced influence over photoluminescence properties, including emission efficiency, and spectral shape, position and dynamics. Further, it is often through their surfaces that semiconductor nanocrystals interact with 'their world', as soluble species in an organic solution, reactants in common organic reactions, polymerization centers, biological tags, electron/hole donors/acceptors, and so on. Controlling organic and inorganic surface chemistry is key to controlling the physical and chemical properties that make NQDs unique compared to their epitaxial quantum-dot counterparts. In the previous section, we discussed the impact of organic ligands on particle growth and particle properties. In this section, we review surface modification techniques that utilize *inorganic* surface treatments. NQDs overcoated with a semiconductor layer are generally referred to as (core)shell NQDs. Thus far, the core-shell motif has permitted enhanced photoluminescence,[20,30–34] improved stability against photochemical oxidation,[20,31,35] enhanced processibility,[36] and band-structure engineering ('Type-II structures' – optical transition energies are not limited to band-gap energies).[37]

3.1 (Core)Shell NQDs

Overcoating highly monodisperse CdSe with epitaxial layers of either ZnS[30,31] or CdS (Figure 7)[20] has become

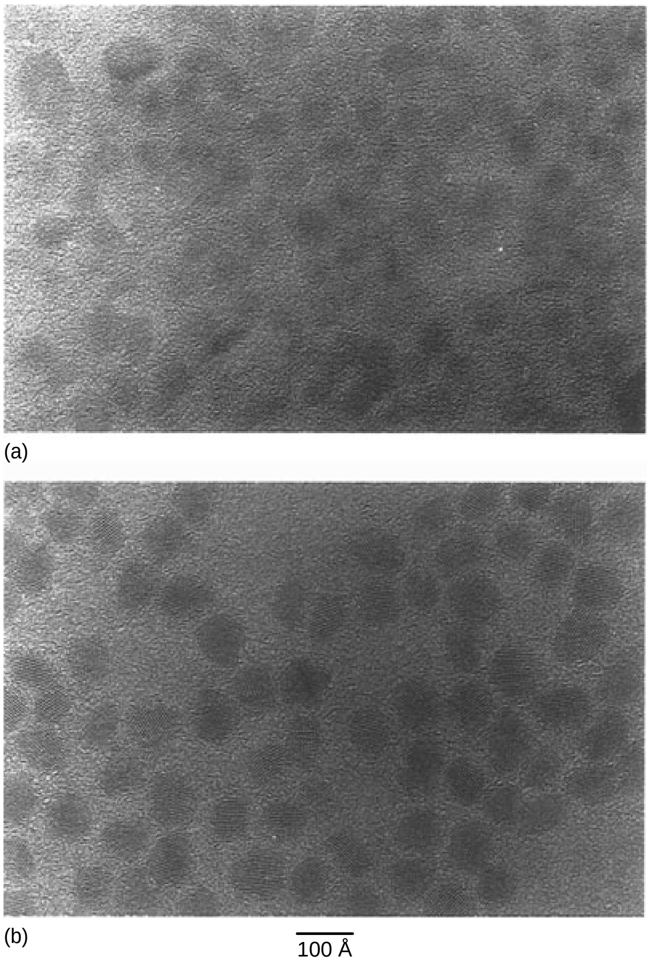

Figure 7 Wide-field HR-TEMs of (a) 3.4-nm diameter CdSe core particles and (b) (CdSe)CdS (core)shell particles prepared from the core NQDs in (a) by overcoating with a 0.9-nm thick CdS shell. Where lattice fringes are evident, they span the entire nanocrystal, indicating epitaxial (core) shell growth. (Reprinted with permission from Ref. 20. © 1997 American Chemical Society)

routine and typically provides almost an order of magnitude enhancement in PL efficiency compared to the exclusively organic-capped starting nanocrystals [5–10% efficiencies can yield 30–70% efficiencies (Figure 8)]. The enhanced quantum efficiencies result from enhanced coordination of surface unsaturated, or dangling, bonds, as well as from improved confinement of electrons and holes to the particle core. The latter effect occurs when the band gap of the shell material is larger than that of the core material, as is the case for (CdSe)ZnS and (CdSe)CdS (core)shell particles. Successful overcoating of III-V semiconductors has also been reported.[32–34]

The various preparations share several synthetic features. First, the best results are achieved if initial particle size distributions are narrow, as some size-distribution broadening occurs during the shell-growth process. Because absorption spectra are relatively unchanged by surface properties, they

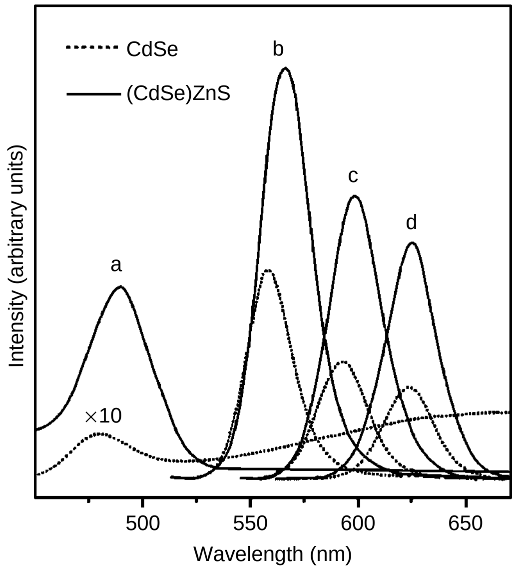

Figure 8 PL spectra for CdSe NQDs and (CdSe)ZnS (core)shell NQDs. Core diameters are (a) 2.3, (b) 4.2, (c) 4.8, and (d) 5.5 nm. (Core)shell PL QYs are (a) 40, (b) 50, (c) 35, and (d) 30%. Trap-state emission is evident in the (a) core-particle PL spectrum as a broadband to the red of the band-edge emission and absent in the respective (core)shell spectrum. can be used to monitor the stability of the nanocrystal core during and following growth of the inorganic shell. Further, if the conduction band offset between the core and the shell materials is sufficiently large (i.e. large compared to the electron confinement energy), then significant redshifting of the absorption band edge should not occur, as the electron wave function remains confined to the core (Figure 9). A large red shift in (core)shell systems, having sufficiently large offsets (determined by the identity of the core/shell materials and the electron and hole effective masses), indicates growth of the core particles during shell preparation. A small broadening of absorption features is common and results from some broadening of the particle size dispersion (Figure 9). Alloying, or mixing of the shell components into the interior of the core, would also be evident in absorption spectra if it were to occur. The band edge would shift to some intermediate energy between the band energies of the respective materials comprising the alloyed nanoparticle.

PL spectra can be used to indicate whether effective passivation of surface traps has been achieved. In poorly passivated nanocrystals, deep-trap emission is evident as a broad tail or hump to the red of the sharper band-edge emission spectral signal. The broad, trap signal will disappear and the sharp, band-edge luminescence will increase following successful shell growth (Figure 8(a)). Note: The trap-state emission signal contribution is typically larger in smaller (higher relative-surface-area) nanocrystals than in larger nanoparticles (Figure 8(a)).

Homogeneous nucleation and growth of shell-material as discrete nanoparticles may compete with *heterogeneous* nucleation and growth at core-particle surfaces. Typically, a combination of relatively low precursor concentrations and reaction temperatures is used to avoid particle formation. Low precursor concentrations support undersaturated-solution conditions and, thereby, shell growth by heterogeneous nucleation. The precursors, diethylzinc and bis(trimethylsilyl) sulfide in the case of ZnS shell growth, for example, are added dropwise at relatively low temperatures to prevent buildup and supersaturation of unreacted precursor monomers in the growth solution. Further, employing relatively low reaction temperatures avoids growth of the starting core particles.[20,31] ZnS, for example, can nucleate and grow as a crystalline shell at temperatures as low as 140 °C[31] and CdS shells have been successfully prepared from dimethylcadmium and bis(trimethylsilyl) sulfide at 100 °C,[20] thereby avoiding complications owing to homogeneous nucleation and core-particle growth. Additional strategies for preventing particle growth of the shell material include using organic capping ligands that have a particularly high affinity for the shell metal. The presence of a strong binding agent seems to lead to more controlled shell growth, for example, TOPO is replaced with TOP in CdSe shell growth on InAs cores, where TOP (softer Lewis base) coordinates more tightly than TOPO (harder Lewis base) with cadmium (softer Lewis acid).[34] Finally, the ratio of the cationic to anionic precursors can be used to prevent shell-material homogeneous nucleation. For example, increasing the concentration of the chalcogenide

in a cadmium–sulfur precursor mixture hinders formation of unwanted CdS particles.[20]

Successful overcoating is possible for systems where relatively large lattice mismatches between core and shell crystal structures exist. The most commonly studied (core)shell system (CdSe)ZnS, is successful despite a 12% lattice mismatch. Such a large lattice mismatch could not be tolerated in flat heterostructures, where strain-induced defects would dominate the interface. It is likely that the highly curved surface and reduced facet lengths of nanocrystals relax the structural requirements for epitaxy. Indeed, two types of epitaxial growth are evident in the (CdSe)ZnS system: coherent (with large distortion or strain) and incoherent (with dislocations), the difference arising for thin (approximately one to two monolayers, where a monolayer is defined as 3.1 Å) versus thick (> two monolayers) shells, respectively.[31] High-resolution TEM images of thin-shell-ZnS-overcoated CdSe QDs reveal lattice fringes that are continuous across the entire particle, with only a small 'bending' of the lattice fringes in some particles indicating strain. TEM imaging has also revealed that thicker shells (>2 monolayers) lead to the formation of deformed particles, resulting from uneven growth across the particle surface. Here, too, however, the shell appeared epitaxial, oriented with the lattice of the core (Figure 10). Nevertheless, wide-angle X-ray scattering (WAXS) data showed reflections for both CdSe and ZnS, indicating that each was exhibiting its own lattice parameter in the thicker-shell systems. This type of structural relationship between the core and the shell was described as *incoherent* epitaxy. It was speculated that at low coverage, the epitaxy is coherent (strain is tolerated), but that at higher coverages, the high lattice mismatch can no longer be sustained without the formation of dislocations and low-angle grain boundaries. Such defects in the core-shell boundary provide non-radiative recombination sites and lead to diminished PL efficiency compared to coherently epitaxial thinner shells. Further, in all cases studied where more than a single monolayer of ZnS was deposited, the shell appeared to be continuous. X-ray photoelectron spectroscopy (XPS) was used to detect the formation of SeO_2 following exposure to air. The SeO_2 peak was observed only in bare TOPO/TOP-capped dots and dots having less than one monolayer of ZnS overcoating. Together, the high-resolution TEM images and XPS data suggest complete, epitaxial-shell formation in the highly lattice-mismatched system of (CdSe)ZnS.

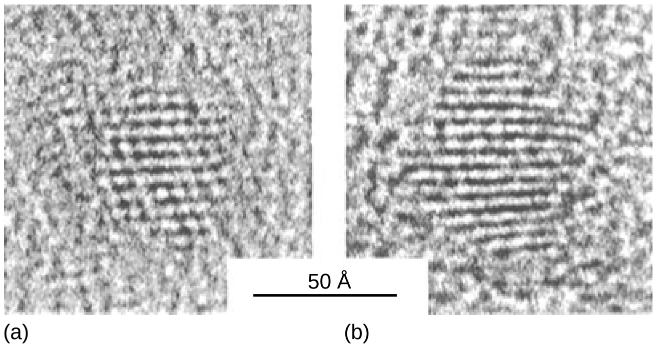

Figure 10 HR-TEM of (a) CdSe core particle and (b) a (CdSe)ZnS (core)shell particle (2.6 monolayer ZnS shell). Lattice fringes in (b) are continuous throughout the particle, suggesting epitaxial (core)shell growth. (Reprinted with permission from Ref. 31. © 1997 American Chemical Society)

The effect of lattice mismatch has also been studied in III-V semiconductor core systems. Specifically, InAs has been successfully overcoated with InP, CdSe, ZnS, and ZnSe.[34] The degree of lattice mismatch between InAs and the various shell materials differed considerably, as did the PL efficiencies achieved for these systems. However, no direct correlation between lattice mismatch and QY in PL was observed. For example, (InAs)InP produced quenched luminescence while (InAs)ZnSe provided up to 20% PL QYs, where the respective lattice mismatches are 3.13% and 6.44%. CdSe shells, providing a lattice *match* for the InAs cores, also produced up to 20% PL QYs. In all cases, shell growth beyond two monolayers (where a monolayer equals the d_{111} lattice spacing of the shell material) caused a decrease in PL efficiencies, likely due to the formation of defects that could provide trap sites for charge carriers [as observed in (CdSe)ZnS[31] and (CdSe)CdS[20] systems]. The perfectly lattice-matched CdSe shell material should provide the means for avoiding defect formation; however, the stable crystal structures for CdSe and InAs are different under the growth conditions employed. CdSe prefers the wurtzite structure while InAs prefers cubic. For this reason, this 'matched' system may succumb to interfacial defect formation with thick shell growth.[34]

The larger contributor to PL efficiency in the (InAs)shell systems was found to be the size of the energy offset between the respective conduction and valence bands of the core and shell materials. Larger offsets provide larger potential energy barriers for the electron and hole wave functions at the (core)shell interface. For InP and CdSe, the conduction band offset with respect to InAs is small. This allows the electron wave function to experience the surface of the nanoparticle. In the case of CdSe, fairly high PL efficiencies can still be achieved because native trap sites are less prevalent than they are on InP surfaces. Both ZnS and ZnSe provide large energy offsets. The fact that the electron wave function remains confined to the core of the (core)shell particle is evident in the absorption and PL spectra. In these confined cases, no red shifting was observed in the optical spectra following shell growth.[34] The observation that PL enhancement to only 8% quantum yield was possible using ZnS as the shell material may have been due to the large lattice mismatch between InAs and ZnS of ∼11%. Otherwise, ZnS and ZnSe should behave similarly as shells for InAs cores.

Shell chemistry can be precisely controlled to achieve unstrained (core)shell epitaxy. For example, the zinc–cadmium alloy, $ZnCdSe_2$ was used for the preparation

of (InP) $ZnCdSe_2$ nanoparticles having essentially zero lattice mismatch between the core and the shell.[32] High-resolution TEM images demonstrated the epitaxial relationship between the layers, and very thick epilayer shells were grown – up to 10 monolayers, where a monolayer was defined as 5 Å. The shell layer successfully protected the InP surface from oxidation, a degradation process to which InP is particularly susceptible.

3.2 Quantum-dot/Quantum-well Structures

Optoelectronic devices comprising two-dimensional quantum-well structures are generally limited to material pairs that are well lattice-matched owing to the limited strain tolerance of such planar systems; otherwise, very thin well layers are required. In order to access additional quantum-well-type structures, more strain-tolerant systems must be employed. As already alluded to, the highly curved quantum-dot nanostructure is ideal for lattice-mismatched systems. Several quantum-dot/quantum-well (QD/QW) structures have been successfully synthesized, ranging from the well lattice-matched CdS(HgS)CdS[38–40] (quantum dot, quantum well, cladding) to the more highly strained ZnS(CdS)ZnS.[41] The former provides emission color tunability in the infrared spectral region, while the latter yields access to the blue–green spectral region. In contrast to the very successful (core)shell preparations discussed earlier in this section, the QD/QW structures have been prepared using ion displacement reactions, rather than heterogeneous nucleation on the core surface (Figure 11). These preparations have been either aqueous or polar-solvent based and conducted at low temperatures (room temperature to – 77 °C). They entail a series of steps that first involves the preparation of the nanocrystal cores (CdS and ZnS, respectively). Core preparation is followed by ion-exchange reactions in which a salt precursor of the 'well' metal ion is added to the solution of 'core' particles. The solubility product constant (K_{sp}) of the metal sulfide corresponding to the added metal species is such that it is significantly less than that of the metal sulfide of the core metal species. This solubility relationship leads to precipitation of the added metal ions and dissolution of the surface layer of core metal ions via ion exchange. Analysis of absorption spectra during addition of 'well' ions to the nanoparticle solution revealed an apparent concentration threshold, after which addition of the 'well' ions produced no more change in the optical spectra. Specifically, in the case of the CdS(HgS)CdS system, ion exchange of Hg^{2+} for Cd^{2+} produced a redshift in absorption until a certain amount of 'well' ions had been added. According to inductively coupled plasma-mass spectrometry (ICP-MS), which was used to measure the concentration of free ions in solution for both species, up until this threshold concentration was reached the concentration of free Hg^{2+} ions was essentially zero, while the Cd^{2+} concentration increased linearly. After the threshold concentration was reached, the Hg^{2+} concentration increased linearly (with each externally provided addition to the system), while the Cd^{2+} concentration remained approximately steady. These results agree well with the ion-exchange reaction scenario, and, perhaps more importantly, suggest a certain natural limit to the exchange process. It was determined that in the example of 5.3 nm CdS starting core nanoparticles, approximately 40% of the Cd^{2+} was replaced with Hg^{2+}. This value agrees well with the conclusion that one complete monolayer has been replaced, as the surface-to-volume ratio in such nanoparticles is 0.42. Further dissolution of Cd^{2+} core ions is prevented by formation of the complete monolayer-thick shell, which also precludes the possibility of island-type shell growth.[39]

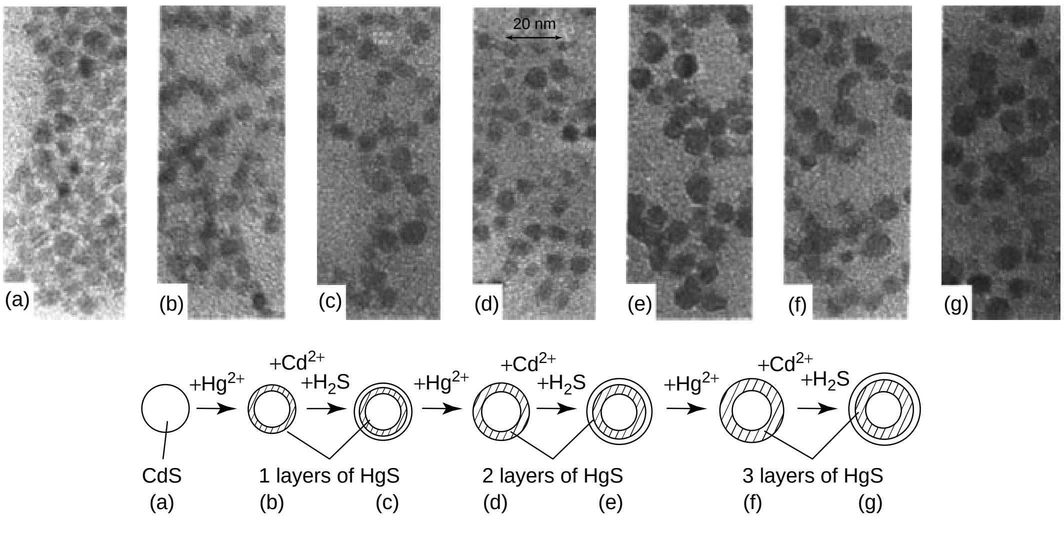

Figure 11 TEMs of CdS(HgS)CdS at various stages of the ion displacement process, where the latter is schematically represented in the figure. (Reprinted with permission from Ref. 39. © 1994 American Chemical Society)

Subsequent addition of H_2S or Na_2S causes the precipitation of the off-cast core ions back onto the particles. The ion replacement process, requiring the sacrifice of the newly re-deposited core metal ions, can then be repeated in order to increase the thickness of the 'well' layer. This process has been successfully repeated for up to three layers of well material. The 'well' is then capped with a re-deposited layer of core metal ions to generate the full QD/QW structure. The thickness of the cladding layer could be increased by addition in several steps (up to 5) of the metal and sulfur precursors.[39]

The nature of the QD/QW structure and its crystalline quality have been analyzed by high-resolution TEM. In the CdS(HgS)CdS system, evidence has been presented for both approximately spherical particles, as well as faceted particle shapes such as tetrahedrons and twinned tetrahedrons. In all cases, well and cladding growth is epitaxial as evidenced by the absence of amorphous regions in the nanocrystals and in the smooth continuation of lattice fringes across particles. Analysis of HR-TEM micrographs also reveals that the tetrahedral shapes are terminated by (111) surfaces that can be *either* cadmium or sulfur faces.[40] The choice of stabilizing agent – an anionic polyphosphate ligand – favors cadmium faces and likely supports the faceted tetrahedral structure that exposes exclusively cadmium-dominated surfaces (Figure 12). In addition, both the spherical particles and the twinned tetrahedral particles provide evidence for an embedded HgS layer in the presumed QD/QW structure. Owing to differences in their relative abilities to interact with electrons (HgS more strongly than CdS), contrast differences are evident in HR-TEM images as bands of HgS surrounded by layers of CdS (Figure 12).

Size dispersions in these low-temperature, ionic-ligand stabilized reactions are reasonably good (~20%), as indicated by absorption spectra, but poor compared to those achieved using higher-temperature pyrolysis and amphiphilic coordinating ligands (4–7%). Nevertheless, the polar-solvent-based reactions give us access to colloidal materials, such as mercury chalcogenides, thus far difficult to prepare using pyrolysis-driven reactions (Section 2). Further, the ion-exchange method provides the ability to grow well and shell structures that appear to be precisely 1, 2, or 3 monolayers deep. Heterogeneous nucleation provides less control over shell thicknesses, resulting in incomplete and variable multilayers (e.g. 1.3 or 2.7 monolayers *on average*, etc.). Stability of core/shell materials against solid-state alloying is an issue, at least for the CdS(HgS)CdS system. Specifically, cadmium in a CdS/HgS structure will, within minutes, diffuse to the surface of the nanoparticle where it is subsequently replaced by a Hg^{2+} solvated ion.[39] This process is likely supported by the substantially greater aqueous solubility of Cd^{2+} compared to Hg^{2+}, as well as the structural compatibility between the two lattice-matched CdS and HgS crystal structures.

4 SHAPE CONTROL

The nanoparticle growth process described in Section 2, where fast nucleation is followed by slower growth, typically leads to the formation of spherical or approximately spherical particles. Such essentially isotropic particles represent the thermodynamic, lowest energy, shape for materials having relatively isotropic underlying crystal structures. For example, under this growth regime, the wurtzite crystal structure of CdSe, having a c/a ratio of ~1.6, fosters the growth of slightly prolate particles, typically exhibiting aspect ratios of approximately 1.2. Furthermore, even for materials whose underlying crystal structure is more highly anisotropic, nearly spherical nanoparticles often result owing to the strong influence of the surface in the nanosize regime. Surface energy is minimized in spherical particles, compared to more anisotropic morphologies.

4.1 Kinetically Driven Growth of Anisotropic NQD Shapes – CdSe As the Model System

Under a different growth regime, one that promotes fast, kinetic growth, more highly anisotropic shapes, such as rods and wires, can be obtained. In semiconductor nanoparticle

synthesis, such growth conditions have been achieved using high precursor, or monomer, concentrations in the growth solution. As discussed previously (Section 2), particle-size distributions can be 'focused' by maintaining relatively high monomer concentrations that prevent the transition from the fast-growth to the slow-growth (Ostwald ripening) regime.[14] Even higher monomer concentrations can be used to effect a transition from thermodynamic to kinetic growth. Access to the regime of very fast, kinetic growth allows control over particle shape. The system is essentially put into 'kinetic overdrive,' where dissolution of particles is minimized as the monomer concentration is maintained at levels higher than the solubility of all of the particles in solution. Growth of all particles is, thereby, promoted.[14] Further, in this regime, the rate of particle growth is not limited by diffusion of monomer to the growing crystal surface, but, rather, by how fast atoms can add to that surface. In this way, the relative growth rates of different crystal faces strongly influence the final particle shape.[42] Specifically, in systems where the underlying crystal lattice structure is anisotropic, for example, the wurtzite structure of CdSe, simply the presence of high monomer concentrations (kinetic growth regime) at and immediately following nucleation can accentuate the differences in relative growth rates between the unique *c*-axis and the remaining lattice directions, promoting rod growth. In other words, the monomer-concentration-dependent transition from slower-growth to fast-growth regimes coincides with a transition from diffusion controlled to reaction-rate-controlled growth and from dot to rod growth. In general, longer rods are achieved with higher initial monomer concentrations, and rod growth is sustained over time by maintaining high monomer concentrations using multiple-injection techniques. Finally, the relative rates of different crystallographic faces can be further controlled by judicious choice of organic ligands.[12,17]

In order to more precisely tune the growth rates controlling CdSe rod formation, high monomer concentrations are used in conjunction with appropriate organic ligand mixtures. In this way, a wide range of rod aspect ratios has been produced (Figure 13).[12,17,42] Specifically, the 'traditional' trioctylphosphine oxide (TOPO) ligand is supplemented with alkyl phosphonic acids. The phosphonic acids are strong metal (Cd) binders and may influence rod growth by changing the relative growth rates of the different crystal faces.[42] CdSe rods form by enhanced growth along the crystallographically unique *c*-axis (taking advantage of the anisotropic wurtzite crystal structure). Interestingly, the fast growth has been shown to be unidirectional – exclusively on the (001) face.[42] The (001) facets comprise alternating Se and Cd layers, where the Cd atoms are relatively unsaturated (three dangling bonds per atom). In contrast, the related (001) facet exposes relatively saturated Cd faces having one dangling bond per atom (Figure 14). Thus, compared to (001), the (001) face (opposite *c*-axis growth) and {110} faces (*ab* growth), for example, are slow growing, and *unidirectional* rod growth is promoted. The exact mechanism by which the phosphonic

(Reprinted with permission from Ref. 42. © 2000 American Chemical Society)

acids alter the relative growth rates is not certain. Their influence may be in inhibiting the growth of (001) and {110} faces or it may be in directly promoting growth of the (001) face by way of interactions with surface metal sites.[42]

Alternatively, it has been proposed that a more important contribution to the formation of rod-shaped particles by the strong metal ligands is their influence on 'monomer' concentrations, where monomer again refers to various molecular precursor species. Specifically, the phosphonic acids may simply *permit* the high monomer concentrations that are required for kinetic, anisotropic growth. As strong metal binders, they may coordinate Cd monomers, stabilizing them against decomposition to metallic Cd.[12]

More complex shapes, such as 'arrows', 'pine trees', and 'teardrops' have also been prepared in the CdSe system, and the methods used are an extension of those applied to the preparation of CdSe rods. Once again, CdSe appears to be the 'proving ground' for semiconductor nanoparticle synthesis. Several factors influencing growth of complex shapes have been investigated, including the time evolution of shape and the ratio of TOPO to phosphonic acid ligands,[42] as well as the steric bulk of the phosphonic acid.[12] Predictably, reaction temperature also influences the character of the growth regime.[12,42] In the regime of rod growth, that is, fast kinetic growth, complex shapes can evolve over time. Rods and 'pencils' transform into 'arrows' and 'pine-tree-shaped' particles (Figure 15). The sides of the arrow or tree points comprise wurtzite (101) faces. As predicted by traditional crystal-growth theory, these slower growing faces have replaced the faster growing (001) face, permitting the evolution to more complex structures.[42] Shape and shape evolution dynamics were also observed to be highly dependent upon phosphonic acid concentrations. Low concentrations ($<$ 10 mol%) of hexylphosphonic acid (HPA), for example, relative to TOPO produced approximately spherical particles, while moderate amounts (20 mol%) yielded rods, and high concentrations (60 mol%) resulted in arrow-shaped particles. As discussed previously, HPA appears to enhance the growth of the (001) face *relative* to other crystallographic faces,

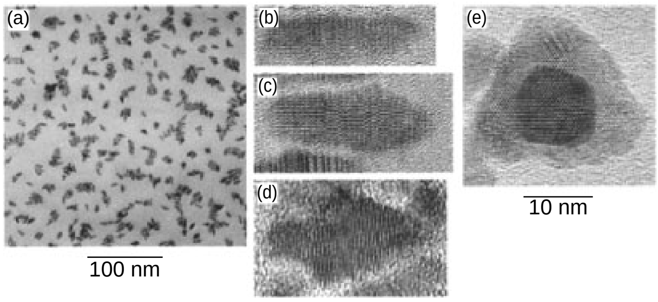

Figure 15 (a) TEMs of a CdSe NQD sample dominated by arrow-shaped particles (60% HPA reaction). (b-d) HR-TEMs demonstrating the shape evolution from (b) pencil- to (c) arrow- to (d) pine-tree-shaped CdSe NQDs. (e) Pine-tree-shaped particle looking down the [001] direction, that is, the long axis. Analysis of lattice spacings obtained by HR-TEM imaging revealed that wurtzite is the dominate phase for each shape and that the angled facets of the arrows comprise the (101) faces. (Reprinted with permission from Ref. 42. © 2000 American Chemical Society)

and higher concentrations simply permit even higher relative growth rates. Therefore, shape evolution to the arrow and tree morphologies proceeds more quickly in the presence of high HPA concentrations. The growth of single-headed arrows, as opposed to double-headed, results from the characteristic unidirectional growth, that is, growth from the (001) face only, and not from the (001) face.

'Teardrop-shaped' particles also arise from the tendency toward unidirectional growth. In this case, rod-shaped crystals are exposed to growth conditions favoring spherical particle shapes, that is, equilibrium slow growth and low-monomer concentrations, causing the rods to become rounded. Monomer concentration is then quickly increased to force elongation of the 'droplet' from one end into particles resembling tadpoles.[42] The growth regime governing the evolution of rods to spherical particles has been termed '1-D to 2-D intraparticle ripening.[12]' Nanoparticle volumes and total numbers remain approximately constant (as do monomer concentrations), while nanoparticle shape changes dramatically. Intraparticle diffusion of *c*-axis atoms to other crystal faces may explain this transformation. The process is distinguished from 'interparticle ripening,' or Ostwald ripening, that is observed at even lower monomer concentrations. Intraparticle ripening is thought to occur when a 'diffusion equilibrium' exists between the nanoparticles and the monomers in the bulk solution.[12] Alternatively, it has also been shown that nanodots can be used to 'seed' the growth of nanorods. Here, the spherical particles are exposed to high monomer concentrations that promote one-dimensional growth from the template particles. Improved short-axis and aspect-ratio distributions have been reported for these rods (Figure 16).[12]

Rod growth dynamics also depend upon the identity of the phosphonic acid. The effectiveness of the phosphonic acid in promoting rod growth depends critically on its steric bulk, or the length of its alkyl chain. Shorter-chain phosphonic acids, such as HPA, more effectively promote rod growth compared to longer-chain phosphonic acids, such as tetradecylphosphonic acid (TDPA). Combinations of longer- and shorter-chain phosphonic acids can be used to readily tune rod aspect ratios[12] and control shape evolution dynamics.

The above morphologies reflect the underlying wurtzite crystal structure of CdSe. Occasionally, however, CdSe nucleates in the zinc-blende phase. When this occurs, a different type of morphology, the tetrapod, is observed. Here, the zinc-blende nuclei expose four equivalent (111) faces that comprise the crystallographic equivalent of the wurtzite (001) faces (alternating planes of Cd or Se). From these (111) surfaces, four wurtzite 'arms' grow unidirectionally. Further addition of monomer either lengthens the wurtzite arms, in the case of 'purely' wurtzite arms, or generates dendritic-like wurtzite branches, when zinc-blende stacking faults are present in the arm ends (Figure 17).[42]

CdSe rod QYs in PL are typically relatively low, ca. 1 to 4%. Like their spherical counterparts, however, rods can be overcoated with a higher band gap inorganic

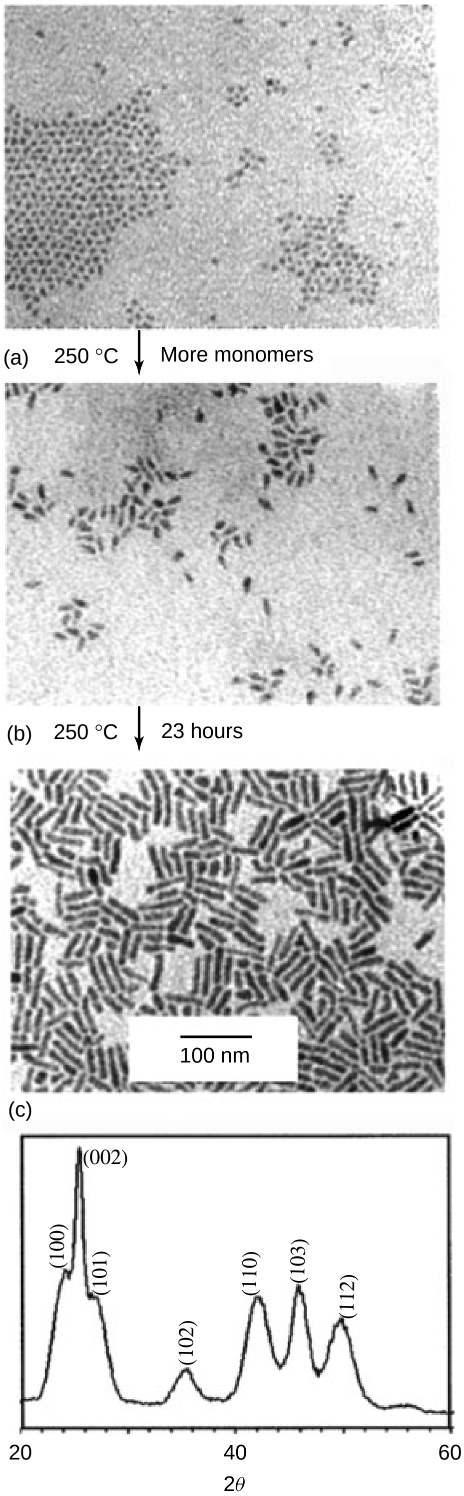

Figure 16 ‘Seeding’ CdSe NQD rod growth for improved size monodispersity. (a) TEM of CdSe dots prepared in 13% TDPA using an injection temperature of 360 °C and a growth temperature of 250 °C. semiconductor, increasing QYs to 14–20%.[43,44] Lattice mismatch requirements for rods are somewhat more severe than for spherical particles, and synthetic steps unique to rod overcoating have been employed in the most successful preparations.[44] As discussed previously (Section 3), spherical nanoparticle systems benefit from having highly curved surfaces, compared to less-strain-tolerant planar systems. Nanorods provide an intermediate case. The average curvature of rods lies between that of dots and films, and, owing to their larger-size/surface area compared to dots, more interfacial strain can accumulate leading to the formation of dislocations. The 12% lattice mismatch between ZnS and CdSe is, therefore, less well tolerated in rods. CdS can be used as a lattice-mismatch ‘buffer layer’ between CdSe and ZnS (only ~4% lattice mismatch with CdSe and ~8% with ZnS). Addition of a small amount of Cd precursor to the shell precursor solution (Cd:Zn of 0.12:1.0) appears to lead to the preferential formation of CdS at the surface of the rods. ZnS growth then proceeds on the CdS. High-resolution TEM images demonstrate uniform and epitaxial growth. Interestingly, QYs remain low, and the benefits of inorganic overcoating in the graded epitaxial approach are only fully realized following photochemical annealing (via laser irradiation) of the rod particles (Figure 18).[44]

4.2 Shape Control Beyond CdSe

Solution-phase preparations of unusually shaped and highly anisotropic particles that are soluble, relatively monodisperse, and sufficiently small to exhibit quantum-confinement effects are thus far limited, but not exclusive to CdSe. CdS and CdTe rods can be prepared using phosphonic-acid-controlled reactions. In addition, CdS rods and multipods can be prepared in a monosurfactant system in which hexadecylamine (HDA) serves both as the stabilizing ligand and as the shape-determining ligand.[45] Here, rod and multipod formation

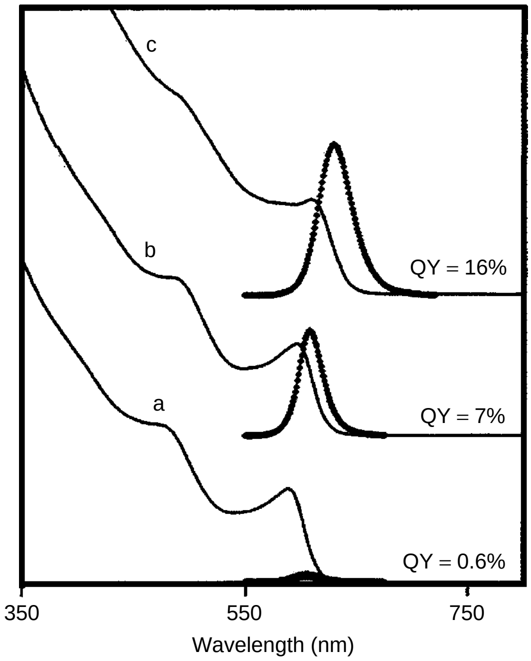

Figure 18 Absorption (solid line) and PL (dashed line) spectra for medium-length (3.3 × 21 nm) CdSe nanorods. (a) Core nanorods without ZnS shell. (b) (Core)shell nanorods with thin CdS-ZnS shells (~2 monolayers of shell material, where the CdS 'buffer' shell comprises ~35% of the total shell). (c) (Core)shell nanorods with medium CdS-ZnS shells (~4.5 monolayers of shell material, where the CdS 'buffer' shell comprises ~22% of the total shell). PL spectra were recorded following photoannealing of the samples[44]

is temperature dependent. Rods form at high temperatures (~300 °C), while bipods, tripods, and tetrapods dominate at lower temperatures (120–180 °C). The dependence of shape on temperature likely results from preferential formation of wurtzite CdS nuclei (thermodynamic phase) at high temperatures and zinc-blende nuclei (kinetic phase) at lower temperatures. As in the CdSe system, the zinc blende {111} faces can support fast growth of (001) wurtzite 'arms.' Significantly, this method allows isolation of tetrapods in ~82% yield (compared to 15–40% by the HPA method) at 120 °C. Size control is less well developed, and particles are relatively large compared to their HPA-derived counterparts. Nevertheless, it is the first significant report of solution-based growth of bipod and tripod morphologies in the II–VI system and provides a more predictable method of producing tetrapods.[45]

The same monosurfactant system can be applied to shape-controlled preparation of the magnetic semiconductor, MnS.[46] At low solution-growth temperatures (120–200 °C), MnS prepared from the single-source precursor, $Mn(S_2CNEt_2)_2$, can nucleate in either the zinc-blende or the wurtzite phase, while at high temperatures (>200 °C) MnS nucleates in the rock-salt phase. Low-temperature growth yields a variety of morphologies: highly anisotropic nanowires, bipods, tripods and tetrapods (120 °C), nanorods (150 °C), and spherical particles (180 °C). The 'single pods' comprise wurtzite cores with wurtzite-phase arms. In contrast, the multipods comprise zinc-blende cores with wurtzite arms, where the arms grow in the [001] direction from the zinc-blende {111} faces, as discussed previously with respect to the Cd-chalcogenide system. Dominance of the isotropic spherical particle shape in reactions conducted at moderate temperatures (180 °C) implies a shift from predominantly kinetic control to predominantly thermodynamic control over the temperature range from 120 to 180 °C.[46] Formation of 1-D particles at low temperatures results from kinetic control of relative growth rates. At higher temperatures, differences in activation barriers to growth of different crystal faces are more easily surmounted, equalizing relative growth rates. Finally, high-temperature growth supports only the thermodynamic rock-salt structure, large cubic crystals. Also, by combining increased growth times with low growth temperatures, shape evolution to 'higher-temperature' shapes is achieved.[46]

Extension of the ligand-controlled shape methodology to highly symmetric cubic crystalline systems is also possible. Specifically, PbS, having the rock-salt structure, has been prepared as rods, tadpole-shaped monopods, multipods (bipods, tripods, tetrapods, and pentapods), stars, truncated octahedra, and cubes.[47] The rod-based particles, including the mono and multipods, retain short-axis dimensions that are less than the PbS Bohr exciton radius (16 nm) and, thus, can potentially exhibit quantum-size effects. These highly anisotropic particle shapes represent truly metastable morphologies for the inherently isotropic PbS system. The underlying PbS crystal lattice is the symmetric rock-salt structure, the thermodynamically stable manifestations of which are the truncated octahedra and the cubic nanocrystals. The PbS particles are prepared by pyrolysis of a single-source precursor, $Pb(S_2CNEt_2)_2$, in hot phenyl ether in the presence of a large excess of either a long-chain alkyl thiol or amine. The identity of the coordinating ligand and the solvent temperature determine the initial particle shape following injection (Figure 19). Given adequate time, particle shapes evolve from the metastable rods to the stable truncated octahedron and cubes, with star-shaped particles comprising energetically intermediate shapes.[47]

As in the CdSe system, the particle shape in the cubic PbS system depends intimately on the ligand concentration and its identity. The highest ligand concentrations yield a reduced rate of growth from the {111} faces compared to the {100} faces, which experience enhanced *relative* growth rates. Further, alkylthiols are more effective at controlling relative growth rates compared to alkylamines. The latter, a weaker Pb binder, consistently leads to large, thermodynamically stable cubic shapes. Finally, reaction temperature plays a key role in determining particle morphology. The lowest temperatures (140 °C) yield the metastable rod-based morphologies, with intermediate star shapes generated at moderate temperatures (180–230 °C) and truncated octahedra isolated at the highest temperatures (250 °C). Interestingly, the rod structures appear

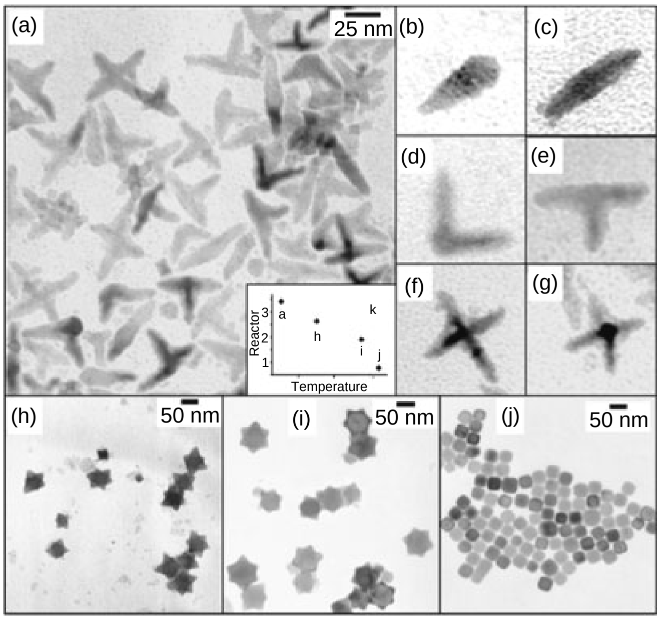

Figure 19 TEMs showing the variety of shapes obtained from the PbS system grown from the single-source precursor, $Pb(S_2CNEt_2)_2$, at several temperatures. (a) Multipods prepared at 140 °C. (b) Tadpole-shaped monopod (140 °C). (c) I-shaped bipod (140 °C). (d) L-shaped bipod (140 °C). (e) T-shaped tripod (140 °C). (f) Cross-shaped tetrapod (140 °C). (g) Pentapod (140 °C). to form by preferential growth of {100} faces from truncated octahedra seed particles. For example, the 'tadpole' shaped monopods are shown by HR-TEM studies to comprise truncated octahedra 'heads' and [100]-axis 'tails,' resulting from growth from a (100) face. The star-shaped particles that form at 180 °C are characterized by six triangular corners, comprising each of the six {100} faces. The {100} faces have 'shrunk' into these six corners as a result of their rapid growth, similar to the replacement of the (001) face by slower growing faces during the formation of arrow-shaped CdSe particles (see above). The isolation of star-shaped particles at intermediate temperatures suggests that the relative growth rates of the {100} faces remain enhanced compared to the {111} faces at these temperatures. Further, the overall growth rate is enhanced as a result of the higher temperatures. The star-shaped particles that form at 230 °C are rounded and represent a decrease in the differences in relative growth rates between the {100} faces and the {111} faces, the latter, higher-activation-barrier surface benefiting from the increase in temperature. A definitive shift from kinetic growth to thermodynamic growth is observed at 250 °C (or at long growth times). Here, the differences in reactivity between the {100} and the {111} faces are negligible given the high thermal energy input that surmounts either face's activation barrier. The thermodynamic cube shape is, therefore, approximated by the shapes obtained under these growth conditions. In all temperature studies, the alkylthiol:precursor ratio was ~80:1, and monomer concentrations were kept high, conditions supporting controlled and kinetic growth, respectively.

III-V semiconductors have proven amenable to solution-phase control of particle shape using an unusual synthetic route. Specifically, the method involves the solution-based catalyzed growth of III-V nanowhiskers.[48] In this method, referred to as the 'solution-liquid-solid mechanism,' a dispersion of nanometer-sized indium droplets in an organometallic reaction mixture serves as the catalytic sites for precursor decomposition and nanowhisker growth. As initially described, the method afforded no control over nanowhisker diameters, producing very broad diameter distributions and mean diameters far in excess of the strong-confinement regime for III-V semiconductors. Additionally, the nanowhiskers were insoluble, aggregating, and precipitating upon growth. However, recent studies have demonstrated that the nanowhisker mean diameters and diameter distributions are controlled through the use of near-monodisperse metallic-catalyst nanoparticles.[49,50] The metallic nanoparticles are prepared over a range of sizes by heterogeneous seeded growth.[51] The solution-liquid-solid mechanism in conjunction with the use of these near-monodisperse catalyst nanoparticles and polymer stabilizers affords soluble InP and GaAs nanowires having diameters in the range of 3.5–20 nm and diameter distributions of ±15–20% (Figure 20). The absorption spectra of the InP quantum wires contain discernible excitonic features from which the size dependence of the band gap has been determined, and quantitatively compared to that in InP quantum dots.[50] Preliminary results indicate that II-VI quantum wires can be grown similarly.[52] A similar approach was applied to growth of insoluble, but size-monodispersed in diameter (4–5 nm), silicon nanowires. Here, reactions were conducted at elevated temperature and pressure (500 °C and 200–270 bar) using alkanethiol-coated

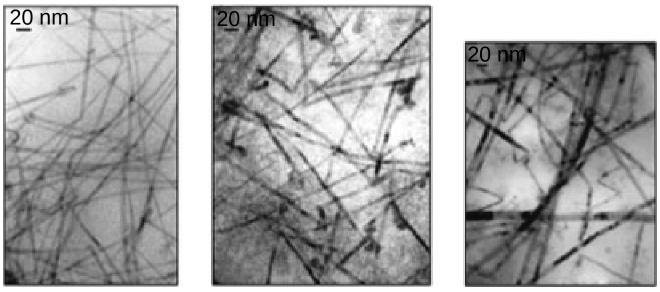

Figure 20 TEM images of InP quantum wires. Mean diameters: (a) 4.49 ± 0.75 nm [±17%; grown from 9.88 ± 0.795 (±8.0%) In-catalyst nanoparticles]; (b) 6.61 ± 1.03 nm; (c) 11.01 ± 2.29 nm. (Ref. 49. Reproduced by permission of Nature Publishing Group (www.nature.com))

gold nanoclusters (2.5 ± 0.5-nm diameter) as the nucleation and growth 'seeds'.[53]

5 PHASE TRANSITIONS AND PHASE CONTROL

5.1 NQDs Under Pressure

NQDs have been used as model systems to study solid–solid phase transitions.[54–57] The transitions, studied in CdSe, CdS, InP, and Si nanocrystals,[56] were induced by pressure applied to the nanoparticles in a diamond anvil cell by way of a pressure-transmitting solvent medium, ethylcyclohexane. Such transitions in bulk solids are typically complex and dominated by multiple nucleation events, the kinetics of which are controlled by crystalline defects that lower the barrier height to nucleation.[54,57] In nearly defect-free nanoparticles, the transitions can exhibit single-structural-domain behavior and are characterized by large kinetic barriers (Figure 21). In contrast to original interpretations, which described the phase transition in nanocrystals as 'coherent' over the entire nanocrystal,[54] the nucleation of the phase transition process was recently shown to be localized to specific crystallographic planes.[57] The simple unimolecular kinetics of the transition still support a single nucleation process; however, the transition is now thought to result from plane sliding as opposed to a coherent deformation process. Specifically, the sliding-plane mechanism involves shearing motion along the (001) crystallographic planes, as supported by detailed analyses of transformation times as a function of pressure and temperature.

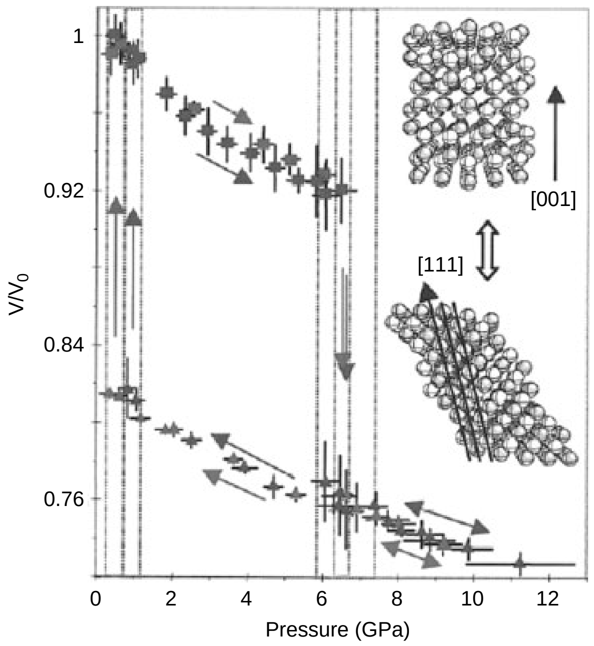

Figure 21 Two complete hysteresis cycles for 4.5 nm CdSe NQDs presented as unit cell volumes for the wurtzite sixfold-coordinated phase (triangles) and the rock-salt fourfold-coordinated phase (squares) versus pressure. Solid arrows indicate the direction of pressure change, and dotted boxes indicate the mixed-phase regions. Unlike bulk phase transitions, the wurtzite to rock-salt transformation in nanocrystals is reversible and occurs without the formation of new high-energy defects, as indicated by overlapping hysteresis loops. The shape change that a sliding-plane transformation mechanism (see text) would induce is shown schematically on the right. (Reprinted figure with permission from J.N. Wickham, A.B. Herhold, and A.P. Alivisatos, *Phys. Rev. Lett.*, 2000, **84**, 923. © 2000 by the American Physical Society)

Because of the large kinetic barriers in nanocrystal systems, their phase transformations are characterized by hysteresis loops (Figure 21).[54,55,57] The presence of a strong hysteresis signifies that the phase transition does not occur at the thermodynamic transition pressure and that time is required for the system to reach an equilibrium state. This delay is fortunate in that it permits detailed analysis of the transition kinetics even though the system is characterized by single-domain (finite-size) behavior. As alluded to, these analyses were used to determine the structural mechanism for transformation. Specifically, kinetics studies of transformation times as a function of temperature and pressure were used to determine relaxation times, or average times to overcome the kinetic barrier, and, thereby, rate constants. The temperature dependence of the rate constants led to the determination of activation energies for the forward and reverse transitions, and the pressure dependence of the rate constants led to the determination of activation volumes for the process.[57] The latter represents the volume change between the starting structure and an intermediate transitional structure. Activation volumes for the two directions, wurtzite to rock salt and rock salt to wurtzite, respectively, were unequal and smaller for the latter, implying that the intermediate structure more closely resembles the 4-coordinate structure. The activation volumes were also shown to be of opposite sign, indicating that the mechanism by which the phase transformation takes place involves a structure whose volume is in between that of the two end phases. Most significantly, the magnitude of the activation volume is small compared to the total volume change that is characteristic of the system (~0.2% vs. 18%). The activation volume is equal to the critical nucleus size responsible for initiating the phase transformation – *defining the volume change associated with the nucleation event.*

The small-size of the activation volume suggests that the structural mechanism for transformation cannot be a coherent one involving the entire nanocrystal.[57] Spread out over the entire volume of the nanocrystal, the activation volume would amount to a volume change smaller than that induced by thermal vibrations in the lattice. Therefore, a mechanism involving some fraction of a nanocrystal was considered. The nucleus was determined not to be three-dimensional, as a sphere the size of the activation volume would be less than a single unit cell. Also, activation volumes were observed to increase with increasing particle size (in the direction of

increasing pressure). There is no obvious mechanistic reason for a spherically shaped nucleus to increase in size with an increase in particle size. Further, additional observations have been made: (1) particle shape changes from cylindrical or elliptical to slab-like upon transformation from the 4-coordinate to the 6-coordinate phase,[55] (2) the stacking-fault density increases following a full pressure cycle from the 4-coordinate through the 6-coordinate and back to the 4-coordinate structure,[55] and (3) the entropic contribution to the free-energy barrier to transformation increases with increasing size (indicating the nucleation event can initiate from multiple sites).[57] Together, the various experimental observations suggest that the mechanism involves a directionally dependent nucleation process that is not coherent over the whole nanocrystal. The specific proposed mechanism entails shearing of the (001) planes, with precedent found in martensitic phase transitions (Figure 22).[55,57] Further, the early observation that activation energy increases with size[54] likely results from the increased number of chemical bonds that must be broken for plane sliding to occur in large nanocrystals, compared to that in small nanocrystals. Such a mechanistic-level understanding of the phase transformation processes in nanocrystals is important as nanocrystal-based studies, owing to their simple kinetics, may ultimately inform a better understanding of the hard-to-study, complex transformations that occur in bulk materials and geologic solids.[57]

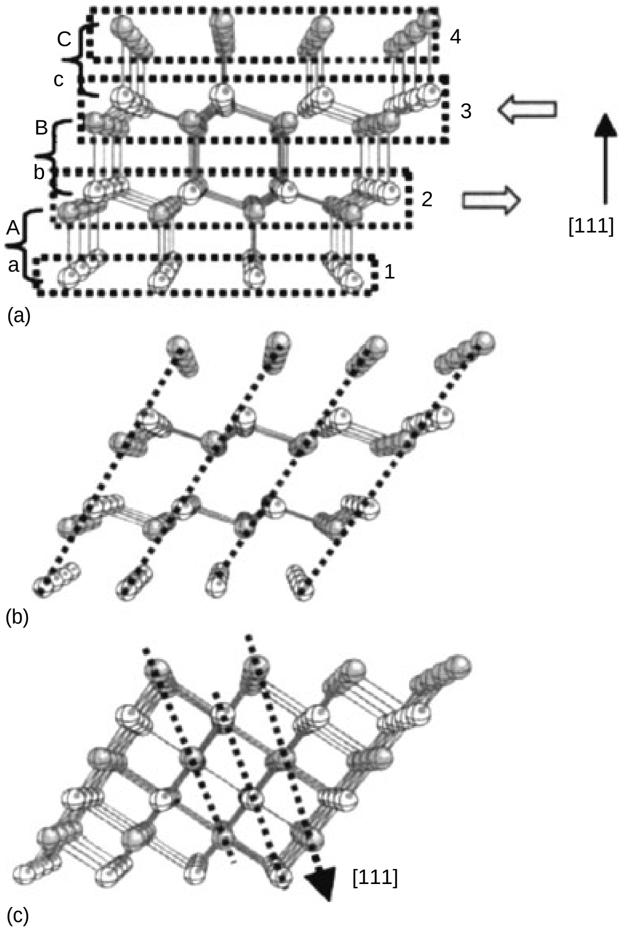

Figure 22 Schematic illustrating the sliding-plane transformation mechanism. (a) Zinc-blende structure, where brackets denote (111) planes, dashed boxes show planes that slide together, and arrows indicate the directions of movement. (b) Structure of (a) after successive sliding has occurred. (c) Rock-salt structure, where dashed lines denote (111) planes. Structures are oriented the same in (a-c). 5.2 NQD Growth Conditions Yield Access to Non-thermodynamic Phases

Phase control, much like shape control (Section 4), can be achieved in nanocrystal systems by operating in kinetic growth regimes. Materials synthesis strategies have typically relied upon the use of reaction conditions far from standard temperature and pressure (STP) to obtain nonmolecular materials such as ceramics and semiconductors. The crystal-growth barriers to covalent nonmolecular solids are high and have historically been surmounted by employing relatively extreme conditions, comprising a direct assault on the thermodynamic barriers to solid-state growth. The interfacial processes of adsorption-desorption and surface migration permit atoms initially located at non-lattice sites on the surface of a growing crystal to relocate to a regular crystal lattice position. When these processes are inefficient or not functioning, amorphous material can result. Commonly, synthesis temperatures of $\geq$400 °C are required to promote these processes leading to crystalline growth.[58,59] Such conditions can preclude the formation of kinetic, or higher-energy, materials and can limit the selection of accessible materials to those formed under thermodynamic control – the lowest-energy structures.[60,61] In contrast, biological and organic-chemical synthetic strategies, often relying on catalyzed growth to surmount or lower energy barriers, permit access to both lowest-energy and higher-energy products,[60] as well as access to a greater variety of structural isomers compared to traditional, solid-state synthetic methods. The relatively low-temperature, surfactant-supported, solution-based reactions employed in the synthesis of NQDs provide for the possibility of forming kinetic phases, that is, those phases that form the fastest under conditions that prevent equilibrium to the lowest-energy structures. Formation of the CdSe zinc-blende phase, as opposed to the wurzite structure, is likely a kinetic product of low-temperature growth. In general, however, examples are relatively limited. More examples are to be found in the preparation of nonmolecular *solid* thin films: electrodeposition onto single-crystal templating substrates,[62] chemical vapor deposition using single-source precursors having both the target elements and the target structure built-in,[63] and reaction of nano-thin-film, multilayer reactants to grow metastable, superlattice compounds.[64–66] One clear

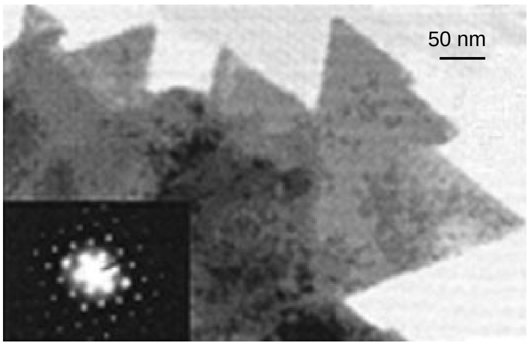

Figure 23 TEM of InS platelets with triangular features; inset, electron-diffraction pattern collected along the [0001] zone axis of a platelet

example from the solution phase is that of the formation of the metastable, previously unknown, rhombohedral InS (R-InS) phase.[67] The organometallic precursor, t-Bu_3In, was reacted with $H_2S(g)$ at $\sim$200 °C in the presence of a protic reagent, benzenethiol. This reagent provided the apparent dual function of catalyzing efficient alkyl elimination and supplying some degree of surfactant stabilization. While the starting materials were soluble, the final product was not. Nevertheless, characterization by TEM (Figure 23) and powder X-ray diffraction (XRD) revealed that the solid-phase product was a new layered InS phase, structurally distinct from the thermodynamic network structure, orthorhombic β-InS. The new phase was 10.6% less dense compared to β-InS, consistent with a low-T, kinetic structure. Further, TEM imaging revealed that the new phase was prepared as nanocrystal platelets (5–20 nm) that self- assembled to form large, micron-scale sheets (Figure 23). The van der Waals surfaces of the nanocrystal *ab* plane (the large-area plane in the platelets) are low-energy, coordinatively saturated 'faces', while the edges of the nanocrystallites are characterized by higher-energy unsaturated sites. Therefore, it is at the edges that the nano-platelets likely attached, generating the larger sheets. Electron-diffraction patterns collected perpendicular to the large-area sheet surfaces and over large areas (collection radii $\approx$150 nm) demonstrated not only that the crystallographic c axes were indeed perpendicular to the sheet surfaces but that the sheets diffracted coherently, as single crystals would (Figure 23). Assembly and attachment of platelets into sheets, therefore, proceeded in a crystallographically coherent fashion resembling a self-assembly process known in natural mineral systems as 'oriented attachment'.[68,69]

1 INTRODUCTION

The discovery of transition metal catalyzed olefin metathesis reactions is one of the most important developments in organic chemistry of the last 40 years.[1] These reactions include ring-closing metathesis (RCM), ring-opening metathesis (ROM), ring-opening metathesis polymerization (ROMP), acyclic diene metathesis polymerization (ADMET) and cross metathesis (CM) (Scheme 1). Chauvin described the mechanism that is currently accepted today. It and a fundamental mechanism for RCM are outlined in Scheme 2.[2] The potency of the olefin metathesis reactions lies in the interrelationship of the various reactions, the reversibility of the metathesis steps, and the fact that the reaction conditions can be readily tailored to give desired product outcomes.

Early olefin metathesis catalysts were transition metal salts combined with main group alkylating agents and reactivity was limited to unfunctionalized olefins because of the harsh operating conditions.[3] The olefin metathesis chemistry of the late 1970s through the early 1990s was dominated by well-defined early and mid transition metal complexes of which (**1a**) (Scheme 3), developed by Schrock, is an excellent example.[4] Complex (**1a**) exhibited remarkable activity for ADMET and ring closure to tri- and even tetra-substituted cyclic products.[5–7] Along with the extraordinary activity, some drawbacks accompanied the group VI-type catalysts, including catalyst synthesis, high sensitivity to oxygen and moisture, and a somewhat narrow substrate scope due to functional group sensitivity.

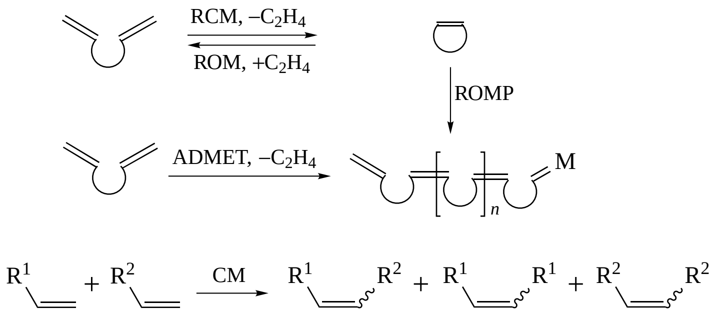
In 1992, the discovery of late metal alkylidene complexes of the type ($L_2X_2Ru{=}CHR$) that could catalyze RCM and ROMP was reported by Grubbs.[8,9] The ruthenium complex (**2a**) (Scheme 3) was more stable, tolerant of a wide range of functional groups and capable of operating under less stringent reaction conditions than the group VI catalysts, although less active. This type of complex was particularly useful for RCM and ROM of highly functionalized molecules as well as ROMP of strained cyclic olefins. The ‘user friendliness’ of complex (**2a**) made olefin metathesis an attractive new reaction for organic chemists and throughout the last 10 years the chemical literature was rich with new applications for olefin metathesis reactions catalyzed by Mo or Ru complexes. These complementary catalysts gave rise to an olefin metathesis revolution for approaching synthetic problems, particularly those in total synthesis.[10]

In 2000 and 2001, reviews on olefin metatheis by Fürstner[11] and Grubbs respectively that outlined the development and progress of olefin metathesis up through the turn of the century[12] focused on the functional group tolerance, scope of reactivity, and mechanism of action of Grubbs ruthenium-based olefin metathesis catalyst (**2a**), and the discoveries of more active catalysts (**2b**),[13] (**3a**),[14–16] and (**4a**).[17,18] Since that time there has been rapid progress in the creation of new catalysts, both ruthenium and molybdenum based, including successful chiral OM catalysts, further elucidation of the mechanism, new methodologies, and an even stronger presence of olefin metathesis as a key reaction in the construction of complex carbon skeletons. The following is an account of the most recent developments in olefin metathesis chemistry.

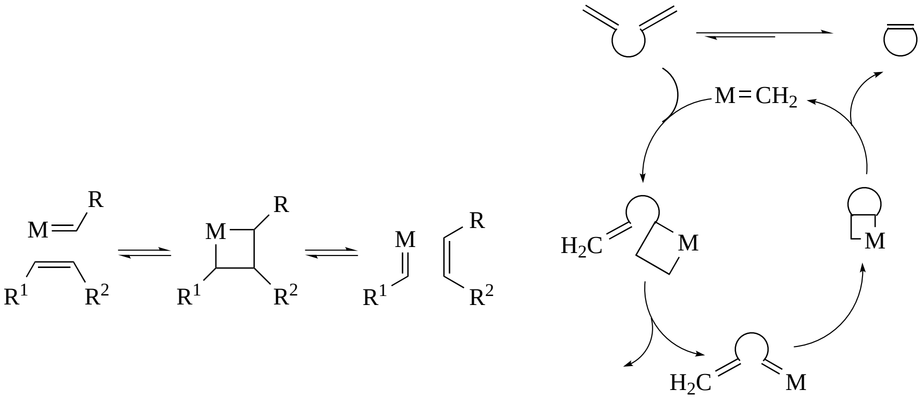
2 NEW CATALYSTS AND APPROACHES

A number of new ruthenium and molybdenum olefin metathesis catalysts have been developed since the turn of the century. These new, very active catalysts build upon prior successful catalysts and insight gained from systematic mechanistic studies.

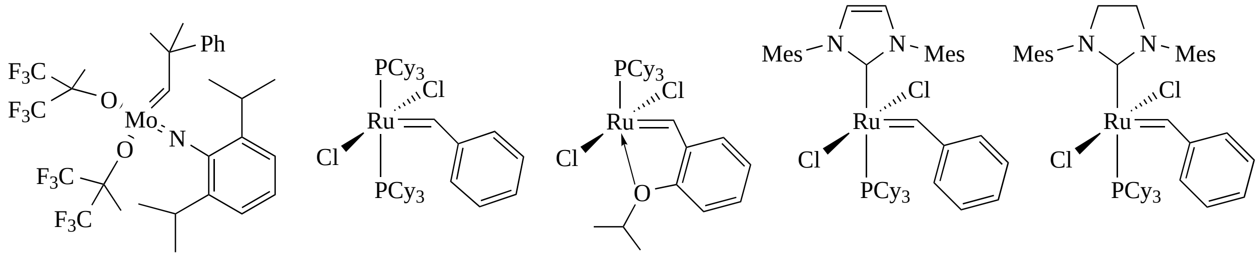
A family of phosphine-free ruthenium-based olefin metathesis catalysts has been developed over the last few years. First, work done independently by Hoveyda and Blechert resulted in the H_2Mes isopropoxybenzylidene (**4b**), a highly active air-stable ruthenium (pre)catalyst for olefin metathesis (Scheme 4).[19,20] Hoveyda described (**4b**) as a recyclable monomeric catalyst also with high activity for ring-opening, ring-closure, and cross metathesis that tolerates



Scheme 1 Types of olefin metathesis reactions



Scheme 2 Mechanism of olefin metathesis and proposed cycle for RCM

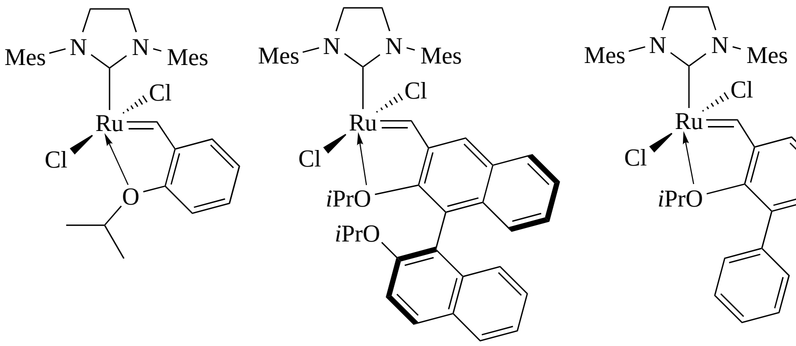


(**1a**) (**2a**) (**2b**) (**3a**) (**4a**)

Scheme 3 Some successful olefin metathesis catalysts

the steric bulk of up to trisubstituted substrates or products. Blechert's report on (**4b**) concludes that the catalytic behaviors of (**4a**) and (**4b**) are distinct and that (**4b**) favors cross metathesis activity. This catalyst prototype led to a number of new catalysts based on aryl alkyl ethers bound to the alkylidene. The first of these was the binol-derived catalyst (**4c**), initially developed for enantioselective catalysis.[21] While reactions with this catalyst were not stereoselective, (**4c**) was air stable yet significantly more active than (**4a**) for RCM with initial rates 10-fold that of the previous benchmark by (**4a**). Catalyst (**4c**) completely converted classical RCM substrates like diallyl diethyl malonate and substrates like *N*-(but-3-enyl)-*N*-tosylbut-3-en-1-amine that have very low reactivity for RCM, while (**4a**) gave only moderate to low conversions under the same conditions. Cross metathesis reaction of linear olefins and electron-poor alkenes with very high trans:cis ratios were also effected by (**4c**).

Blechert then discovered the related catalyst (**4d**) while trying to elucidate the factors that made (**4c**) more active than (**4b**).[22] The ligand structure of (**4d**) is similar to that of (**4c**) in that the benzylidene ether ligand has a bulky group ortho to the ruthenium-coordinating ether moiety. Catalyst(**4d**) is so

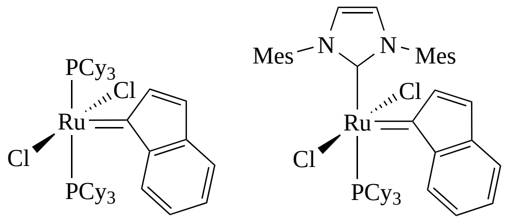


(**4b**) (**4c**) (**4d**)

Scheme 4 Phosphine-free ruthenium complexes for olefin metathesis

active that 1 mol% ring-closes *N*-tosyldiallylamine in 90 min at 0 °C. For all reactions tested, including RCM, CM, RCM-CM, and ROMP, (**4d**) was significantly more active than (**4a**). The high activity of this catalyst is thought to be because of the rapid dissociation of the bulky ligand leading to the active 14-electron species. Catalyst (**4d**) is the most functional group tolerant Ru containing olefin metathesis catalyst reported to date. It successfully mediates ROM-CM reactions of unprotected amines and sulfur containing compounds with metathesis partners of varying degrees of bulk giving products in high yield.[23]

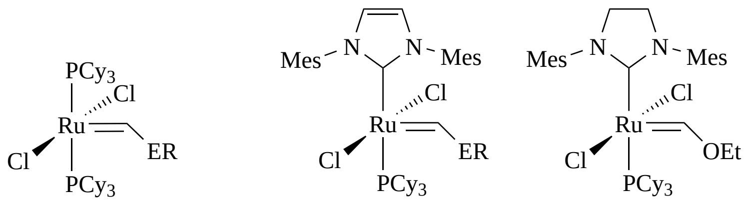
Fürstner developed ruthenium indenylidene (readily accessible from commercially available diphenyl propargyl alcohol) (**2c**) and (**3b**) (Scheme 5) versions of the alkylidene (**2a**) and (**3a**) with (**2c**) being superior to (**3b**) in yield, reaction rate, and tolerance to polar functional groups.[24] Catalyst (**2c**) was more active than (**2a**) for RCM and it was applied to RCM to form functionalized rings from 5 to 21 members. For all reported ring closures, compared cases (**2c**) was equal to or superior to (**2a**). The functional group tolerance and activity made (**2c**) the best catalyst for the RCM approach to the synthesis of the ADE ring system of Nakadomarin A.



(**2c**) (**3b**)

Scheme 5 Indenylidene versions of olefin metathesis active complexes

Grubbs synthesized and characterized a series of (**2a**), (**3a**), and (**4a**) analogs with electron-rich alkylidenes having the general structure $LPCy_3Cl_2Ru{=}C(H)ER$, ($L = PCy_3$, IMes, H_2IMes) (ER = OEt, SEt, SPh, N(carbazole), N(pyrrolidinone)) and determined their efficacy as olefin metathesis catalysts of electron-rich olefins with the goal of developing a general metathesis method for creating difunctional olefins (Scheme 6).[25] These Fischer-carbene complexes (*see Fischer-type Carbene Complexes*) have similar X-ray structures to their parent complexes, but were

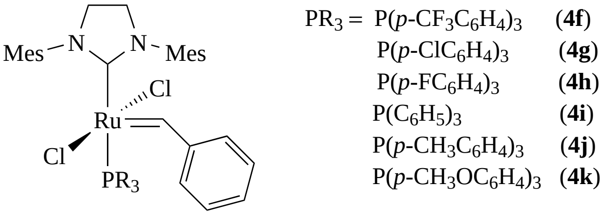


ER = OEt	**(2d)**	ER = OEt	**(3c)**	(**4e**)
SEt	**(2e)**	SEt	**(3d)**	
SPh	**(2f)**	N(carbazole)	**(3e)**	
N(carbazole)	**(2g)**	N(pyrrolidinone)	**(3f)**	
N(pyrrolidinone)	**(2h)**			

Scheme 6 Electron-rich analogues of olefin metathesis active complexes

more stable than their parent complexes and significantly lower in activity with the overall reactivity trend E = C > N > S > O with even the O analogs exhibiting some activity. In this report, synthesis of difunctional olefins was not achieved because methylidene intermediates are not formed and the reaction cannot proceed by the metathesis mechanism.

Very recently, Grubbs and coworkers completed an analysis based on insight from mechanistic work on the relative rates of phosphine dissociation and olefin coordination (vide infra) in ruthenium alkylidene catalyzed olefin metathesis reactions. The study was based on numerous analogues of (**4a**), having different phosphine groups, for example, (**4e**), (**4f**), and (**4g**). Rates for ROMP of cyclooctadiene with the most potent of these new complexes were 340-fold greater than with (**4a**) (Scheme 7).[26]



Scheme 7 Electron deficient analogues of (**4a**)

3 MECHANISM AND THEORY

The mechanism of (**2a**) was extensively explored during the late 1990s.[27] These studies supported two different pathways for the potential mechanism of the Ru type olefin metathesis catalysts, described in Scheme 8. The first pathway (a) begins with olefin coordination followed by phosphine dissociation and alkylidene rotation where alkylidene and olefin are cis to each other and undergo metallacyclobutane (*see Metallacycle*) formation and formation of product. The other pathway (b) considered begins with phosphine dissociation and olefin coordination trans to the remaining phosphine, and metallacyclobutane formation trans to the phosphine. Experiments favor the latter hypothesis; although the mechanism in Scheme 9 best fits the overall experimental data. Bulkier electron-donating phosphine ligands in the (**2**) family increase activity, which is suggested to be caused by the electron richness provided by phosphine to metal center donation that allows one phosphine to dissociate and also can stabilize the 14-electron metallacyclobutane intermediate. Recently developed catalysts of the (**2**), (**3**), and (**4**) families have activities that could only partially be explained by ligand donation, prompting many groups to reexamine the mechanism of ruthenium-catalyzed olefin metathesis.[13–17] Since the catalysts discussed above can be varied by a modular approach, all that was needed was for the appropriate mechanistic questions to be asked.

3.1 Experimental Results

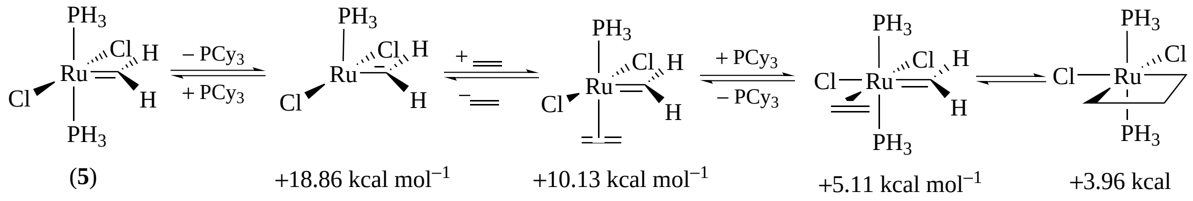
Grubbs took a closer look at mechanism with regard to the greater activity of (**4a**) versus (**2a**).[28] To this point, it had been argued that the greater catalytic activity of (**4a**) was caused by the dihydroimidazolinium ligand's better ability to promote dissociation of phosphine through its higher steric bulk (*see Steric Effect*) and greater electron donation; leading more quickly to the active 14-electron species.[14,17] Careful kinetic analysis of phosphine exchange reactions and reactions with ethyl vinyl ether supported a dissociative pathway and showed that during the progress of the reaction neither did phosphine dissociate faster in (**4a**) nor were the initiation rates faster. What appeared to matter was the ratio of the rate of phosphine rebinding to olefin binding, that is, k_{-1}/k_2. This ratio is lower in (**4a**) by four orders of magnitude than in (**2a**) (Scheme 10). Thus, even though (**4a**) is slower to dissociate phosphine than (**2a**), once phosphine is dissociated, the 14-electron species prefers to bind olefin rather than rebind phosphine. A related result was determined by work on ADMET kinetics of 1,9-decadiene by Wagener. This study revealed a stronger temperature dependence on reaction rate for (**4a**) when compared to (**2a**). The rate of polymerization at 30 °C, for reactions catalyzed by (**2a**), was twice that for (**4a**). At higher temperatures, (**4a**) was the more active catalyst. The reason for the greater temperature sensitivity of (**4a**) was postulated to be the difference in phosphine dissociation rates for the two precatalysts.[29]

3.2 Theoretical Work

A number of theoretical studies support the results of the experimental work by Grubbs and Wagener. Chen performed a quantum mechanical/molecular mechanics (QM/MM) study on the olefin metathesis reaction comparing (**2a**) and (**4a**). The enthalpy of activation predictions from this study is consistent with the experimental values found by Grubbs in that the shape of the ligand, threefold symmetry of phosphine and twofold symmetry of carbene, influenced the dissociation energetics. The QM/MM results indicate that phosphine dissociation is always rate limiting for (**4a**), while the rate-limiting step of (**2a**) has a metallocylobutane structure.[30]

Cavallo performed density functional theory (DFT) (ADF) calculations on (**2a**), (**3a**), (**4a**), and their various proposed catalytic cycle intermediates.[31] The data from this work agrees with experimental results in the activation energies for phosphine exchange and binding energies for ethene; heteroleptic (*see Heteroleptic Compound*) phosphine/NHC-based complexes have a higher propensity to bind olefin (longer C=C and shorter Ru-olefin distances) than bisphosphine complexes. Each of the energy barriers measured was found to be less than 8 kcal mol^{-1}, with (**3a**) and (**4a**) having a lower olefin insertion barrier than (**2a**). Metallacycles were slightly more stable than olefin bound intermediates for (**3a**) and (**4a**) while the (**2a**)-derived metallacycle was higher in energy, consistent with Chen's QM/MM work.[30] The bulky NHC ligand's major role appears to be to crowd the alkylidene moiety and thus destabilize the phosphine-free, olefin-free intermediate, *not* to promote phosphine dissociation electronically.

Thiel performed DFT calculations on a more simplified data set, utilizing PH_3 in place of PCy_3 and imidazol-2-ylidene for IMes, looking at the electronics of both associative and dissociative pathways for the mechanism (*see* ***Mechanisms of Reaction of Organometallic Complexes***).[32] This study showed that the dissociative mechanism with trans olefin coordination is favored and that the relative rates of phosphine dissociation and olefin coordination can be affected by phosphine choice. The results of the calculations are rationalized by a steric analysis, arguing that the C_2-symmetric NHC is less able to exert steric pressure on the C_3-symmetric



(5)

Scheme 11 Intermediates in pathway A

phosphines. Thiel concludes that the most effective catalysts will have one weak and one strong σ-donor ligand.

The low-energy barrier to the rate-determining step in olefin metathesis using (**2a**) was supported by DFT (B3LYP) studies on the orbital interactions of (**2a**) with particular interest in the ruthenacyclobutane.[33] A C–C α-agostic (*see Agostic Bonding*) interaction in the metallacyclobutane gives a flat potential energy surface going from ruthenium alkylidene coordinated olefin to ruthenium alkylidene' and olefin'. In addition, strong ruthenium alkylidene/olefin π orbital interactions agree with the low-energy barrier to the rate-determining step of olefin metathesis.

A DFT (B3LYP) study on the mechanism of (**2a**) in olefin metathesis was also recently published using bisphosphine methylidene models.[34] The authors concluded from this work that the active catalyst in olefin metathesis is $(PR_3)_2Cl_2Ru{=}CH_2$, not the higher energy carbenoid complex $((PR_3)_2ClRu–CH_2Cl)$, and that there exist three reaction pathways, A, B, and C. Pathway A is most consistent with a dissociative pathway (Scheme 11). Pathway B and C both have higher activation energies than does A and begin with ethylene coordination to the bisphosphine complex, forming a low-energy ($-2.01\ \text{kcal mol}^{-1}$) intermediate; pathway B loses a phosphine, which leads to a high energy barrier to formation of the metallacyclobutane. The energetics of pathway C are dictated by formation of carbenoid species en route to the metallacyclobutane.

Nolan and Cavallo showed only small metrical differences in bond length among the various ligands like IMes and H_2IMes even though there was a large difference in the efficacy of the corresponding catalysts (**3a**) and (**4a**). This was taken to indicate that catalytic ability is quite sensitive to the donor properties of the ligands.[35]

Grubbs and coworkers performed a systematic study on a large number of olefin metathesis initiators that differed only in the phosphine ligand; wherein the phosphine dissociation rate constants, relative rates of phosphine reassociation, RCM, and ROMP rates were determined.[26] A linear free energy (LFE) relationship was found between the strength of the phosphine σ-donation and catalyst initiation rate but no LFE relationship was found with reassociation rates. Overall, among the initiators examined, the p-CF_3triphenylphosphine substituted species had the highest relative reactivity to (**4a**): 340 higher rate in polymerization of COD (cyclooctadiene) and an eightfold increase in rate for RCM of diethyl 2-allyl-2-cinnamylmalonate (Table 1).

These recent findings indicate overall that the ligand that remains on the metal affects the energetics of the catalytic cycle, specifically olefin coordination, and the accessibility of the metallocyclobutane structure, the properties of the phosphane ligand control initiation rates, and thus how much of the catalyst can enter the catalytic cycle. The results of these careful analyses (Table 2) are sure to germinate the next generation of efficacious olefin metathesis catalysts.

4 RECENT METHODOLOGY DEVELOPED UTILIZING OLEFIN METATHESIS

4.1 Advances in the Construction of Small Heterocycles and Carbocycles

The predictable construction of heterocycles and highly functionalized carbocycles with or without intracycle asymmetry is paramount to synthesis of biologically important compounds and other areas of organic synthesis.[36–38] A number of methodological advances have been reported utilizing RCM for the construction of previously inaccessible rings.[39]

Table 1 Relationship of rates and activities (polymerization of cod) of various catalysts of type (**4**)

Complex	Precatalyst phosphine	k_1 (s^{-1})	k_{-1}/k_2	Activity relative to (**4a**)
(**4a**)	PCy_3	0.13 ± 0.01	1.25	1
(**4f**)	$P(p\text{-}CF_3C_6H_4)_3$	48 ± 2	7.3	340
(**4g**)	$P(p\text{-}ClC_6H_4)_3$	17.9 ± 0.4	45	95
(**4i**)	$P(C_6H_5)_3$	7.5 ± 0.6	2.3	50
(**4k**)	$P(p\text{-}CH_3OC_6H_4)_3$	1.8 ± 0.1	7.5	10

Table 2 Summary of recent experimental and theoretical mechanistic work

Author	Method	Mechanism support
Grubbs	Phosphine exchange reaction kinetics on (**3a**) and (**4a**)	The ratio of rates of olefin coordination to phosphine reassociation dictate rate of reaction, and permit the slower to initiate heteroleptic (**3a**) and (**4a**) to be more active catalysts.
Wagener	ADMET kinetics (**2a**) and (**4a**)	Reaction rates using (**4a**) were much more temperature dependant than those using (**2a**). Indicating that phosphine dissociation is an energy barrier for (**4a**) processes.
Chen	QM/MM (**2a**) and (**4a**)	Ligand shape (phosphine vs. NHC) is linked to rate of dissociation of trans phosphine. Phosphine dissociation is always slow step for (**4a**) while metallocyclobutane formation is the energetic barrier for (**2a**)
Cavallo	DFT (ADF) (**2a**), (**3a**) and (**4a**)	Lower lower insertion barriers for NHC-precatalysts than for (**2a**). (**2a**) had higher energy metallacyclobutane
Thiel	DFT (BP86) Analogues of (**2a**) and (**3a**)	Dissociative, trans olefin coordination, phosphine geometry superior to NHC geometry for dissociating phosphine
Suresh and Koga	DFT (B3LYP) Analogue of (**2a**)	Nearly flat potential energy surface going from Ru-alkylidene with coordinated olefin to ruthenacyclobutane to ruthenium alkylidene' with coordinated olefin' caused by C–C agostic interactions
Bottoni	DFT (B3LYP) Analogue of (**2a**)	3 Competing pathways support associative and dissociative mechanisms and finds carbenoids significant contributors as intermediates
Grubbs	Kinetics on heteroleptic compounds	Sigma donation of phosphine directly related to initiation rates in heteroleptic compounds rates of phosphine reassociation not directly linked
Cavallo and Nolan	Calorimetry and crystal-structure measurements (**3a**) and (**4a**)	Electron donation is main difference between (**3a**) and (**4a**) activity

Much of the increase in scope is linked to the higher functional group tolerance and activity of (**4a**).

A need for a synthetic entry toward simple and structurally complex alkaloids prompted development of methodology to prepare a variety of azabicyclo[*n*.3.1] alkenes in good yields utilizing protected 2,6-*cis*-dialkenyl piperidines, prepared from glutarimide or 4-methoxy pyridine and catalyzed by (**2a**) and (**4a**) (equation 1).[40,41]

Madsen was able to synthesize conduritols (cyclic polyalcohols) via RCM metathesis of tartaric acid or sugar derivatives using (**2a**) or (**4a**), making available a number of the possible conduritol diastereomers in just a few steps from the chiral pool (Table 3).[42]

The 1,2-dihydroquinoline and quinoline structural units, ubiquitous in natural products, were synthesized utilizing ene–ene or ene–enol RCM.[43] The authors explored catalysis with (**2a**) and found it brought many substrates to >90% isolated products (50 °C, 1 h) while (**4a**) took all substrates reported to nearly quantitative conversion (Table 4).

Complex (**3a**) proved to be efficient for the formation of a variety of adjacent cyclic ethers via triple RCM from readily synthesized acyclic hexaenes.[44] The reaction, which proceeds under mild to somewhat forcing conditions, gives moderate to good yields of the desired tricyclic ethers over the alternative RCM products (equation 2).

4	 (**18**)	(**2a**)	 (**19**)	98

Liu and coworkers prepared a number of bicyclic ethers by applying en-yne-ene metathesis with (**2a**) or (**4a**) to chiral bisallyloxybut-1-ynes to give various bicyclic ethers with interesting biological properties from a common starting material.[45] Using 3 mol% (**2a**), the 3,4-bisallyloxybutynes gave a [4.4.0] bicycle as the major product with small amounts of [5.3.0] bicycle. The 3-allyloxy4-but-2-enyloxy analogue gave only [5.3.0] bicyclic ethers when 2 mol% (**4a**) was used (Table 5).

α-Phosphono lactone analogues of cytidine and cytosine arabinose diphosphates were constructed via a Lewis acid (*see Lewis Acids & Bases*) catalyzed asymmetric allyl

addition to arabinose aldehyde followed by RCM.[46] The RCM step was examined using (**2a**) and (**4a**), with (**4a**) giving better conversion to lactone product in good yields (equation 3).

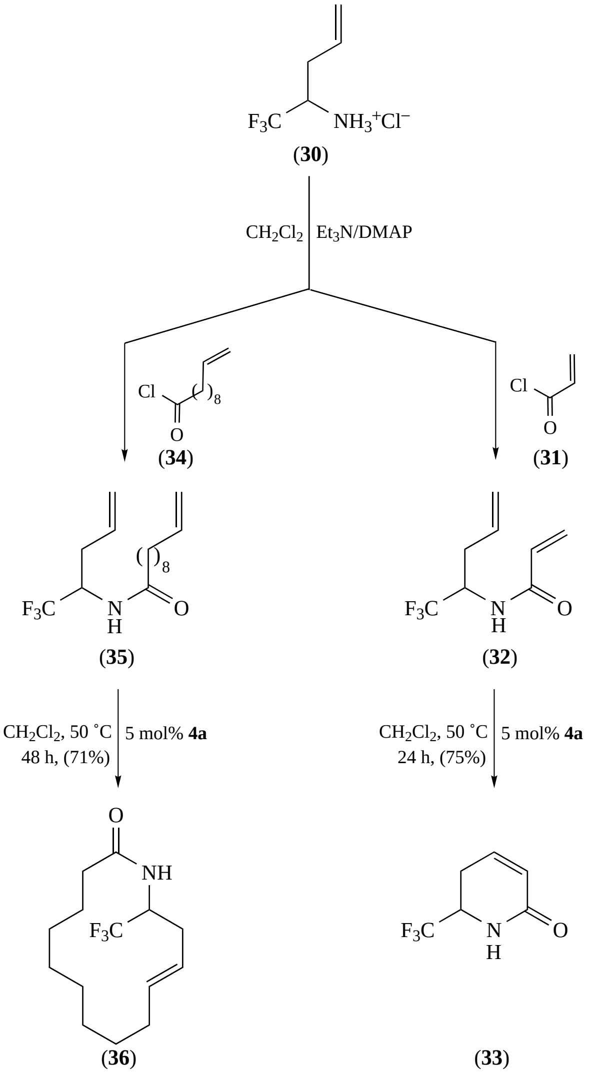
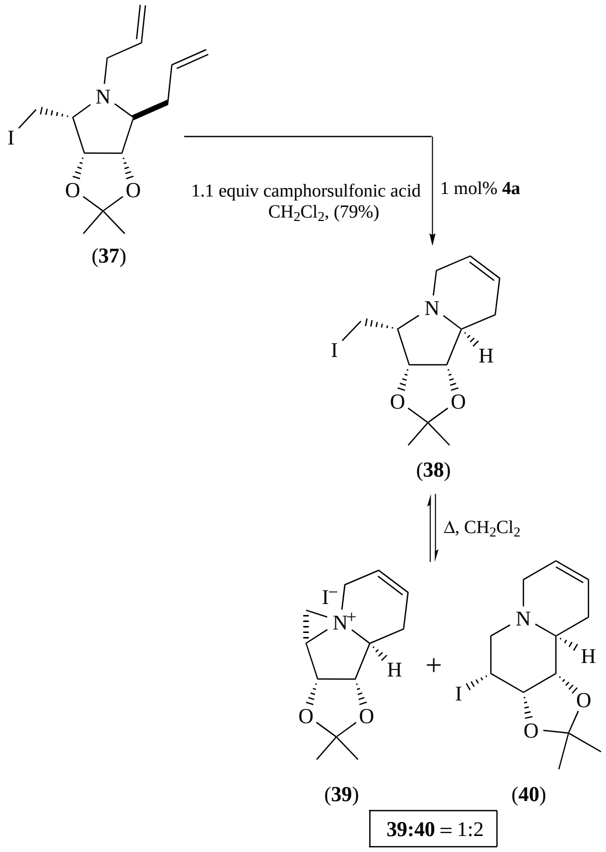
Efficient routes to α-trifluoromethylated nitrogen heterocycles of various sizes for applications in synthesis of CF_3 tagged bioactive molecules were achieved in two steps from α-(trifluoromethyl)homoallylamines via ene–ene or ene–yne metathesis catalyzed by (**2a**) and with better conversions by (**4a**) (equation 4).[47]



(4)

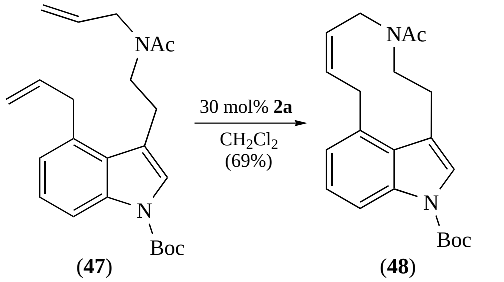
An efficient new methodological pathway for the preparation of the polyhydroxylated alkaloids, indolizidines, and quinolizidines was developed through (**4a**) catalyzed RCM/allylic amination or, alternatively, RCM/haloamination strategies (equation 5), starting from a methyl furanoside precursor.[48]



(5)

Meyers used (**2a**) under a variety of conditions to ring close a number of enantiopure lactams to form spirocycles ranging in size from 5 to 8 members in 18–24 h reaction times that could then be converted to different targets in just a few steps (Table 6).[49]

Snieckus developed a RCM approach to analogues of ergot alkaloids employing (**2a**). This route is the first to access *seco-C*/D ring ergot alkaloid cores and it does so with good efficiency (equation 6).[50]



(6)

The synthesis of unsymmetrical nonadjacently linked tetrahydrofurans was accomplished by Mootoo through (**4a**) catalyzed cross metathesis of the protected substituted-tetrahydrofuran components.[51] These compounds are potential intermediates for acetogenins having potent antitumor activity

Table 6 Ring closure metathesis to give a variety of spirocycles

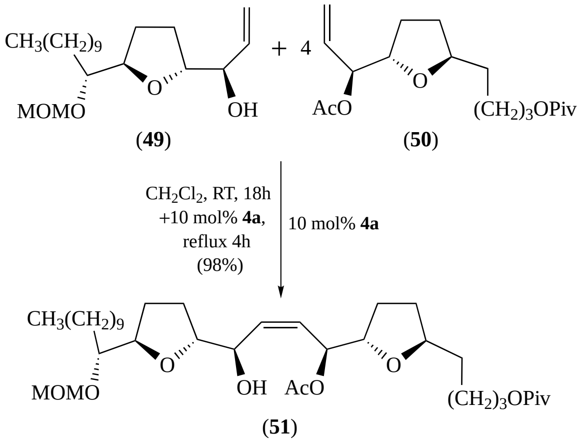
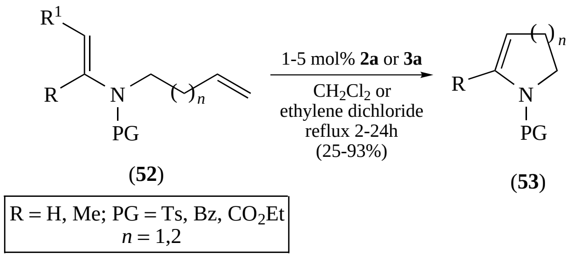
(equation 7).

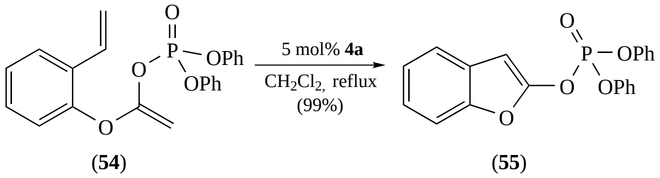


(7)

Rutjes utilized (**2a**) and (**3a**) for ring-closing olefin metathesis of enamides.[52] The five and six-membered ring products were available in good yields for the most part, although forcing conditions were sometimes required (equation 8). Hanson pursued the synthesis of cyclic enol phosphates via RCM utilizing (**4a**).[53] Five- and six-membered heterocycles (X = O, NTs, S, SO_2) were achieved in good to excellent yields with 5 mol% catalyst (equation 9).

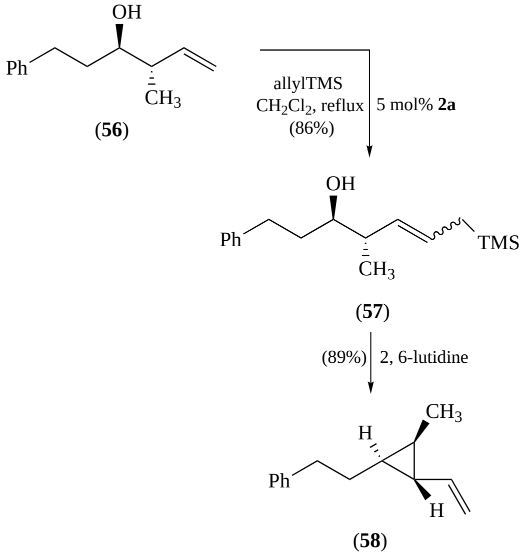


(8)



(9)

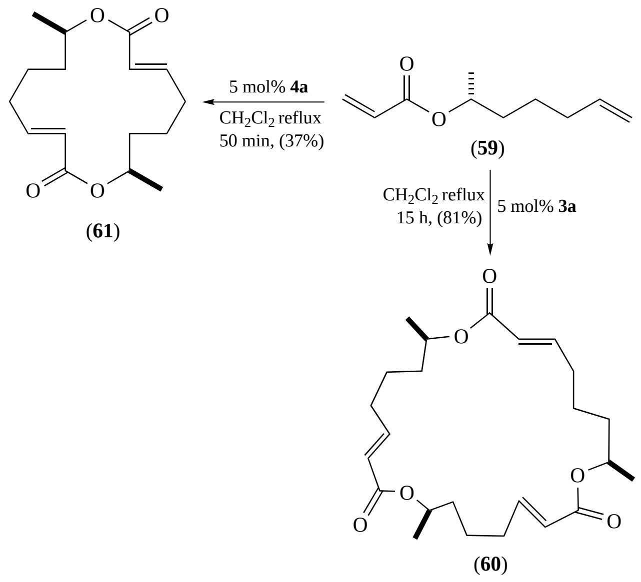
The high selectivity of olefin metathesis with (**2a**) was key in the formation of diverse nonracemic vinyl cyclopropanes from chiral homoallylic alcohols and allyl chlorodimethylsilane in three steps, or allyl trimethylsilane in two steps, giving diastereomerically pure cis or trans isomers.[54]



(10)

4.2 Macrocycles and Supramolecular Structures

Naturally occurring macrocycles are often highly functionalized, often having heterocycles in the ring. In many cases, successful synthesis of macrocycles hinged on ring-closing lactonizations and lactamizations.[55–59] With the advent of efficient RCM, macrocycle synthesis gained a new avenue of approach that allowed the formation of rings without the reliance on functional group transformations.[60–62] Numerous reports utilizing (**2a**) for the formation of macrocycles have been published, while (**4a**) has allowed the scope of this type of transformation to broaden significantly. Similarly, olefin metathesis has been an important synthetic route in the formation of supramolecular structures; this section covers some recent advances in these areas utilizing (**2a**).

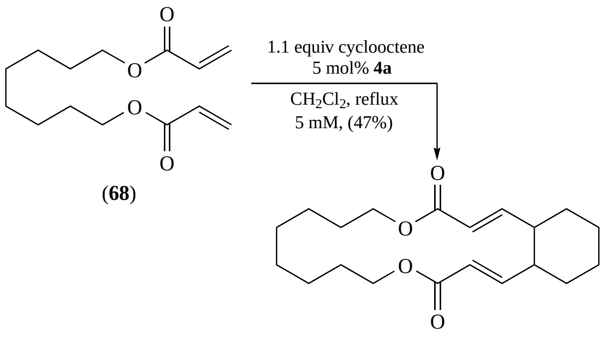


(11)

Table 7 Formation of macrolactones from α,β-unsaturated esters catalyzed by (**4a**)

Entry	Diene	[], mM	Product(yield)
1	 (**62**)	6	 (**63**) (81%)
2	 (**64**)	3	 (**65**) (82%)
3	 (**66**)	1	 (**67**) (78%)

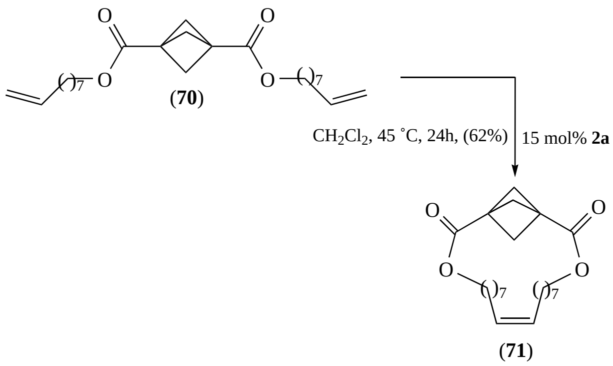
Olefin metathesis has become a leading method for assembling macrocycles. Of particular efficacy in these reactions are the second-generation catalysts like (**4a**). Fürstner reported that dienes with ester functionality could be cyclized to form 14-membered lactones as the thermodynamic products. Chiral macrocycles were also achieved by ring-closing dimerizations and trimerizations of chiral dienes (equation 11).[63] Grubbs also reported successful use of (**4a**) to ring close, dimerize, and trimerize ester-containing dienes to form a variety of macrolactones. The driving force for formation of RCM products over CM products was seen to be the low concentrations (Table 7).[64] In related work, Grubbs was able to access a variety of macrocycles that were derived from differing parent compounds. Ring sizes from 18 to 36 members were obtained in low to moderate yield via ring expansion utilizing functionalized straight chain dienes and cyclopentenes and cyclooctenes at low concentrations (equation 12). The strength of this strategy lies in the ease of access to a variety of ring sizes through adjustment of stoichiometry and concentrations.[65]



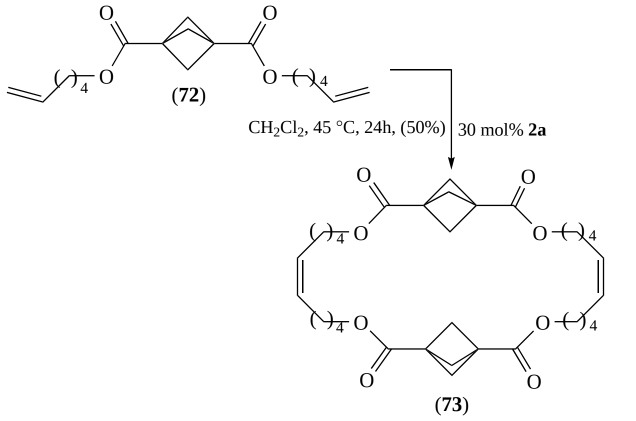
(**68**) (**69**) (12)

Olefin metathesis was successfully applied in the creation of end functionalized polybutadiene oligomers employing self-metathesized (using **2a**) viologen-based pseudo[2]rotaxane dimers as chain transfer agents in the polymerization of 1,5 cyclooctadiene catalyzed by (**4a**) to create porphyrin containing [3]rotaxanes.[66] This report expands upon methodology for end functionalizing polybutadienes reported by Grubbs.[67,68]

Paddlanes having a bicyclo[1.1.1]pentane core have been synthesized from dicarboxylate esters and 1,3 difunctionalized bicyclo[1.1.1]pentanes using (**2a**) catalyzed olefin metathesis (equations 13 and 14).[69]

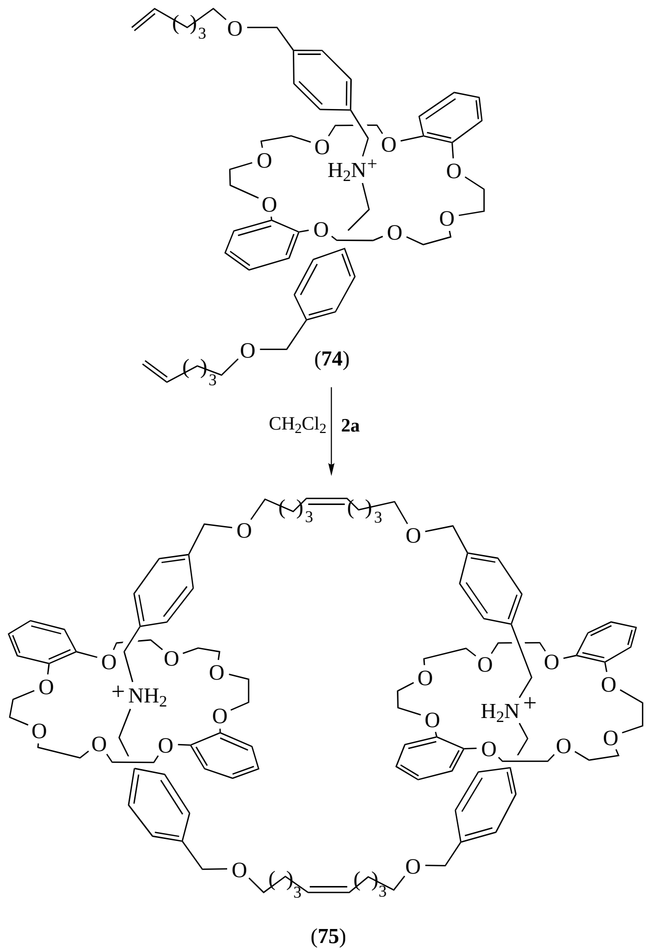


(**70**) (**71**) (13)



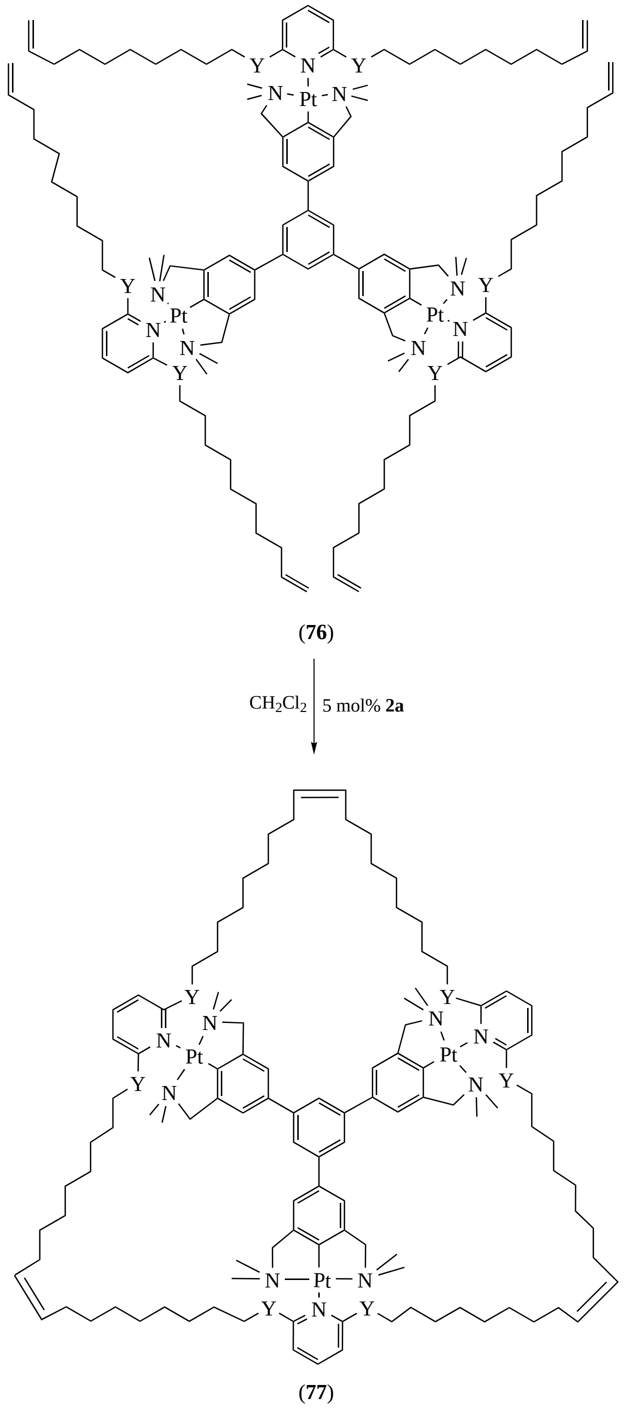
(14)

[3]Catenane synthesis was achieved by utilizing alkene terminated pseudorotaxanes of various lengths and (**2a**) expanding on work reported earlier by Smith,[70] resulting in modest concentration and ring size dependent yields (2–35%) of desired products, equation (15).[71]



(15)

Van Koten and coworkers took advantage of the combination of a shape persistent reusable cationic template and olefin metathesis to form trigonal functionalized macrocycles from 2,6-diolefin substituted pyridines catalyzed by (**2a**) in moderate to good yields (equation 16).[72] The controllable binding modes allow easy liberation of the macrocycle from the template. Upon reduction of the alkenes, these flexible macrocycles were efficient hosts for the parent template. This strategy can be utilized for the formation of nitrogen and oxygen functionalized macrocycles.

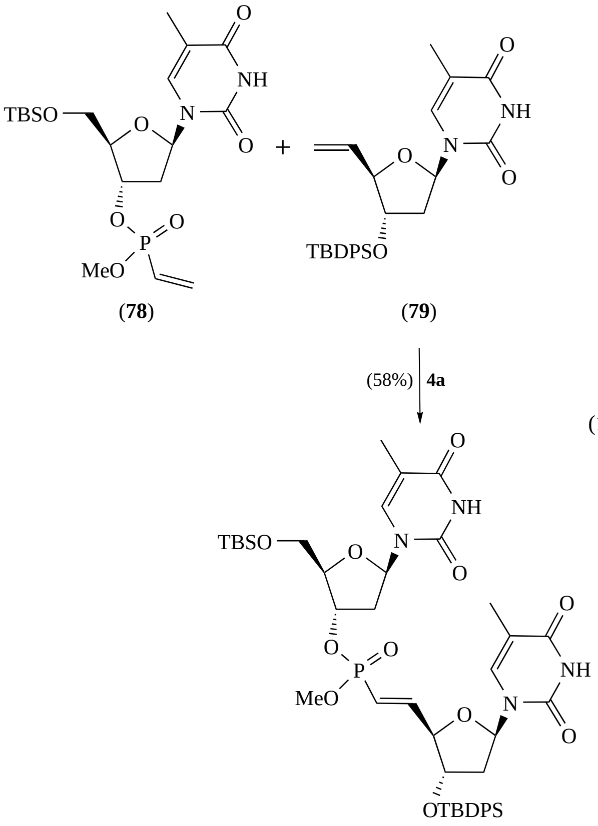


(16)

4.3 Cross Metathesis

It was recognized early that efficient olefin cross metathesis could provide new methods for the synthesis of complex molecules. However, neither (**1a**) nor (**2a**) were very effective at *intermolecular* cross metathesis owing to poor reaction selectivity (cross vs. intramolecular metathesis) and low E:Z ratios (*see (E) & (Z) Isomers*).[73–75] The advent of more active and functional group tolerant olefin metathesis catalysts recently made cross metathesis a viable route for constructing a large variety of functionalized acyclic alkenes.

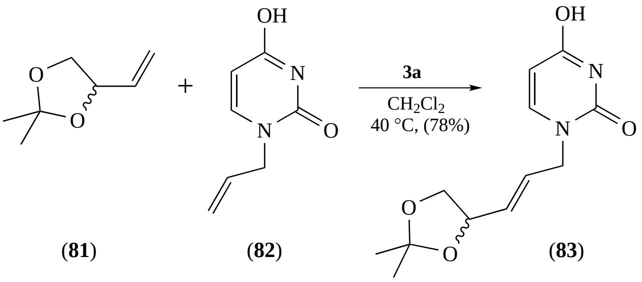
Grubbs used (**4a**) to efficiently install functional groups that might otherwise be added via C–H activation or allylic oxidation pathways (Scheme 12). Among the breadth of compound types accessible through these cross metathesis strategies were substituted vinyl-phosphonic, boronic, and carbonyl esters, which were synthesized in good to excellent yields.[76]



(**78**) (**79**) (**80**)

(17)

Several examples of the use of (**4a**) catalyzed cross metathesis of protected allylic sugars, or vinyl substituted heterocycles or vinylated functional groups have been reported. Vinylphosphonate-linked nucleotide dimers were synthesized by cross metathesis using complex (**4a**), achieving products with E:Z ratios of >20:1 in moderate to good yields (equation 17).[77] A metal-mediated route to acyclic nucleosides developed by Agrofoglio and coworkers produced nucleosides in two steps from parent pyrimidines and purines.[78] The first step is Pd catalyzed allylation, and the second step is (**3a**) catalyzed cross metathesis of a protected allylic diol with yields over the two-step process in the 40–60% range (equation 18).

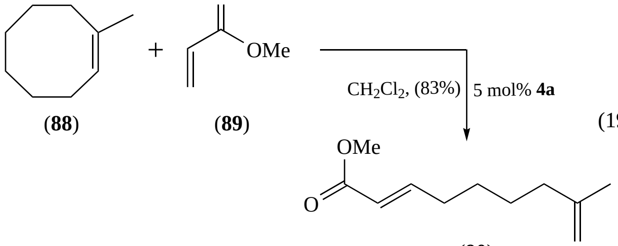


(**81**) (**82**) (**83**)

(18)

Complex (**4a**) gave cross metathesis products of protected allyl-galactosides and allyl halides as a convenient route to substituted-allylhalides in good yields and high E:Z selectivities, illustrating the power of cross metathesis to bring functionalities together in few steps.[79] Protected olefinic carbohydrate was linked during peptide assembly, or to a peptide fragment, in the development of strategies for forming C-neoglycopeptides designed for modeling cellular recognition and its relationship to disease.[80] Many different C-glycoside/amino acid combinations were successfully linked although the E:Z ratios were not described. Efficient access to iminosugar C-glycoside building blocks was provided by (**4a**) catalyzed cross metathesis. The methodology is general and gives access to these structurally diverse bioanalogous compounds for potential application in biomimetic chemistry.[81] Examples of cross metathesis with protected sugars and glycosides are illustrated in Scheme 13.

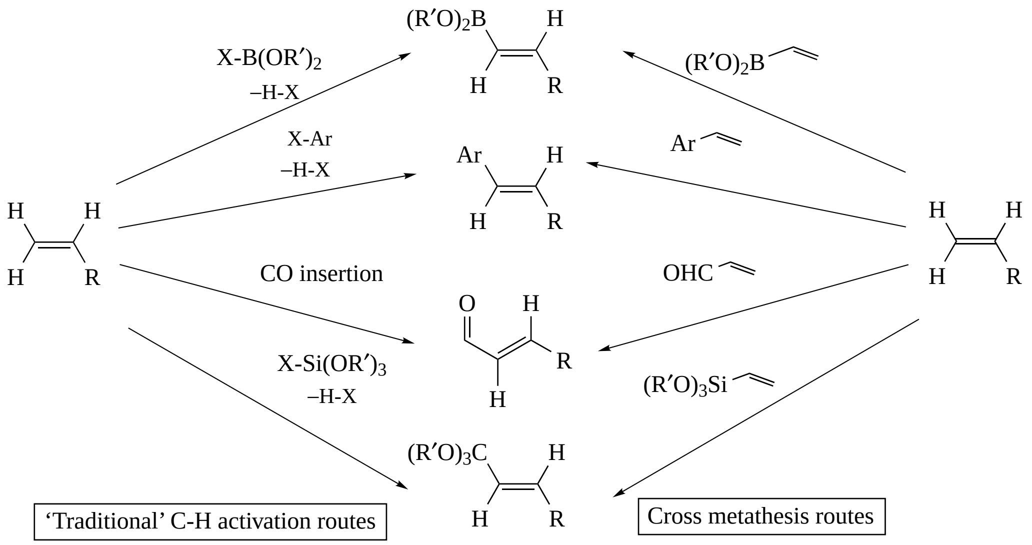
Grubbs found that (**4a**) ring-opened cyclic olefins, and then react with an acrylate to produce end functionalized linear olefins, giving a ring-opened cross metathesis product (ROCM) with two olefins with differing reactivity (equation 19).[82] Key to the distribution of products was the relative rates of ring-opening and cross metathesis with the functionalized olefin.



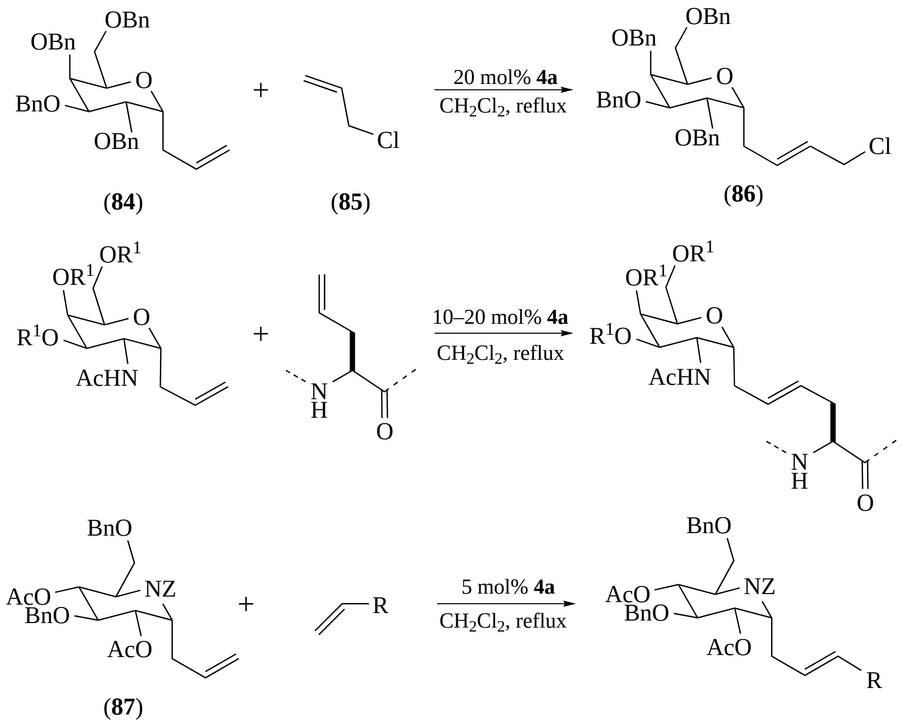
(**88**) (**89**) (**90**)

(19)

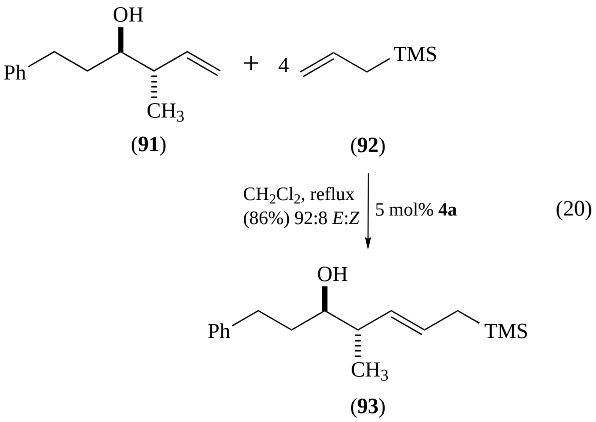
Taylor reported kinetically controlled cross metathesis of homoallylic alcohols and allyl trimethyl silane with (**4a**) gave products with high E-olefin selectivity and good yields via a five-membered chelate intermediate (equation 20).[83]



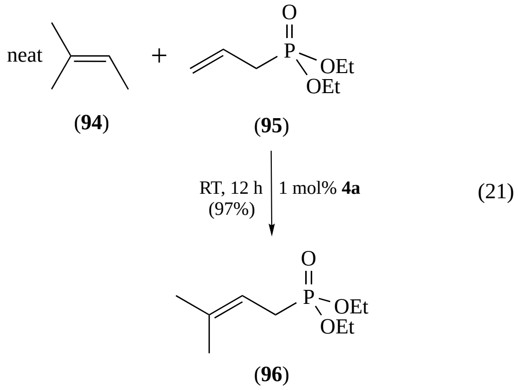
Scheme 12 Cross metathesis as a reaction equivalent to vinyl C–H activation processes of substitution and insertion



Scheme 13 Cross metathesis of protected sugars catalyzed by (**4a**)



Grubbs reported the use of (**4a**) in the synthesis of symmetrical trisubstituted olefins, wherein isomer selectivity is not an issue.[84] Isolated yields using neat isobutylene or 2-methyl-2-butene as both reactant and solvent and a variety of functionalized metathesis partners were good to excellent under low catalyst loadings, providing a viable alternative to the Wittig reaction (equation 21).



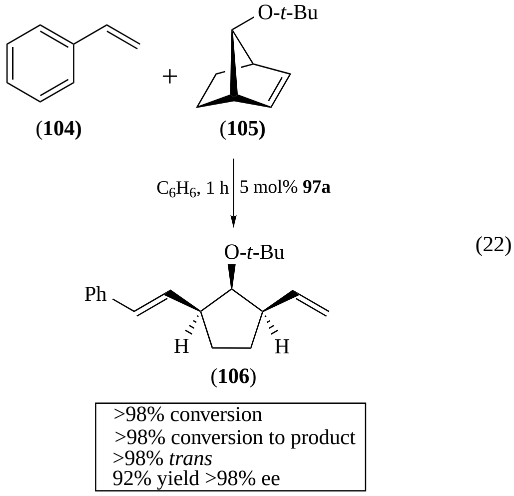
Cross metathesis of chiral allylic alcohol or amine moieties and styrene to create phenyl analogues of the parent compounds was achieved using (**4a**). The phenyl group, in conjugation with the parent molecule, lends a stronger extinction coefficient to the molecules, making the species more amenable for analysis by circular dichroism.[85]

4.4 Asymmetric Olefin Metathesis

Along with better efficacy in cross metathesis, one of the areas of olefin metathesis that was awaited eagerly is the area of asymmetric olefin metathesis. As of 2000, only a few reports for evidence of asymmetric induction, all of which were catalyzed by molybdenum complexes, had been published.[86–89]

Schrock and Hoveyda have reported the synthesis and activity of a number of chiral molybdenum-based catalysts for enantioselective olefin metathesis (for example, **97a, b**) (Scheme 14); to date, the majority of successful enantioselective (*see Enantioselectivity*) olefin metathesis has been reported from their labs utilizing this family of compounds.[90] Key to the success of these catalysts is the enantiopure diolate ligands, the substituted biphenolate or binaphtholate, that limit the trajectory of olefin approach. These catalysts have been applied to both asymmetric ring-opening and ring-closing metathesis (AROM and ARCM) respectively as well as tandem AROM-cross-metathesis reactions. Initial successful entries in this category are the biphenolate (**97a**) and the binaphtholate (**97b**). The octahydrobinaphtholate, (**97c**), was successful in kinetic resolution of racemic polyenes, achieving $k_{rel} = >25$ for a variety of substrates. Complexes (**97a**), (**97b**), and (**97c**) all promoted desymmetrization but (**97c**) gave consistently high k_{rel} in kinetic resolutions (Table 8) as well as good desymmetrization results.

A later report describes AROM/CM of norbornyl alkenes and styrene coupling partners to create asymmetrically functionalized cyclopentanes with alkenyl groups that can be further elaborated.[91] High yields (>98%) of trans (>98) cross metathesis products (predominantly the desired ring-opened, A–B metathesis product) can be achieved using (**97a**) (equation 22).



A variety of new catalysts has been developed through the Schrock/Hoveyda collaboration. Analogs of (**97a**) having silyl groups para to the hydroxy positions were created with the aim of attaching the catalyst to a support to increase ease of catalyst/product separation and to retard bimolecular decomposition of alkylidene intermediates.[92] These silyl substituted analogues, (**97d**) and (**97e**), have comparable capabilities to the parent compound (Table 9), and thus are attractive candidates for synthesis of heterogenized analogs.

Schrock reported catalysts related to (**97c**) with a variety of substituents at the 3,3′ position of the octahydrobinaphtholate ligand including benzhydryl, (**97f**), and mesityl, (**97g**) (Scheme 15).[93] This ligand type is easier to access than either biphenol or binaphthol derived species, since the axially chiral biaryl construct is already in place and substitutions are nearly

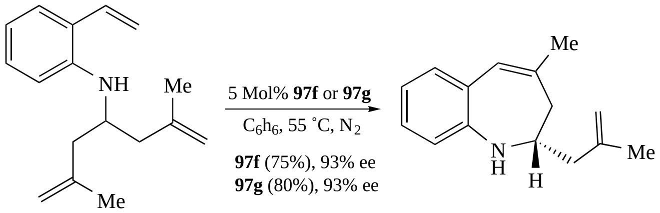
exclusive at the 3,3′ positions. These complexes and others in the family were effective for desymmetrization of allylic ethers (Table 9, entries 4 and 5) and asymmetric ring closure of tertiary *and* unprotected secondary amines.[94] Results from the secondary amine metathesis illustrated that the aryloxy bond to the Mo is robust enough to withstand potential N–H-based protonation (equation 23).



(**109**) (**110**)

(23)

Analogs of (**97a**), (**97b**), (**97f**), and (**97g**), with 2,6-dichlorophenylimido instead of 2,6-diisopropylphenylimido (**97h**), (**97i**), (**97j**), and (**97k**), respectively (Scheme 16) were also synthesized.[93] These complexes were found to have similar activity and scope to the parent complexes, giving enantioselective RCM of unprotected tertiary amines with good yields and enantioselectivities exceeding 90%.[95]

A related catalyst (**97i**), bears an alkylimido ligand instead of an arylimido (Figure 1).[96] This catalyst exists as the syn isomer and has activities not available in the arylimido species, effecting AROM/CM of norbornyl ethers and allyl boronate in 90% ee and good yield with a 13:1 trans:cis ratio (equation 24).

Promising results were obtained for the AROM/RCM of norbornyl trienes with (**97i**) (ees up to 96% and 80% yield of the desired product were reported) (equation 25).

As with many catalytic systems, additives can play an important role. During optimization of the asymmetric rearrangement of cyclopentenyl tertiary ethers to chiral cyclohexenyl tertiary ethers, Hoveyda found a strong solvent effect on the enantioselectivity of the reaction using (**97b**).[97] Lewis basic (*see Lewis Acids & Bases*) additives were used to modify the catalyst since (**97i**) is Lewis acidic and coordination could change the equilibration of the Mo-alkylidene isomers and, thus, could alter the enantioselectivity. Coordination of Lewis base to the metal center might also change the 'fit' of the chiral pocket. Addition of 10 equiv (vs. substrate) of THF substantially increased the enantiomeric excess of the product in the model transformation (Table 10). It was surmised that the effect was coordinative rather than an effect of the change in solvent polarity. The discovery of this additive effect led to the successful synthesis of enantioenriched spyrocylcic ethers in up to 96% ee without yield erosion.

Hoveyda explored the development of a robust chiral catalyst that would operate in air and was recoverable or recyclable.[98] To accomplish this, he turned to ruthenium-based catalysts and applied some of what had been learned about effective olefin metathesis catalysis to date. First, there is improved performance when the dissociating ligand is an ether tethered to the alkylidene at the 2 position, rather than a phosphine. Second, an electron-rich ligand such as H_2IMes gives improved catalyst stability. Utilizing these concepts in conjunction with a large chiral element on the imidazolinium ligand led to (**119a**) in good yield (Scheme 17). The racemic version of this new catalyst performed RCM only sluggishly under forcing conditions, but 90% of the catalyst was recovered after 98% conversion to products. Asymmetric AROM/CM of tricyclic norbornenes and styrene by (**119a**) under moderate conditions led to nearly quantitative conversions, moderate yields, high trans:cis ratios, high ees, and approximately 90% recovered catalyst. Complex (**119a**) operated in air using undistilled tetrahydrofuran to give AROM/CM of 7-oxonorbornenes and styrene to give similar results in yield, isomer ratios, and ees as seen under rigorously dry and air-free conditions. Hoveyda and coworkers then systematically explored the effect of substituents on the binaphtholate moiety and the aryl alkyl ether alkylidene

to optimize this type of catalyst for activity.[99] The most successful catalysts, (**119b**) and (**119c**), had steric crowding near the ether group to enhance activation to the 14-electron species. In addition, (**119c**) had a CF_3 group at the 6-position of the naphthol portion of the chiral element (Scheme 17, Table 11).

Grubbs examined the effect that a C_2 symmetric imidazolinium ligand would have on dichloro-, dibromo-, and diiodoruthenium alkylidene catalysts (**112a–f**) (Scheme 18).[100] The new complexes had activities and stabilities similar to the parent complex (**4a**) and were thus tested for asymmetric induction in enantioselective desymmetrization reactions. The k_{rel} using these new complexes were low, leading to very low ees; however, selectivity was strongly boosted, with NaI as an additive (k_{rel} = up to 19). The selectivity results were rationalized to be a result of side-on olefin coordination followed by halide ligand reorganization.

Schreiber applied (**4a**)-catalyzed RCM in the development of some of the facets of diversity-oriented synthesis toward the stereochemical control of macrocycle skeletal diversity. In this work, he showed that a chiral element such as an amino alcohol, even many bonds from the ring closure, can influence the stereochemical outcome of RCM of otherwise identical complex substrates like a chiral auxiliary via diastereomeric transition states. Depending on which isomer is used, a completely different reaction pathway is observed.[101]

4.5 Tandem and Sequential Reactions

Organometallic catalysts and reagents normally mediate a single transformation; however, their expense requires high turn over efficiency. Another way to increase their efficiency is to participate in sequential reactions where multiple transformations are performed sequentially in the same pot by a single catalyst or with complementary catalysts.

Grubbs reported tandem olefin metathesis/hydrogenation as a means to make saturated cyclic products and a one-pot RCM/transfer dehydrogenation/hydrogenation route to (*R*)-(−)-Muscone utilizing (**4a**) (Scheme 19).[102] Snapper and coworkers took advantage of the isomerization side reaction that occurs in unpurified OM catalysts to generate cyclic enol ethers using catalyst (**4a**) in moderate to good overall yields from acyclic dienes (equation 26).[103]

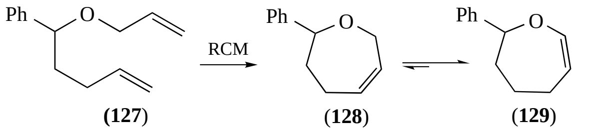
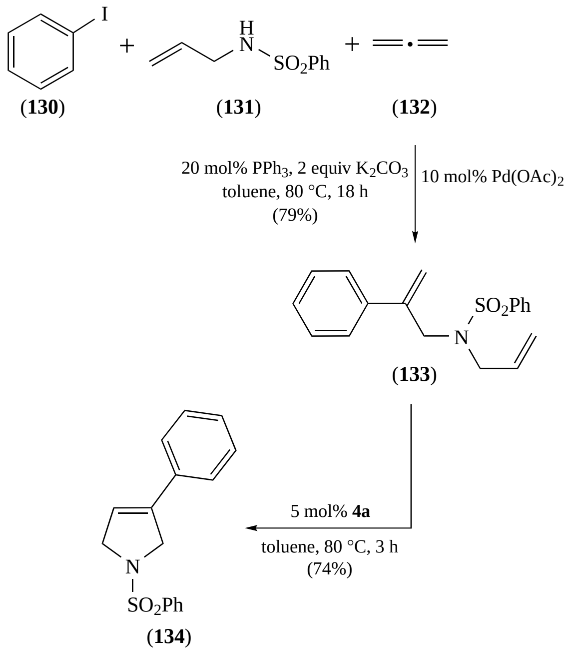
(26)

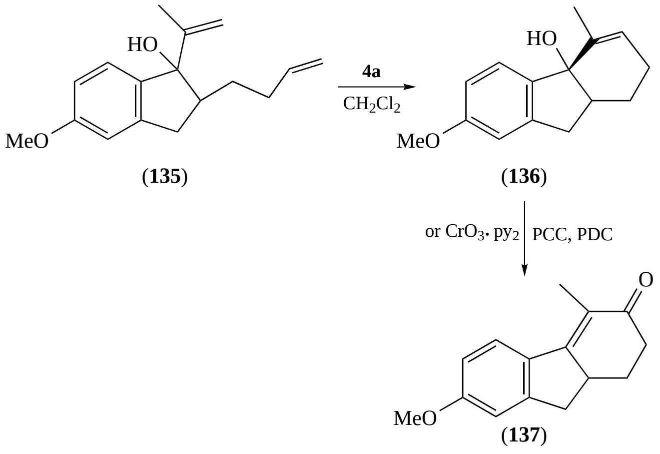


(27)

A combination of palladium catalyzed allylic acetate isomerization and ruthenium-catalyzed RCM effected 3-acetylcyclopentenes and tertiary cyclopentenols in one-pot in moderate to good yields.[104,105] Grigg explored sequential reactions utilizing palladium catalyzed allene insertion/nucleophile incorporation and (**4a**) for RCM to give in two steps a variety of five- and six-membered heterocycles in overall good yields (equation 28).[106] A similar process was reported by Ruitijes.[52] In related work, Grigg also explored allenylation/RCM/1,3-dipolar cycloaddition from aryl iodides, allene, CO, and allylic sulfonamides to construct complex heterocycles as products of sequential Pd and Ru (**4a**) catalyses.[107]

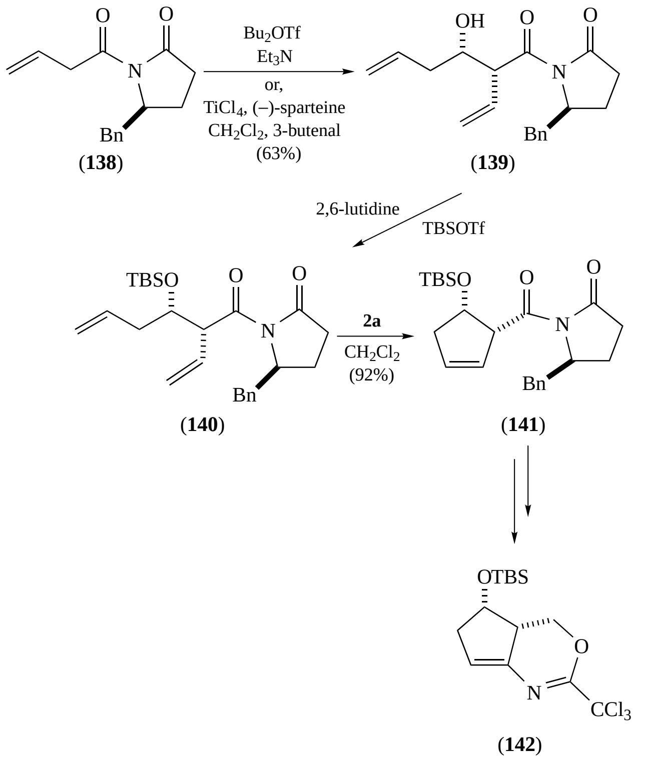


(28)

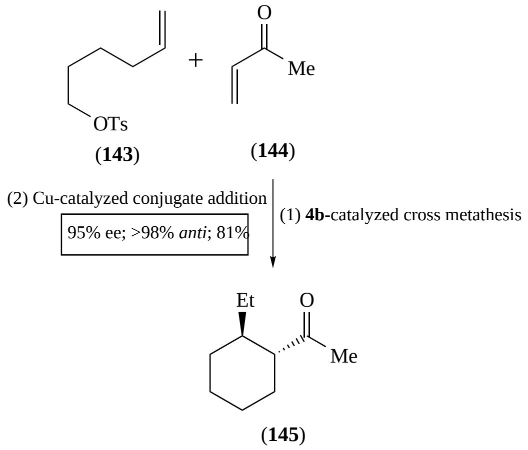


(29)

A synthetic route to α,β-disubstituted cycloalkenones via a four step one-pot synthesis employed (**4a**) for RCM and then oxidative rearrangement giving products in low to moderate overall yields as a way to access estrogen receptor ligand tetrahydrofluorenones (equation 29).[108] Crimmins reported an asymmetric aldol-olefin metathesis approach to the synthesis of functionalized cyclopentenes exploiting the acyclic stereocontrol of the aldol reaction with efficient (**2a**) catalyzed RCM (equation 30).[109]



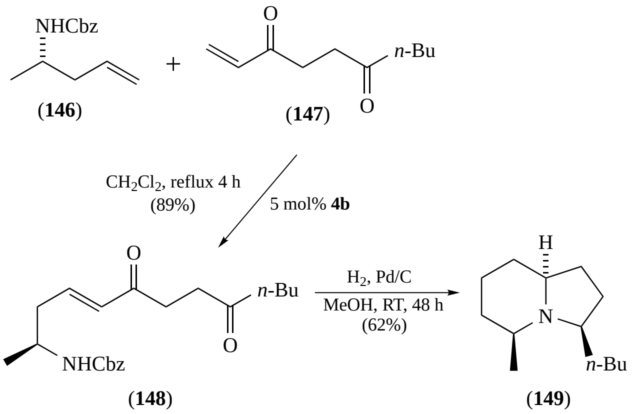
(30)



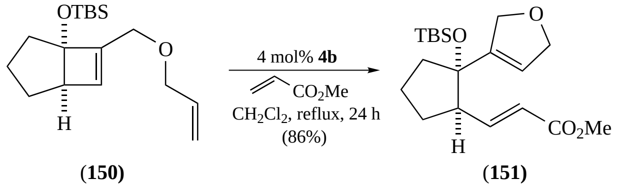
(31)

Hoveyda and coworkers recently developed sequential catalytic cross metathesis/asymmetric conjugate addition utilizing (**4b**) to make acyclic aliphatic enones (equation 31).[110] Blechert developed a synthetic route toward bicyclic N-heterocycles that hinged on cross metathesis and double reductive amination to access compounds like

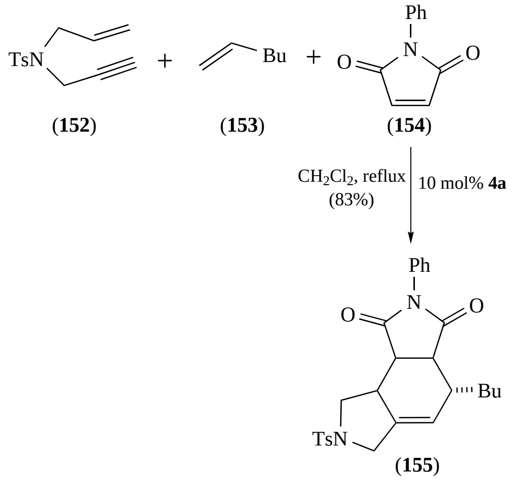
R below using (**4b**) (equation 32).[111] Snapper utilized (**4a**) and (**4b**) for ring-opening cross metathesis/oxy-Cope rearrangement, giving medium ring-containing bicycles as well as stereochemical insight for these transformations (equation 33).[112] Lee and coworkers utilized (**4a**) to achieve one-pot, stereoselective three-component tandem Enyne/cross metathesis/Diels–Alder reactions in good to excellent yields (equation 34).[113]



(32)



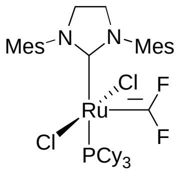
(33)



(34)

4.6 Other Methodological Developments

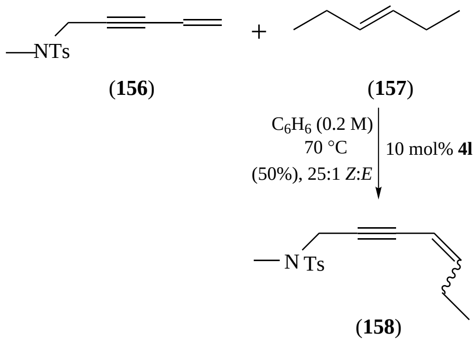
Some of the progress in catalyst development has been made by simple application modifications like the suspension of (**4a**) in paraffin, allowing for ease of benchtop use.[114] The solid had acceptable activity even after benchtop storage without precaution for nearly two years and the paraffin was readily removed via flash chromatography.



(**4m**)

Figure 2 Electron-poor alkylidene complex (**4m**)

RCM using (**4a**) was reported to be strongly accelerated by microwave radiation, giving quantitative conversions of substrates like diethyl diallylmalonate in 15 min while thermal conversions for the same time was only 3%.[115] Chang and coworkers expanded the scope of substrates for cross and RCM conjugated eneynes utilizing the bis-bromopyridine substituted catalyst (**41**) (equation 35). The reaction requires elevated temperatures and long reaction times but gives products in up to 70% yield with as much as a 25:1 Z:E isomer ratio.[116]

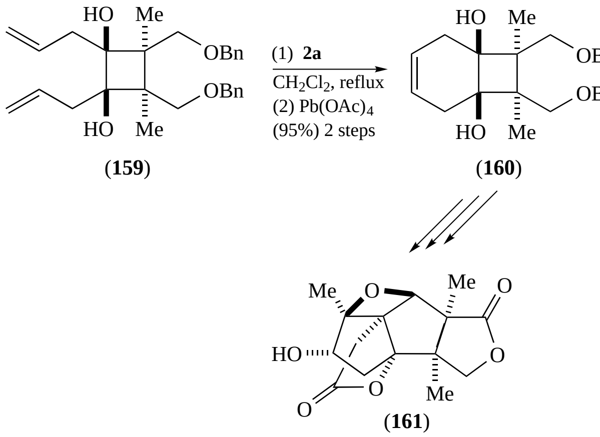


(35)

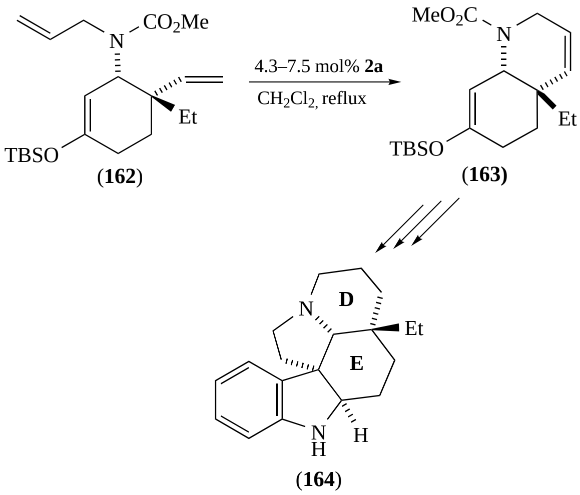
Grubbs and coworkers used (**4a**) to perform olefin metathesis with 1,1-difluoroethelyene; a metathesis partner that had theretofore been unavailable for reaction consideration.[117] While metathesis did occur, the difluoro carbene Ruthenium complex (**4m**) (Figure 2) was not an effective catalyst itself; thus, little if any turnover was observed, although this did provide a potential convenient pathway for constructing dihalocarbene-metal complexes.

5 APPLICATION OF OLEFIN METATHESIS TOWARD TOTAL SYNTHESIS PROBLEMS

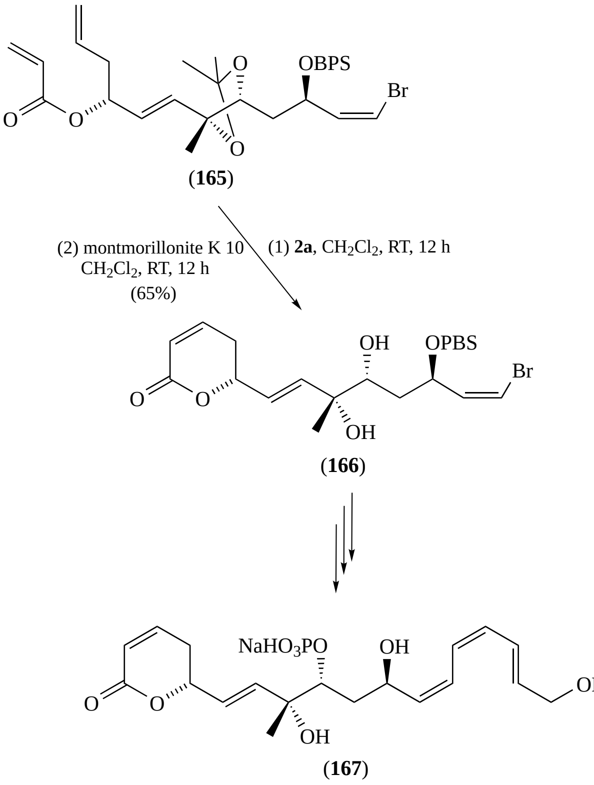
Much of the bias of the foregoing section was on methodology that could be geared to the synthesis of classes of natural products and biologically relevant molecules (vide supra). What follows are some specific recent highlights in syntheses of small, medium, and large ring compounds formed by RCM, and larger molecules constructed or elaborated by cross metathesis. The diverse synthetic strategies are unified by the integral role olefin metathesis played in the successful completion of the target compounds.



(36)



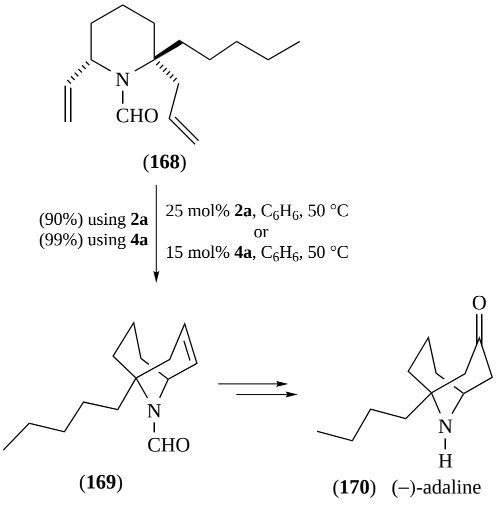
(37)



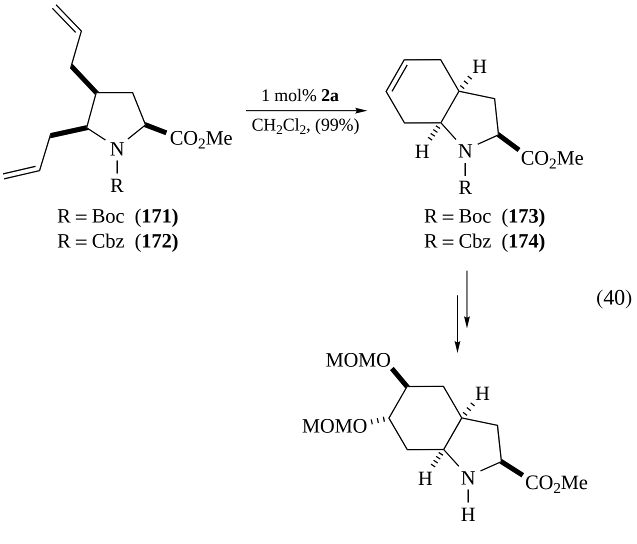
(38)

5.1 Synthesis of Natural Products Containing Small Rings

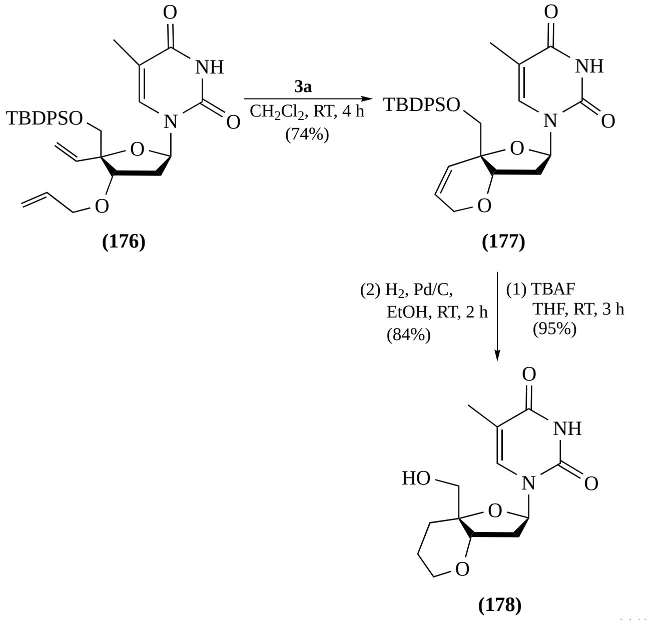
Functionalized five- and six-membered rings are ubiquitous in natural products. Often RCM is a critical step for the successful synthesis of these carbocycles and heterocycles. Inoue and Hirama utilized (**2a**) for RCM of the *meso* diene precursor which could then be modified through a desymmetrization protocol to the desired merrilactone A (equation 36).[118] Rawal's syntheses of the pentacyclic aspidosperma alkaloids utilized olefin metathesis in the construct of the DE ring using (**1a**) to obtain the desired product in 88% isolated yield for this system. There was a significant difference between the performance of (**1a**) and (**2a**), the molybdenum catalyst providing complete conversion in 1 h at 60 °C as compared to only partial conversion in 10 h at the same temperature for (**2a**). However, the catalyst of choice for gram scale reactions was (**2a**) (equation 37).[119] Falck used (**2a**) catalyzed for the ring closure of the chiral six-membered lactone in the total synthesis of (+)-Fostriecin with good yield under mild conditions (equation 38).[120] Kibayashi and coworkers reported the asymmetric total synthesis of (−)-Adaline where and acyl protected amine diene underwent quantitative ring closure to form the Δ^3homotropane using 25 mol% (**2a**) or 15 mol% (**4a**) (equation 39).[121] One mol% (**2a**) accomplished ring closure in the bicyclic core of the marine natural product Dysinosin A in nearly quantitative yield by Hanessian and coworkers (equation 40).[122]



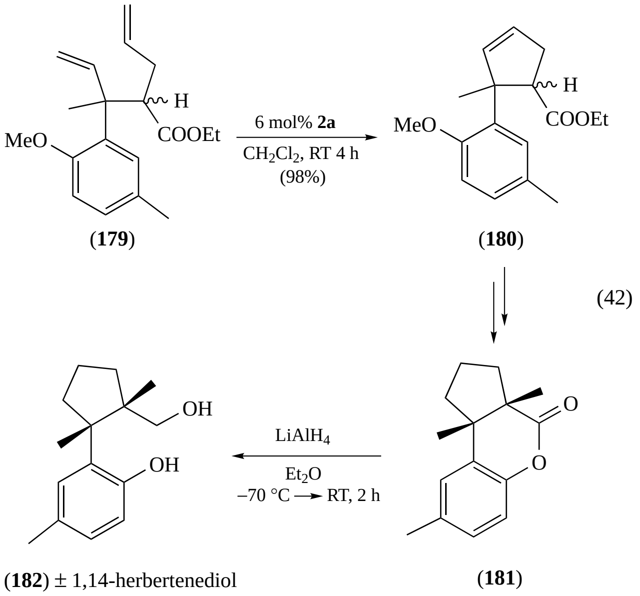
(39)

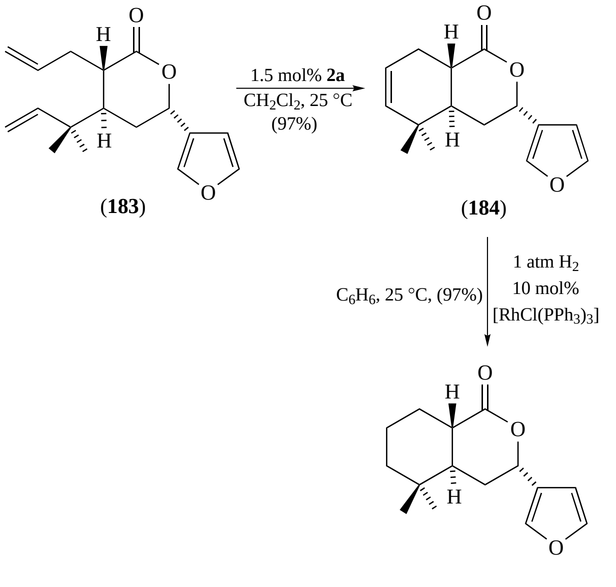


(**175**) octahydroindole core of dysinosin A



(41)

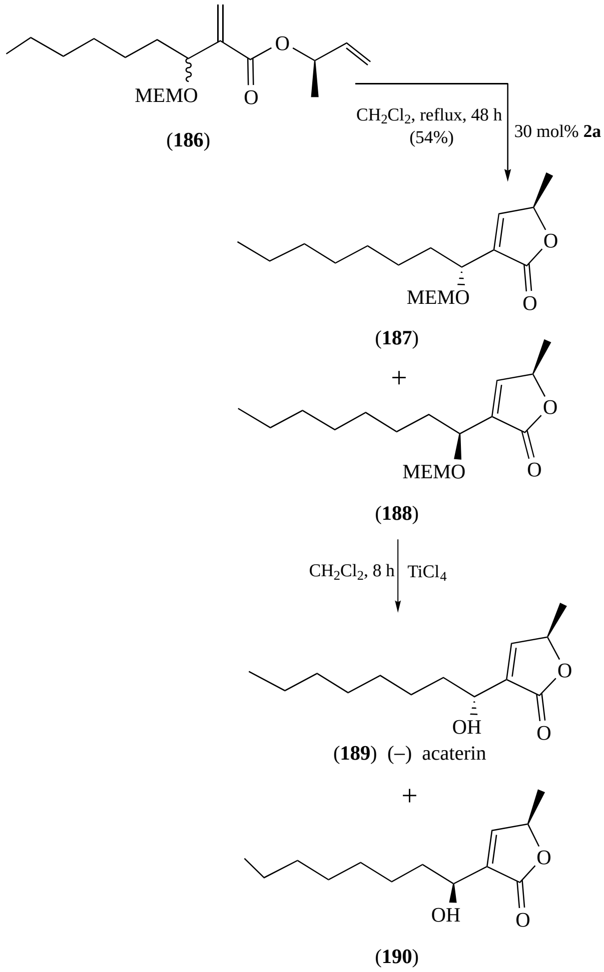




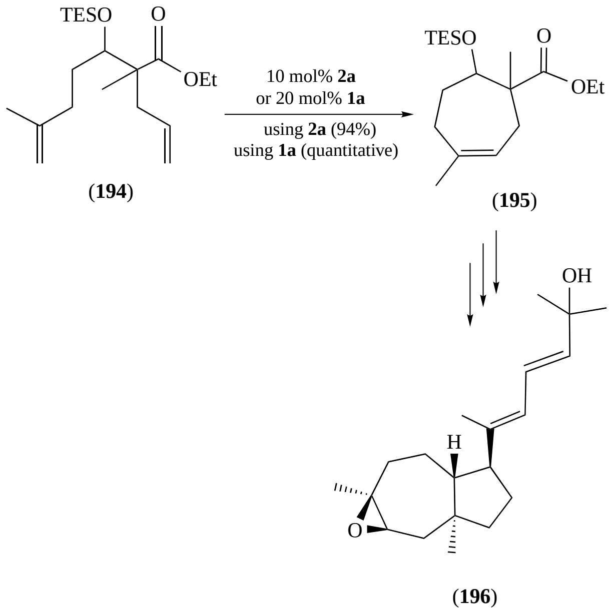
(**185**)

(43)

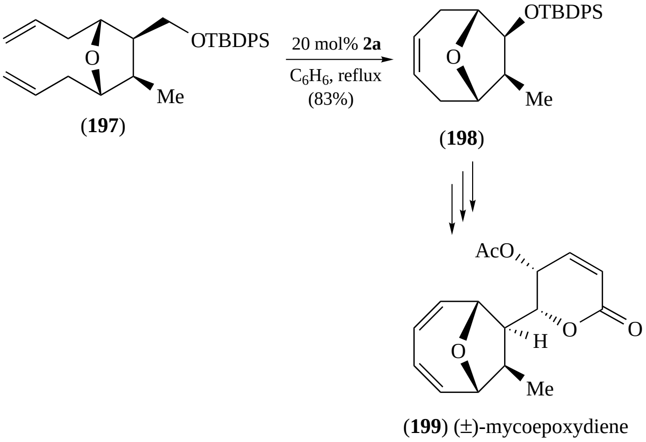
RCM with (**3a**) and reduction are the final steps in Lebreton's syntheses of bicyclic thymidine nucleoside analogues as part of a program of development of less toxic anti-AIDS drugs (equation 41).[123] Srikrishna used a RCM inspired strategy and (**2a**) for the construction of the five-membered carbocycle in (±)-1,14-herbertenediol (equation 42), and (±)-11-*epi*-herbertenolide.[124] Metz used RCM catalyzed by (**2a**) or less effectively (**4a**) in the formation of both six-membered rings as part of the enantioselective syntheses of Ricciocarpins A and B (equation 43).[125] RCM with (**2a**) to form a five-membered chiral lactone was the key step in Singh's synthesis of (−)-acaterin from a Baylis-Hillman adduct in good overall yield (equation 44).[126]



(44)



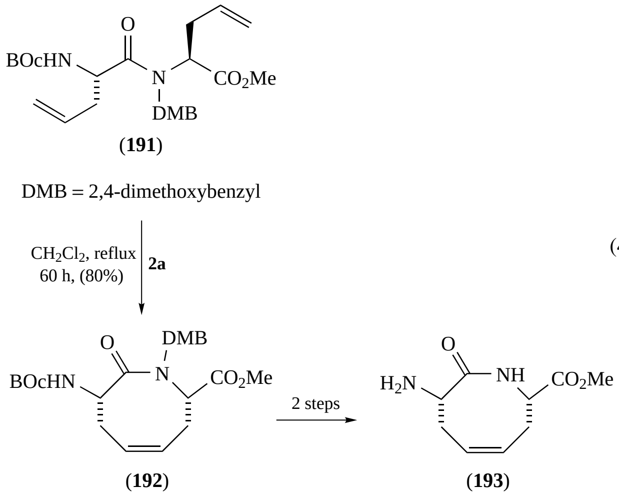
(46)



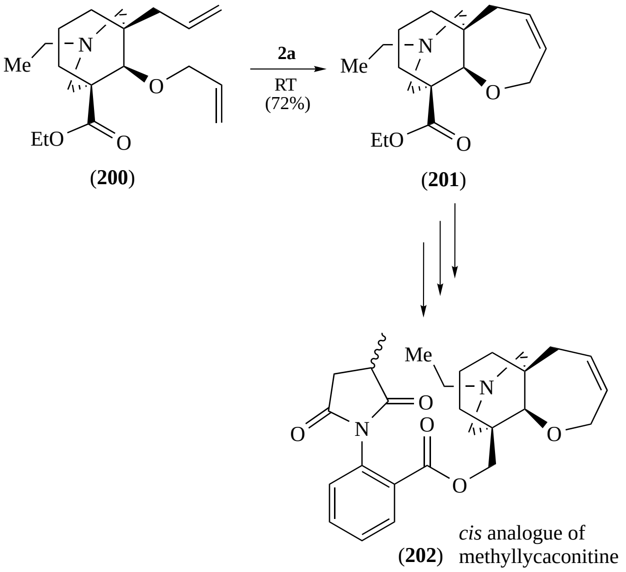
(47)

5.2 Synthesis of Natural Products Containing Medium Rings

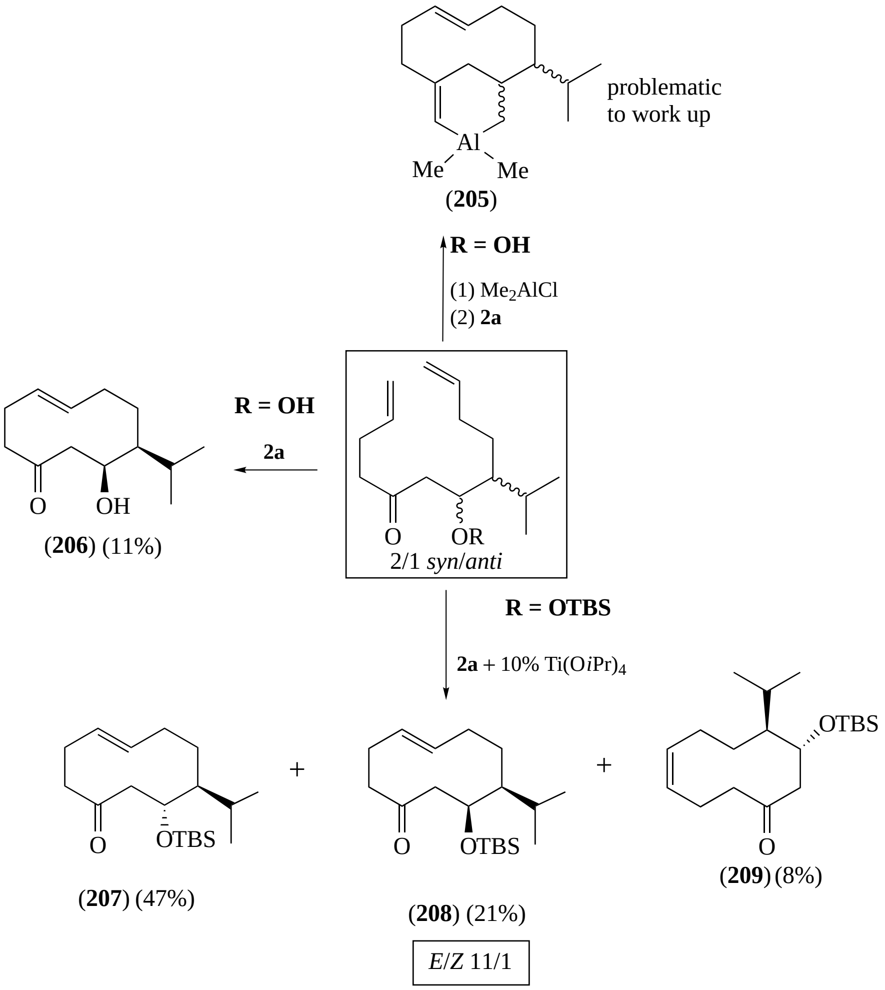
The formation of medium size rings (8–10-membered) presents challenges based on strain and entropy (Scheme 20).[39,127] Reitz utilized RCM by (**2a**) of diallyl glycine to give the eight-membered cyclic olefin in equation (45).[128] Two steps convert it to a scaffold for peptidomimetic synthesis.



(45)

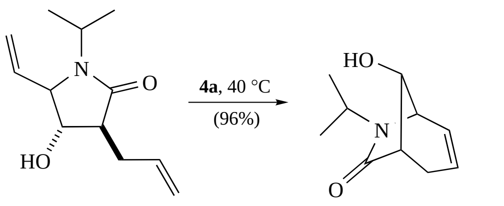


(48)

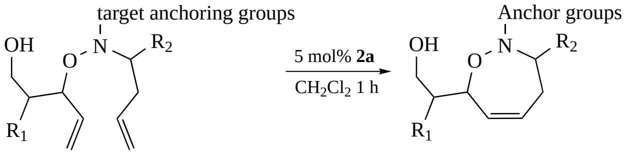


Scheme 20 Various ring closure routes to form 10-membered rings en route to sesquiterpene natural products

Similar in difficulty to formation of the 8–10-membered rings is the synthesis of trisubstituted seven-membered rings.[129] Tori prepared these seven-membered carbocycles in good to high yield utilizing (**2a**) (equation 46).[130] Elaboration of these intermediates led to the successful total synthesis of liverwort diterpenes. Ring-closing olefin metathesis is often used late in a synthetic strategy to obtain functionalized cyclic compounds. Tadano, on the other hand, used (**2a**) catalyzed RCM relatively early in the synthetic scheme with many steps of further elaboration to arrive at (±)-mycoepoxydiene.[131] Brimble utilized (**2a**) to achieve late stage RCM to form the seven-membered B ring in high yield as a part of the stereodivergent synthesis of ABE ring analogs of methyllycaconitine, a potent antagonist of the α7 nAChR in mammalian neuronal membranes (equation 48).[132] Martin disclosed an efficient formal synthesis of (−)-Peduncularine where the key step is near quantitative ring closure using (**4a**) catalyst (equation 49). Closure with (**2a**) required protection of the alcohol and led to the product with much lower yield.[133] Koskinen reported the first 10-membered carbocycle formed by olefin metathesis in moderate yield and high E/Z selectivity using (**2a**) combined with Ti(O*i*-Pr)$_4$. This reaction protocol led to the successful synthesis of a pine foliage sesquiterpene.[134]



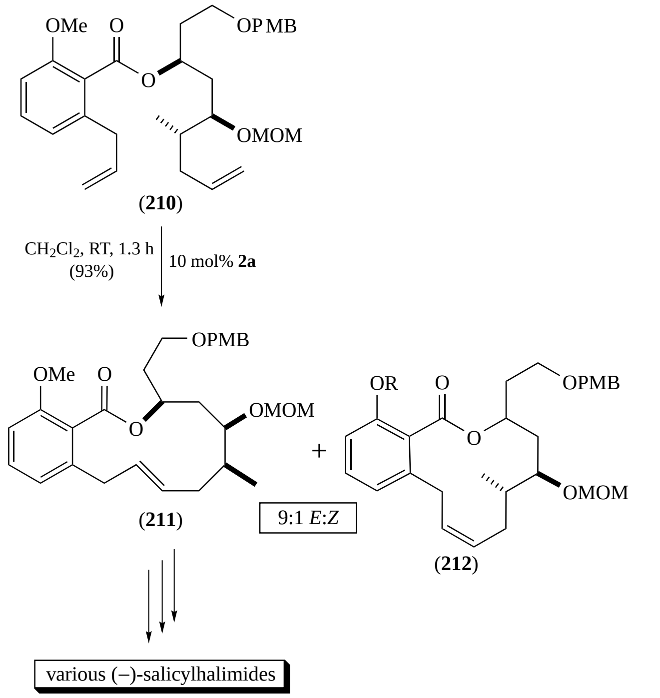
(203) (204) (−)-peduncularine (49)



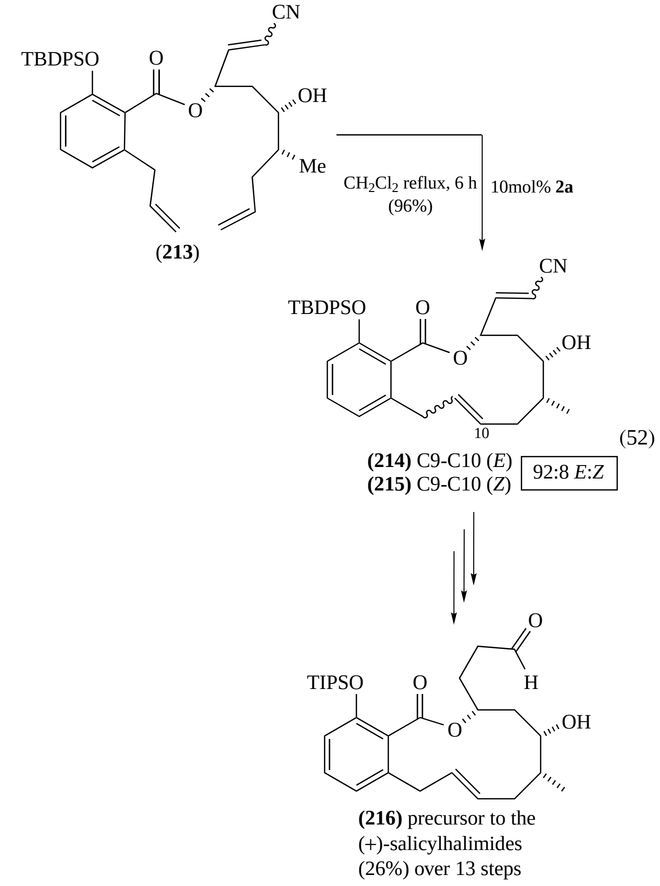
(50)

Verdine utilized RCM as a key step in the synthesis of a library of bifunctional small molecules to screen for heterodimerizer (potential synthetic antitumor agents)

(equation 50).[135] Again, the key step to the success of the scheme is ring-closing olefin metathesis to make the tetrahydro-oxazepine skeleton in all possible isomers, which was accomplished utilizing (**2a**).



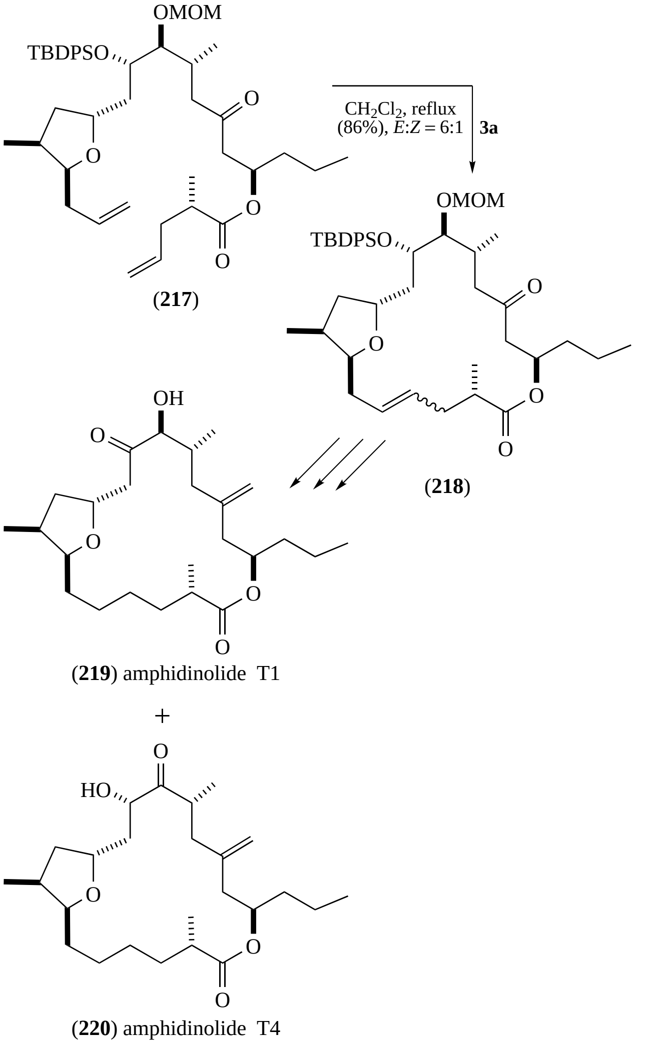
(51)



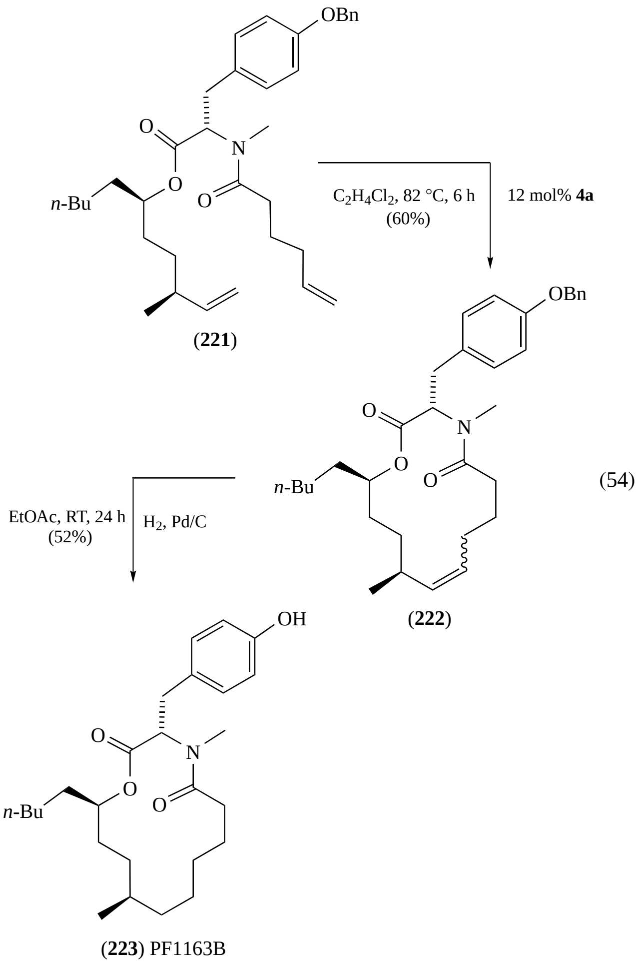
(52)

5.3 Macrocyclic Natural Product Synthesis

The synthesis of functionalized macrocycles becomes increasingly important with the discovery of more and more key, biologically active natural products, and the desire to increase the efficacy of these agents while reducing their human toxicity through medicinal chemistry discovery. De Brabander reported the total synthesis of Salicylhalamide A and related compounds. The 12-membered benzolactone ring contains an E-alkene that was selectively formed during RCM using (**2a**) (equation 51). Catalyst (**4a**) was efficient at ring closure but for these substrates had a much lower E:Z selectivity.[136] Georg and coworkers targeted the salicylihalamides as well, utilizing a chiral pool approach with ring closure by olefin metathesis. While the route differed, the E-selectivity for the ring bound olefin remained a challenge. This group also found that (**2a**) had superior selectivity leading to chromatographically separable products in a 2:1 ratio (equation 52).[137]

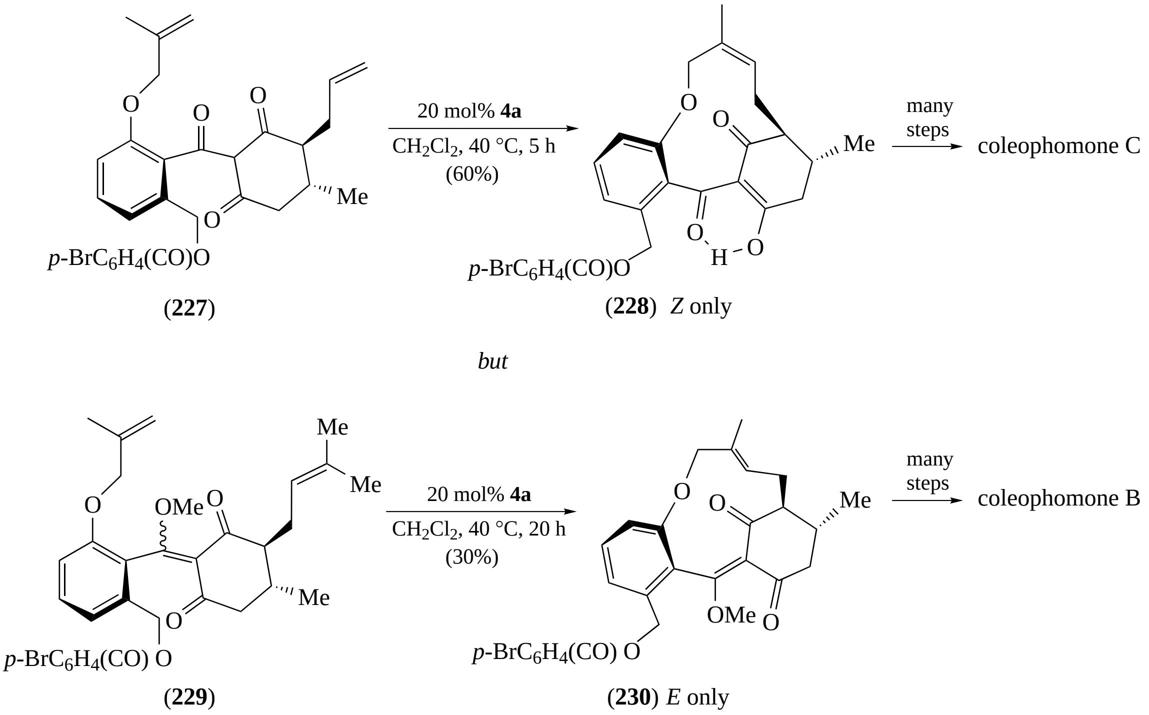


(53)

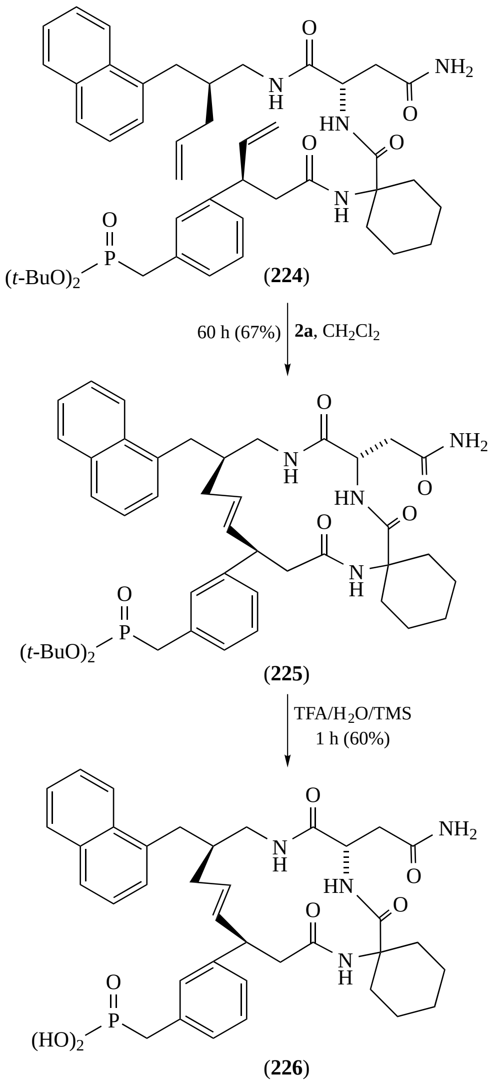


Fürstner utilized (**3a**)-catalyzed RCM to close the 19-membered ring of various amphidinolides (equation 53). The E:Z ratio was approximately 6:1 although selectivity was not crucial since the alkene moiety was reduced by palladium catalyzed hydrogenation. Complex (**4a**) was used for ring closure to access another diastereomer.[138] The key step in Gesson's total synthesis of antifungal agent (−)-PF1163B was (**4a**) catalyzed ring closure to the 13-membered ring, which was achieved in good yield (equation 54).[139]

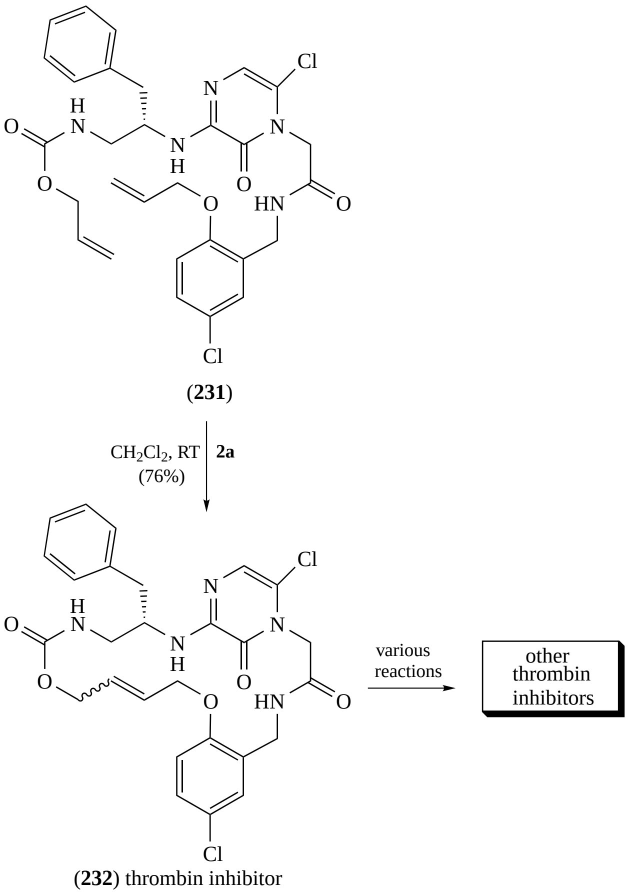
Burke utilized (**2a**) to catalyze RCM in his design of a globally constrained Grb2 SH2 inhibitor (equation 55). Here the parent compound is an open-chain molecule and olefin metathesis provides an avenue for rigidifying that functionalized skeleton.[140] Kingston synthesized paclitaxel analogues designed to favor the T-paclitaxel conformation using (**2a**) catalyzed olefin metathesis as the ring-closing step.[141] The total synthesis of Woodrosin I, a glycoside macrocycle, relied on the efficacy of RCM. In this case, Fürstner successfully utilized both (**2a**) and (**2c**) to give nearly quantitative closure of the diolefinic precursor.[142] Nicolaou was able to apply RCM to as part of his synthesis of coleophomones B and C, which differ only at the alkene moiety, B being E and C being Z. The success of this synthetic pathway was a combination of the efficacy of (**4a**) with the discovery of a single step that gave the isomeric RCM precursors in high yield and easily separable from one another (Scheme 21).[143]



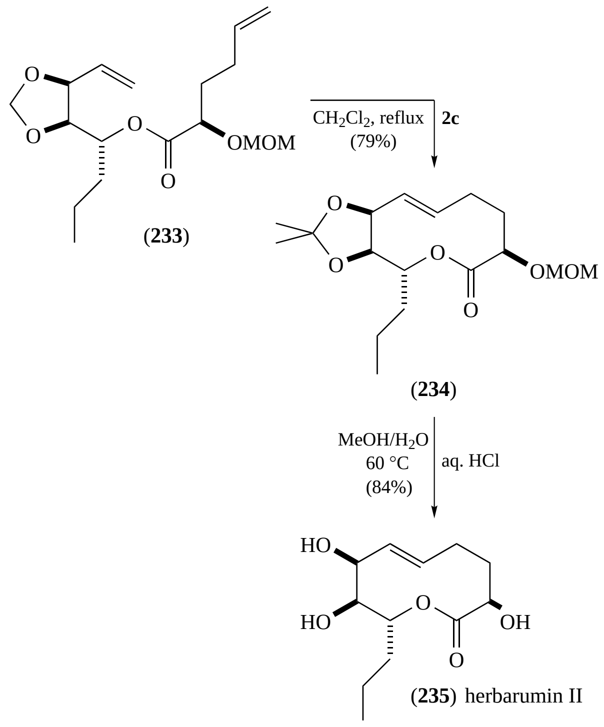
Scheme 21 Small differences in dienes lead to exclusively Z or E ring-closed products in synthetic strategy for coleophomones B and C



(55)

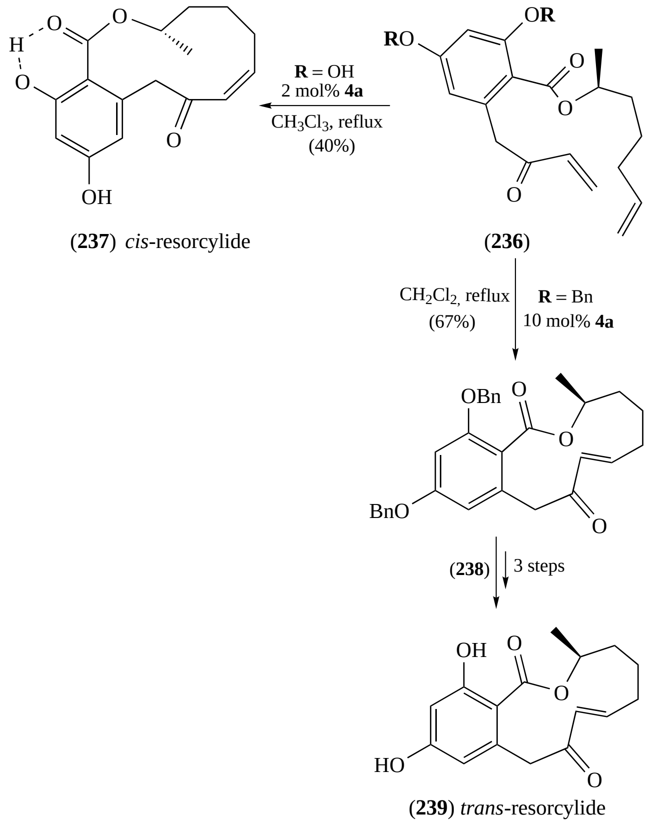


(56)



(57)

Nantermet constructed 20-membered thrombin inhibitors from highly functionalized diolefin scaffolds using (**2a**)-catalyzed RCM. The stereochemistry of the ring closure was 3.5:1 E:Z, although the alkene was ultimately reduced (equation 56).[144] Fürstner utilized RCM to complete the synthesis of the phytotoxic lactones herbarumin I and II (equation 57). These 10-membered macrocycles contain an E-alkene, which was obtained in high yield and stereoselectivity 7:1 E:Z using (**2c**) under kinetic control while (**3a**) provided only the Z-isomer.[145] Stereospecific total synthesis of trans- and cis-resorcylide from a common precursor was achieved by allowing or blocking hydrogen bonding to access the two isomers and ring closing with (**4a**) to give the 12-membered ring (equation 58).[146]

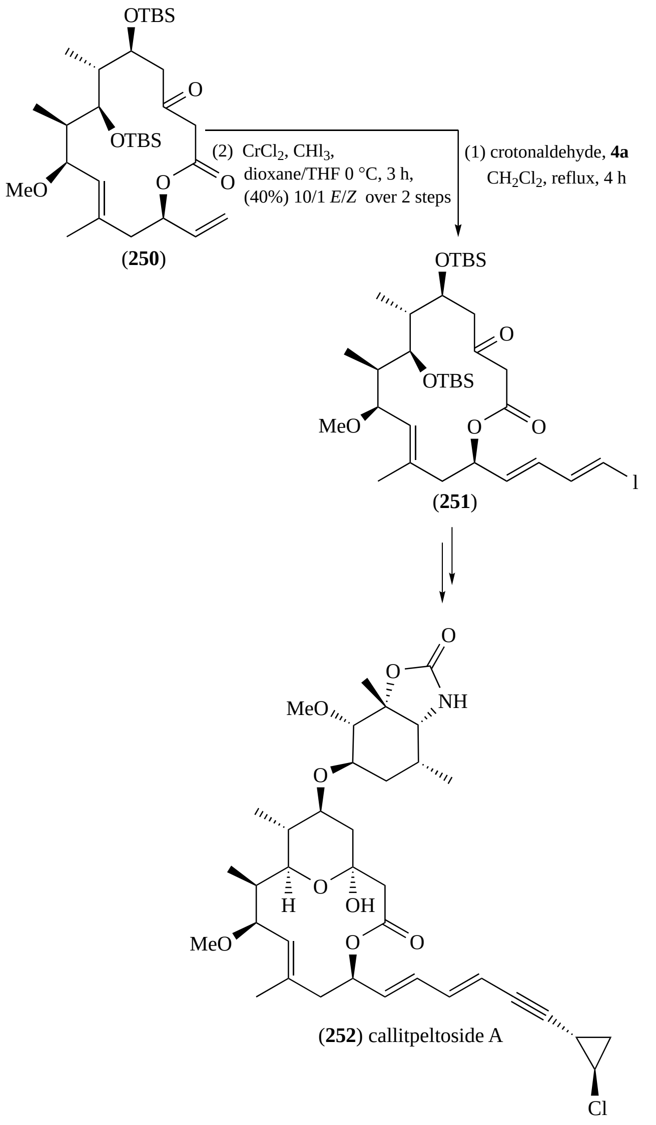


(58)

Epothilone macrolides are an emerging class of potent antitumor agents that might have high potential in cancer chemotherapy via microtubule stabilization. Olefin metathesis has played an important role in the Danishefsky laboratories in the syntheses of epothilones, illustrated in Scheme 22. Key to the Danishefsky strategy was to utilize (**4a**) catalyzed RCM for ring closing only on terminal monosubstituted olefin and then to reduce the disubstituted olefin to the alkane. This route is highly efficient for ring closure and reduces the optimization and separation necessary for the relative stereochemistry of the 12,13-trisubstituted olefin that was completed in a separate step prior to ring closure.[147] Numerous epothilone analogs became easily in reach using this convergent RCM strategy (Scheme 22a, b), allowing biological structure-reactivity studies to be completed on a series of related epothilones, lending insight to the import of ring size to the antitumor efficacy of this class of compounds.[148] This strategy allowed the Danishefsky group to explore the effect of trifluoromethyl analogues of epothilones leading to an effective antitumor agent that is more stable than the parent compound (Scheme 22c).[149] This work ultimately led to a group of epothilone analogues whose accessibility is clearly due to the efficient convergent synthetic route (Scheme 22d).[150] This family of compounds in early studies proves to be better potential drug candidates than the naturally derived parent compounds provided by the designed in features that give more stable and bioavailable agents.

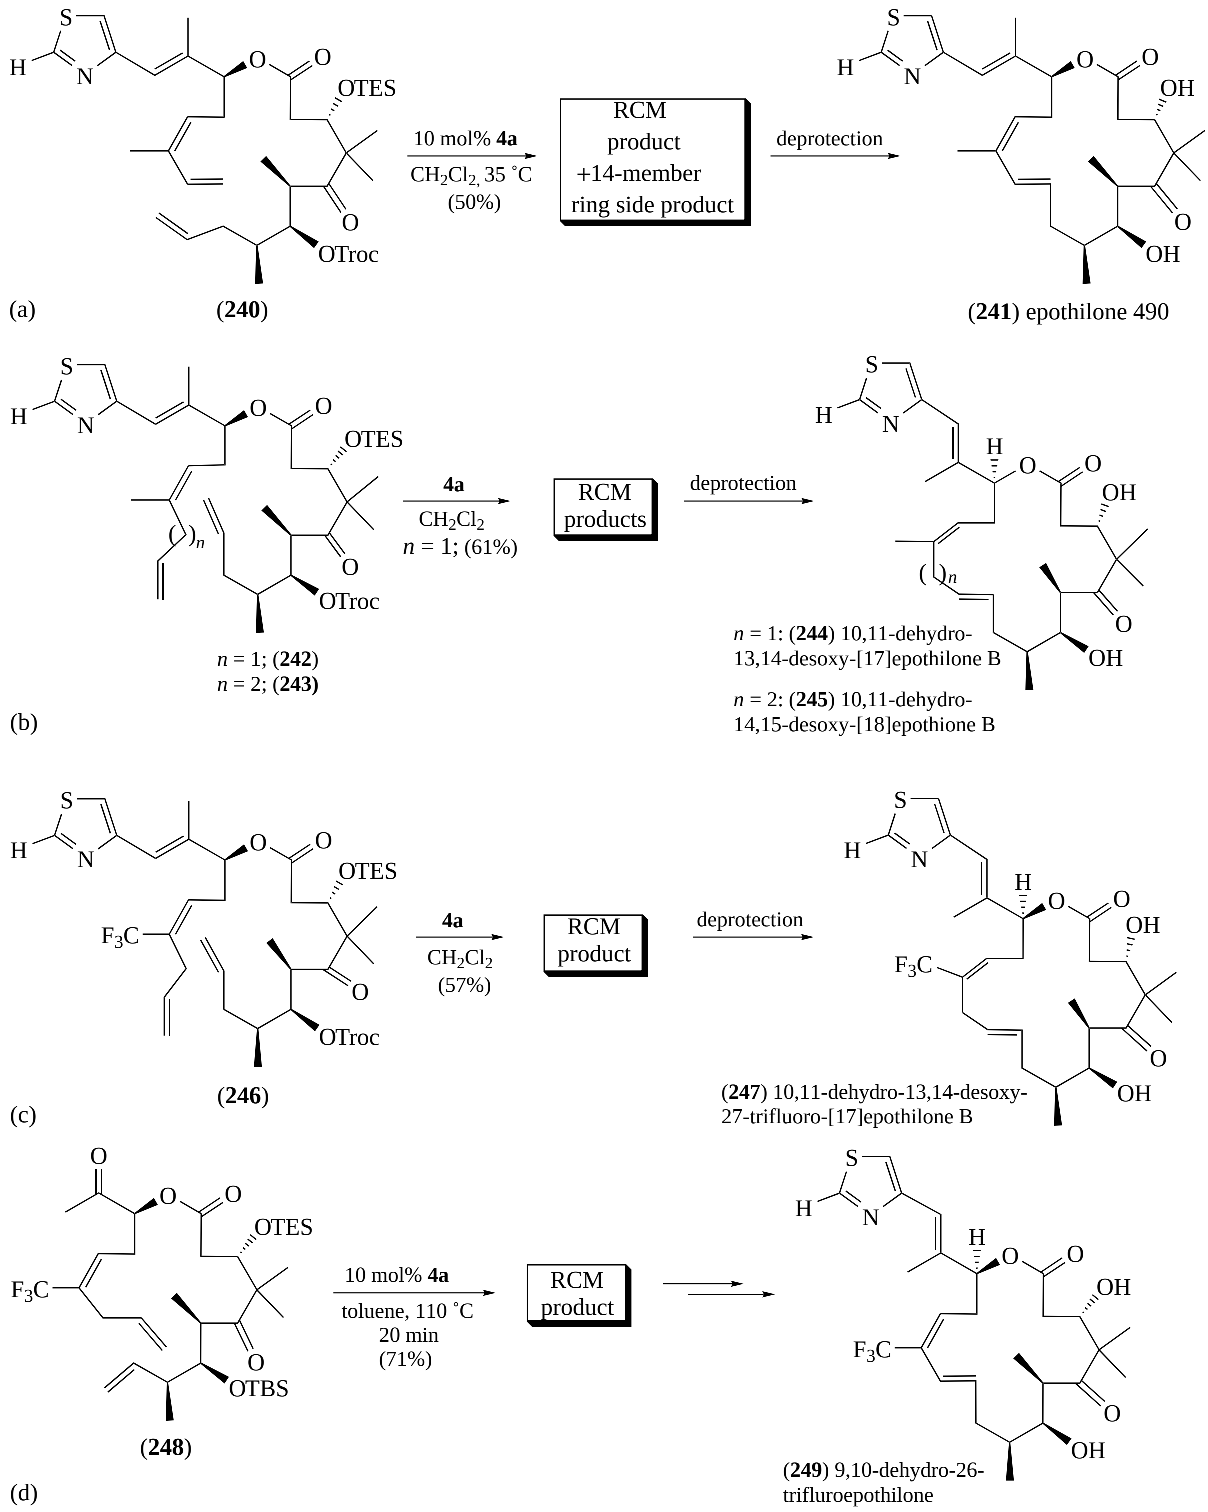
5.4 Cross Metathesis in Synthesis

With the advent of efficient cross metathesis catalysis, this reaction is being seen in a variety of total syntheses and analogue synthesis strategies. Two areas where cross metathesis has been particularly useful are the addition of side chains or heterodimerization and the formation of homodimers.



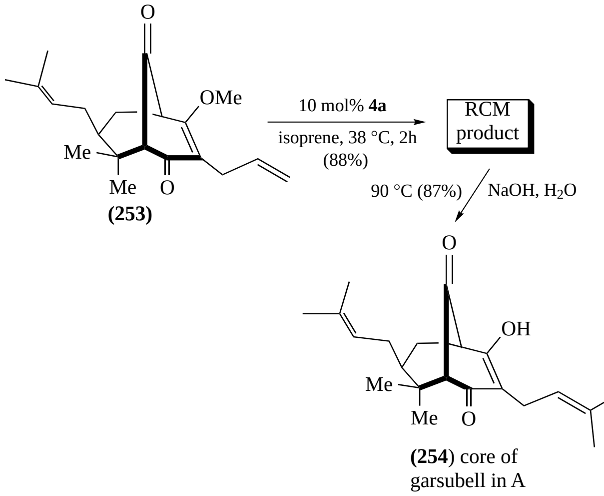
(59)

Trost used (**4a**) catalyzed cross metathesis as a part in the construction of callipeltoside side chains with both high yield and high E:Z ratio (equation 59).[151] Diver also used (**4a**) catalyzed cross metathesis to modify the MeBmt side chain of cyclosporin A to give resin bound protein affinity agents.[152] Stoltz used (**4a**) catalyzed prenylation to elaborate one of the side chains in his work toward the synthesis of Garsubellin A and related phloroglucins (equation 60).[153] Miller reported high-yielding hetero cross metathesis of a Proline–Glycine

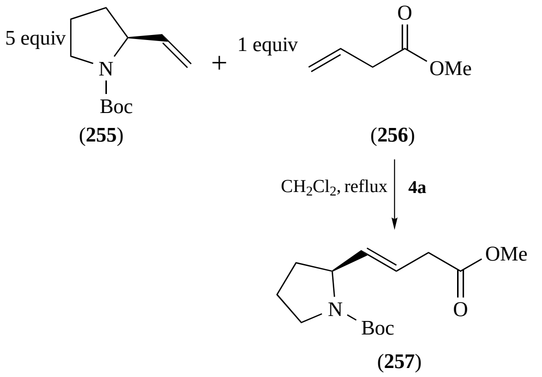


Scheme 22 Use olefin metathesis to access different epothilones

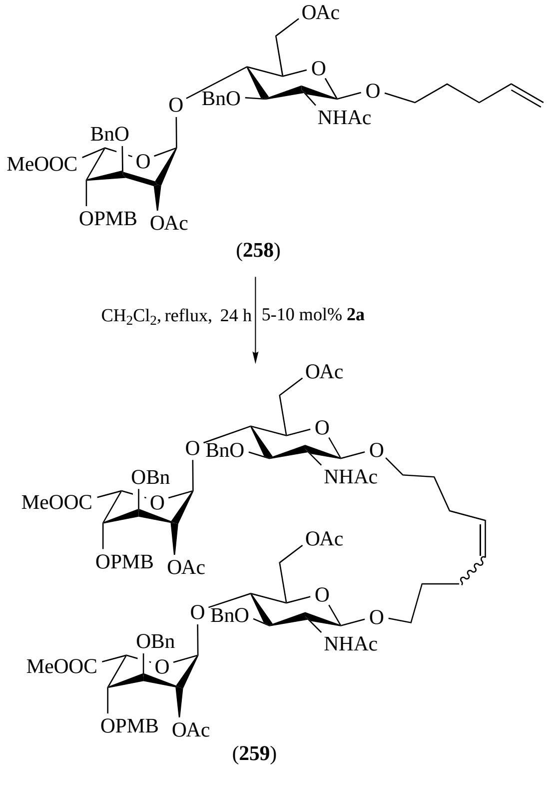
isostere to give 83% yield of the desired product in high E:Z ratio under optimized conditions with (**4a**) (equation 61).[154]



(60)

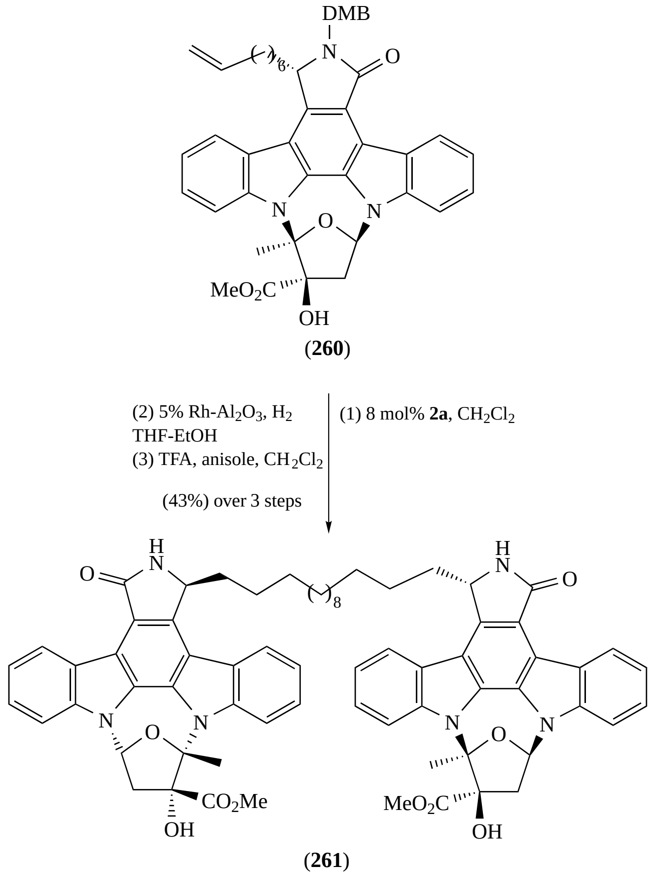


(61)



(62)

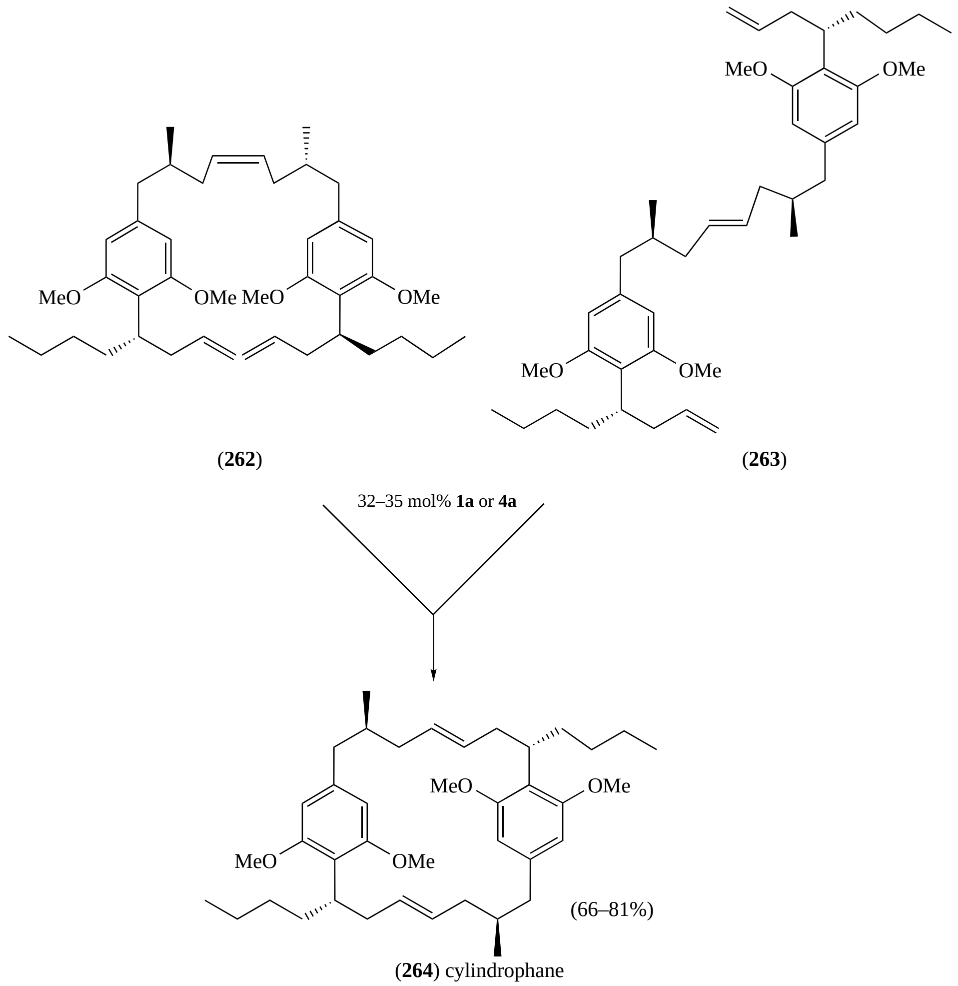
Chaikof and coworkers used (**2a**) to effect the homo cross metathesis on derivatives of heparan sulfate and hyaluronan to explore how neutral tether dimers compare to the parent compounds as agonists of antagonists of GAG dependent events (equation 62).[155] Wood also prepared dimers of K252a in 87% yield via cross metathesis with (**2a**) and subsequent Rh hydrogenation to explore the chemical biological effect of dimerization with a 14-carbon linker at the C7 position.[156] Smith utilized (**1a**), (**2a**), and (**4a**) catalyzed cross metathesis to access (−)-cylindrophanes A and F via dimerization of a precursor diolefin (equation 64). It was surmised that the reversible nature of olefin metathesis results in the desired head to tail homodimers, the thermodynamically preferred product, with (**1a**) giving the most efficient results. An extension of this strategy was to start with a head to tail acyclic dimer and subject that to ring closure. This also led to the only desired product in 15 to 20% higher yield than when using the monomers.[157]



(63)

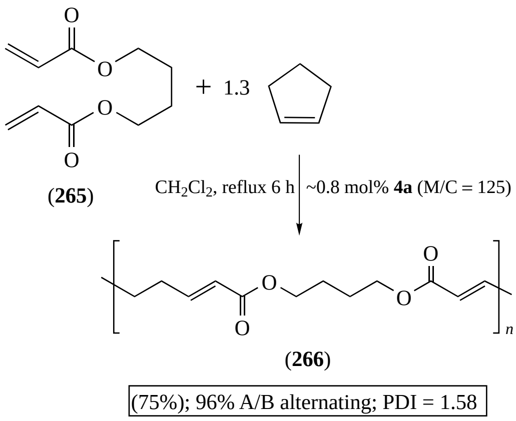
6 OLEFIN METATHESIS FOR THE FORMATION OF POLYMERS AND MATERIALS

Coughlin and Emrick utilized a benzyl phosphine oxide substituted styrene in olefin metathesis by (**2a**) to make



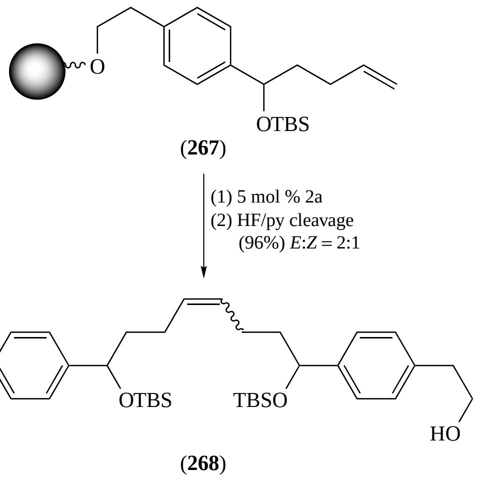
(64)

polyolefin–cadmium selenide composites where the radiating olefin chains help keep the CdSe particles (*see* ***Semiconductor Nanocrystal Quantum Dots***) dispersed.[158]



(65)

Ruthenium complex (**4a**) provided a new general route to alternating copolymerization utilizing cyclooctene and diacrylates via olefin metathesis (equation 65).[159] Nuclear magnetic resonance (NMR) studies demonstrated that under the reaction conditions cyclic monomers like cyclooctene undergo ROMP at a high rate while acyclic diacrylate monomers insert into the chain slowly. The overall process, coined as ROIMP (ring-opening insertion metathesis polymerization), results in polymers with A,B alternation ranging from 94 to 99% in yields ranging from 75 to 99% and having moderate PDI (1.43–2.06), with a careful balance of catalyst loading and reaction concentration key to successful, highly alternating polymerizations.

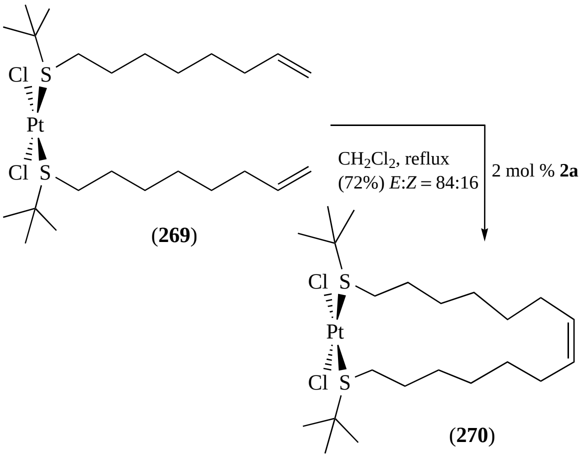


(66)

Schreiber utilized intra-site olefin metathesis as a key step in synthesizing C_2-symmetric functionalized dimeric molecules for the close association of proteins.[160] Both (**2a**) and (**4a**) were effective at 5 mol% giving very high conversions to the dimerized product (equation 66). The E:Z ratios of the linked bead dimerized molecules were similar to what was found in analogous solution reactions.

Olefin metathesis under mild conditions was instrumental in the preparation of pthalocyanine polymers of high molecular weight without use of a radical initiator by Kimura and Shirai using (**2a**).[161]

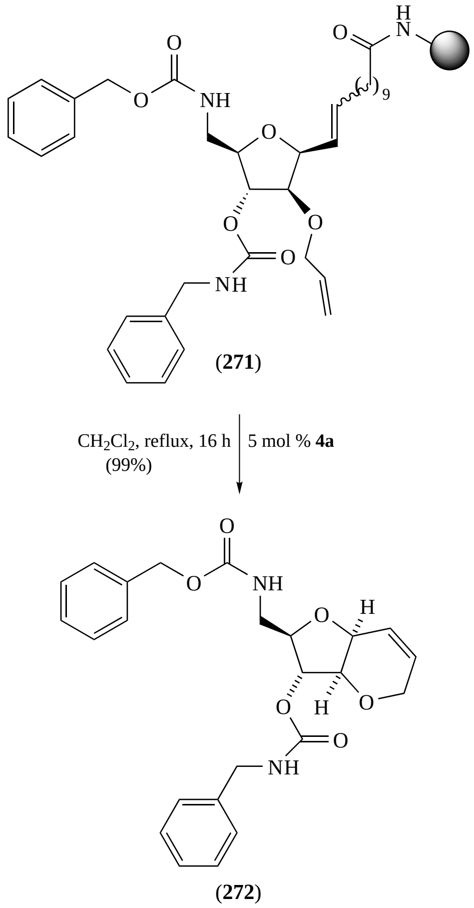
(**2a**) was also utilized in the attachment of polymer to a silica face (*see* ***Supported Organotransition Metal Compounds***).[162] In this strategy, an allyl group is attached to the substrate bound silicon that then reacts in a cross metathesis fashion with (**2a**). Then this surface bound Ru-alkylidene catalyzes ROMP of norbornene to give alkyl silicon terminated polymer film that is thus attached to the surface in controllable density and polymer thickness.



(67)

Gladysz has relied on the functional group tolerance and efficiency of olefin metathesis reactions catalyzed by (**2a**) to develop a variety of transition metal containing ligands and other functionalities with a central theme of creating metalamacrocycles, equation (67).[163,164] The types of transformations accomplished on a variety of olefin bearing organometallic fragments include intermolecular linking of olefin-substituted cyclopentadiene, intramolecular cyclizations of platinum thioethers, and allyl substituted phosphines. Terminal olefins on of metal-bound phosphanes also underwent intramolecular cross metathesis of cis-, trans-, and fac- ligands.

Overkleeft and van Boom utilized the (**4a**) catalyst to develop mannitol-derived fused oxacycle scaffold for the construction of combinatorial libraries.[165] The RCM of the highly functionalized conformationally fused cyclic products also cleaves it from the library bead, (equation 68).

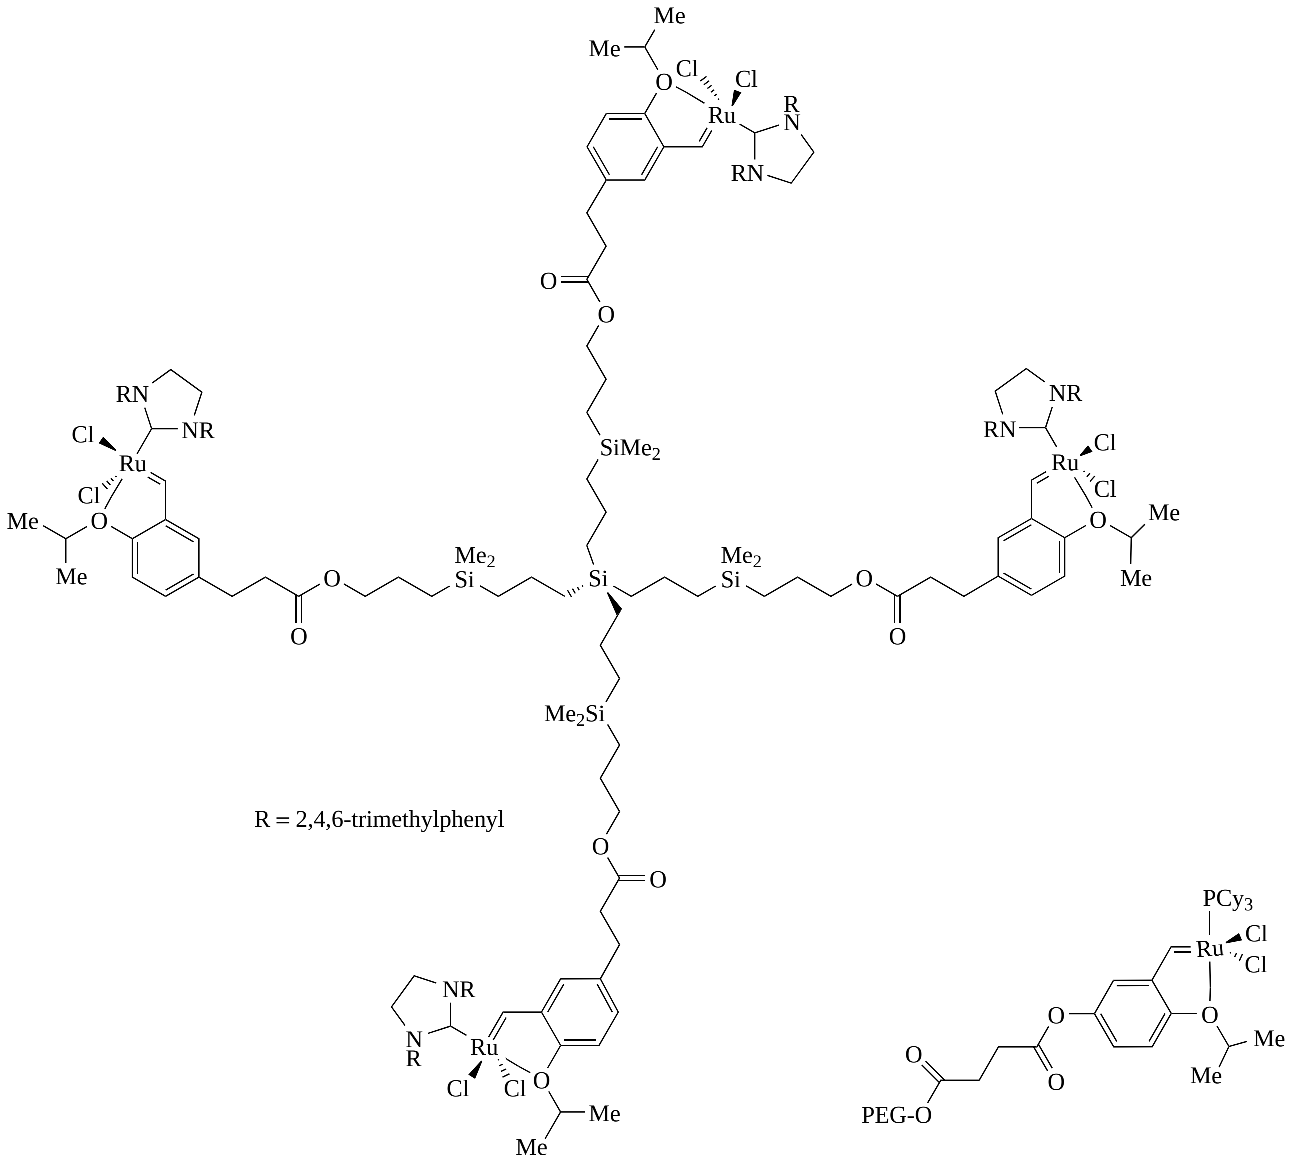


(68)

7 GREEN CHEMISTRY UTILIZING OLEFIN METATHESIS CATALYSTS

One of the areas garnering attention in catalysis research has been the development of 'green' or environmentally benign catalytic systems. For olefin metathesis, the trend has been to develop catalytic systems that can be efficiently recycled. Success in this area has multiple implications for OM processes. First, a recyclable catalyst will give overall more turnovers per catalyst molecule, and thereby be more economical. Second, a catalyst that can be efficiently recycled (low loss of activity over repeated uses) leaches less Ruthenium into the product and thus less expensive processing costs. To this end immobilization of the olefin metathesis catalysts on a variety of solid supports and utilization of nonorganic solvent systems have been explored.

A few examples of polymer supported olefin metathesis have been reported recently. Hoveyda formed styrenyl ether complexes of several ruthenium-based olefin metathesis catalysts that were then incorporated into a dendrimer structure (**273**) (Scheme 23), reporting good conversions over 6 cycles albeit with diminishing ruthenium content.[19,20] Yao used a similar chelating ligand to incorporate olefin

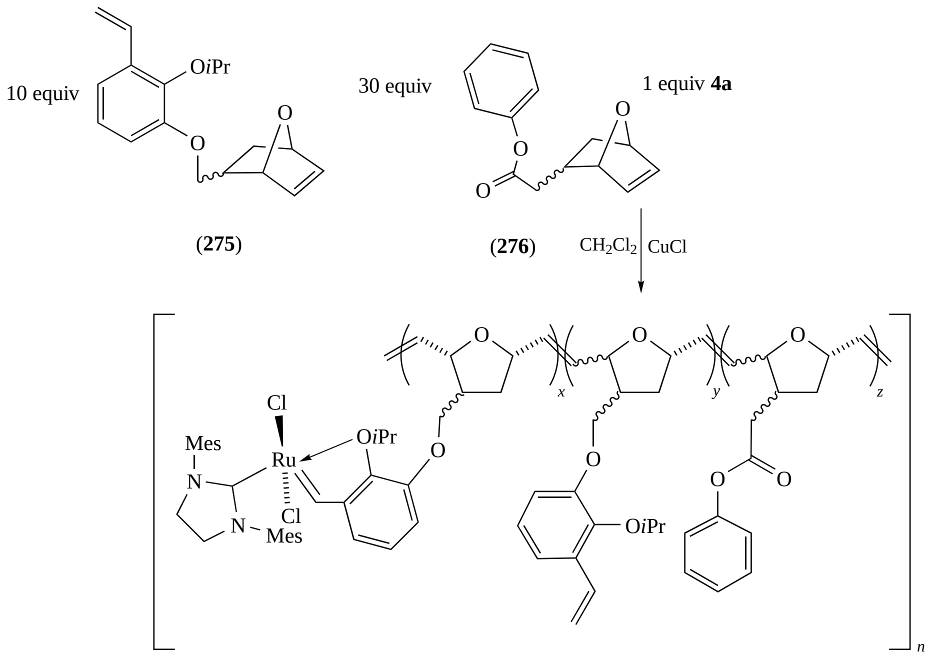


(**273**) (**274**)

Scheme 23 Recoverable catalysts

metathesis catalysts into polyethylene glycol (PEG) showing only minor loss of activity for RCM over 8 cycles (**274**) (Scheme 23).[166]

Blechert took advantage of the fact that the alkylidene group of any of the family of the ruthenium-based RCM catalysts can be substituted by a reaction with a pendant vinyl group of a divinyl benzene-containing polymer. Applying this idea, he created a PEG based system in which the styrenyl ether is pendant from the polymer backbone.[167] The strategy for building the catalyst relies on the ROMP of isoproxystyrene-oxanorbornene ether utilizing (**4a**) as catalyst and CuCl as phosphine scavenger (equation 69). The resulting red polymeric product has a high level of ruthenium incorporation and shows good activity with a variety of RCM ROM-CM and tandem metathesis reactions giving quantitative conversions. Recovery of the catalyst is achieved by adding hexane or diethyl ether to the reaction mixture. The RCM of *N*-tosyldiallylamine was tested for catalyst recyclability. The catalyst performed without visible loss of reactivity giving quantitative conversions in 1 h for the first 5 runs, with reactivity tailing off for runs 6 and 7; although quantitative conversion was still achieved, cycle 8 proved to be the limit of the performance of this catalyst. Ruthenium content of the products of the first four cycles was less than 0.004%. The parent homogeneous complexes react with the polymer to give a known catalyst loading



(277) x:y:z = 1:9:30

(69)

per gram of polymer. Because of the nature of RCM, the catalyst is free during the course of the RCM reaction and is recaptured by the support when the catalyst is not turning over, thus providing benefits of both homogeneous (solvated catalyst substrate complex) and heterogeneous (recoverable, recyclable) catalyst behavior.

A number of researchers have heterogenized olefin metathesis active complexes in polymers containing pendant vinyl groups via different methodologies. Barrett and coworkers formed (**278**) via reaction of (**3a**) with a lightly cross-linked solvent swellable vinylated polystyrene[168] or Merrifield resin to form a bead-supported catalyst that could be directly compared to their previously reported similarly supported (**2a**) (**279**) (Scheme 24).[169] Results from this study are described in Table 12.

The formation of (**281**) from (**280**) is nearly quantitative for the first 4 cycles under the described reaction conditions (Table 6, entry 1); these results compare favorably to those for (**279**) under different reaction conditions (entry 2). Although these results are not strictly comparable, (**278**) appears to have greater longevity overall. The heterogenized catalyst is also active for the formation of heterocycles with only slight attenuation of efficacy (entries 3 and 4). For the described system, additives are quite important to the successful recycling of the catalyst. Addition of 5 mol%

1	 (**280**)	 (**281**)	(**278**)	100	100	97	86	60	32
2			(**279**)[a]	100	100	50	10	–	–

Entry 1. Toluene 50 °C for 2 h, 2.5 mol% (**274**), 10 mol% 1-octene. Entry 2. CH_2Cl_2 at 25 °C for 40 min, 5 mol% (**275**), 10 mol% 1-hexene.

triphenylphosphine promoted quantitative conversion of (**280**) to (**281**) with just 0.25 mol% (**278**). Blechert also used a Merrifield resin to heterogenized olefin metathesis catalyst through an ether linkage on the backbone of (**4a**).[170]

Jafarpour and Nolan developed (**282**), (**283**), and (**284**) (Scheme 25) through the reactions of (**2a**), (**3a**), and (**4a**) with a highly cross-linked polydivinyl benzene macroporus polymer or monolith.[171,172] These polymers, developed for molecular imprinting,[173] have a permanent pore structure and do not need to be swollen by solvent for substrate access to the pendant catalyst. Results from the ring closure of (**280**) are described in Table 13. The polymer bound analogs have similar or better activity when compared to the free parent catalysts. The activity of these catalysts (particularly **284**) is maintained at over at least 4 cycles without the use of additives. There is, on average, a loss of 5% of total ruthenium from the polymer after 4 cycles using this methodology.

Kobayashi took advantage of π arene-ruthenium complexes (*see Arene Complexes*) to develop a polystyrene-OM catalyst system in which the catalyst was not connected to the polymer via an alkylidene; instead, the cationic ruthenium reacts through an appended allenylidine, (**285**) (Figure 3).[174] Upon appropriate activation conditions, the catalyst gives moderate to good conversions using high catalyst loadings (20 mol%) and long reaction times.

Lamaty reported olefin metathesis catalysts supported by various connectivities to PEG (Scheme 26).[175] These catalysts are soluble yet can be recovered upon addition of nonpolar solvent. The best of these catalysts, an analog of (**4b**), where the isopropyl group is replaced by PEG (**287**), could be recycled five times with only moderate loss in reactivity.

Scheme 27 Other types of recoverable olefin metathesis catalysts

Grela and coworkers attached (**4b**) to butyl diethyl silyl polystyrene to yield catalyst (**289**) in three steps.[176] The catalyst had good activity toward formation of trisubstituted alkene products in RCM and CM processes. The catalysts retained efficacy for up to 6 cycles and could be used sequentially on different substrates without cross contamination.

Hoveyda and Schrock attached (**97a**) to polymer via attached styrene groups yielding the first reported supported chiral molybdenum olefin metathesis catalyst, (**290**) (Scheme 27).[177] Supported complex (**290**) is less active than (**97a**), but it gives similar ranges of *ee*s for enantioselective transformations like desymmetrization. The catalyst is recyclable and, even though the conversions have eroded, the enantioselectivity is still relatively high, Table 14.

Fourkas and Hoveyda immobilized (**4b**) on sol–gel via a norbornyl ester linkage combining the release return mechanism with the ease of a monolith-type heterogeneous system; one such supported catalyst is (**291**).[178] This strategy provides a number of potential advantages in that the support substrate is macroscopic and can be manipulated using tweezers. Commercial grade sol gels give consistent loading and invariant porosity under different reaction conditions. Utilizing this system in CH_2Cl_2, the authors found conversion to analytically pure products with low ruthenium leaching under the same conditions for 4 cycles; with additional reaction time allowances, the sol–gel catalysts were active to 15 cycles without using additives to increase the efficiency of ruthenium rebinding to the support. Table 15 illustrates the capabilities of (**291**) as a recyclable catalyst for the same reaction or from one reaction type to another.

Another strategy for recovering and reusing catalysts is to depart from traditional solvents. Fürstner utilized complex (**2d**) in catalysis in supercritical CO_2 ($scCO_2$), an ecologically benign reaction medium that can be used in place of organic solvents in an increasing number of organic transformations.[179] Even though (**2d**) is not soluble in $scCO_2$, isolated yields of products are similar to those under homogeneous reaction conditions, although the reaction times are much greater in general. Table 16 outlines the results for $scCO_2$ reactions catalyzed by (**2d**) from an initial study in this area.

Buijsman and coworkers found the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate ([bmim]PF_6) to be an efficient solvent for RCM using (**2a**) and (**4a**)[180] and an alternative that allowed recycling of the catalyst, albeit at higher temperatures than typical RCM in dichloromethane. The good reactivity and the green solvent characteristics of ionic liquids makes this initial study notable. A further development in this area was made by Mauduit and Guillemin synthesizing a variant of the (**4b**) catalysts with a more cationic Ru center but tethered to a [bmim]PF_6-like center, (**314**).[181] This catalyst was successfully recycled 10 times yielding >95% for *N*,*N*-diallyltosylamine, while the nontethered analog gave high yields only under the first cycle. The catalyst was also successfully recycled 3–8 times on other substrates. Yao reported a similar tethered ionic liquid catalyst, (**315**), that also gave good levels of recyclability.[182]

(**315**)

Even with immobilized catalysts being developed, removal of ruthenium by-products remains an important challenge. Georg and coworkers found that addition of 50 equiv (relative to ruthenium) of dimethyl sulfoxide or triphenylphosphine oxide brought ruthenium levels in reaction mixtures down from 50 to 1–2 µg mg^{-1}.[183] The ruthenium levels in purified products are similar to those reported by Grubbs, where the metal was removed as trishydroxymethylphosphine complexes,[184] and those from the $Pb(OAc)_4$ oxidation of ruthenium reported by Paquette.[185]

8 SUMMARY

Olefin metathesis is a class of reaction that is evolving both in the quality of the catalysts and in the myriad of synthetic goals in which the reaction can play a part. With each year, our mechanistic understanding grows, and with this comes insightful research exploiting new findings, pushing the boundaries of performance and scope. The modular nature of these catalysts, and reversibility of many of the steps in the catalytic cycle, has allowed rapid progress in: (1) catalytic activity; (2) functional group tolerance; (3) new reaction pathway development; (4) exploration of an ever broadening range of substrate types; (5) cascading reactions and tandem reaction; (6) enantioselective olefin metathesis with both molybdenum and ruthenium; (7) development of different routes to make these catalysts more environmentally friendly. In light of the rapid advances seen since 2001, it is likely that we will be treated to even more exciting reports in this area in the years to come.

1 INTRODUCTION

Reactions that form carbon–carbon bonds are of fundamental importance in organic synthesis. Given this, it is somewhat surprising that the cross-coupling reaction, arguably the most powerful tool for this purpose available to the modern-day synthetic organic chemist, rarely makes it into the curriculum of the typical introductory course in organic chemistry. However, as this reaction continues to gain importance in academic and industrial laboratory settings, this oversight will probably be remedied in the near future.

Indeed, one does not need to look far in the literature to see how the cross-coupling reaction has gained prominence in recent years. At the time of writing this contribution (May, 2004), a keyword search on the Chemical Abstracts Database for 'cross, coupling, palladium' retrieves over 2700 articles, 1200 since the year 2000. Recent compilations of reviews have also been plentiful. Diederich's and Stang's *Metal-Catalyzed Cross-Coupling Reactions*,[1] and Negishi's all-encompassing *Handbook of Organopalladium Chemistry for Organic Synthesis*[2] are two must-haves for any chemist performing research in this area. Furthermore, recent issues of the *Journal of Organometallic Chemistry* and *Topics in Current Chemistry* have been completely devoted to the subject.

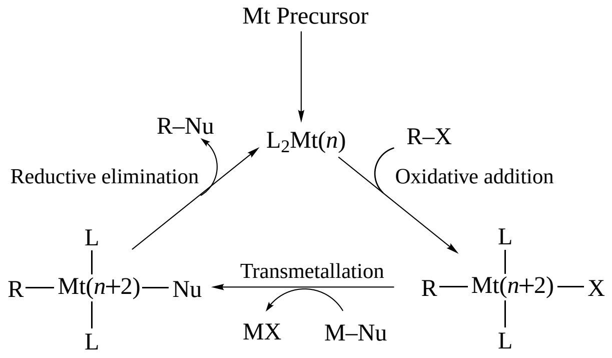
A cross-coupling reaction can be partially defined by equation (1), where Nu is a carbon (or heteroatom) nucleophile (*see Nucleophile*), R–X is an electrophilic substrate, X is a halogen or other appropriate leaving group, and M is a metal or metalloid. At first glance, it would appear that simple nucleophilic substitution reactions should fall under this definition. However, what makes the cross-coupling chemistry special is its ability to perform transformations that cannot be accomplished with simple substitution chemistry.

$$\text{R–X} + \text{M–Nu} \xrightarrow[\text{Catalyst}]{\text{Transition metal}} \text{R–Nu} + \text{MX} \qquad (1)$$

Consequently, to narrow the definition a bit further, we will adhere to Negishi's suggestion[3] and define cross-coupling reactions as those that follow some variation of the mechanism depicted in Scheme 1 (where Mt is a transition metal, L is an ancillary ligand (*see Ancillary Ligand*), and n is the oxidation state of the reduced metal in the catalytic cycle). This mechanism is supported by stoichiometric studies on isolated metal complexes (mostly where Mt = Pd, $n = 0$, L = triphenylphosphine) thought to be the intermediates in this cycle.

This is not to say that all cross-coupling reactions follow the same reaction pathway. Indeed, recent studies performed under conditions that more closely match those of the cross-coupling catalysis indicate that the actual mechanism depends upon the catalyst precursor, as well as the identities and concentrations of anions (which change as the reaction progresses) and cations (including the identity of M) present in the reaction.[4] The situation is muddied further by the fact that sterically hindered phosphines, chelating ligands, and metals other than palladium are increasingly being used in cross-coupling protocols. Conclusions drawn from studies on classical palladium complexes do not necessarily hold for these new systems.

Nevertheless, most would agree that whatever the details, the fundamental steps of oxidative addition (*see Oxidative Addition*), transmetallation (*see Transmetalation*), and reductive elimination (*see Reductive Elimination*) are intimately involved in the catalytic cycle, and Scheme 1 provides us with a starting point for rationalizing why certain protocols work better than others. Furthermore, for the synthetic organic chemist, what matters is that the reactions work, not so much the hows and whys of the process. So, for most of us, the understanding provided by this mechanism is sufficient. This does not mean, however, that the details are unimportant. For the organometallic chemist, on whose shoulders lie the development of next generations of catalysts, a thorough understanding of the microscopic steps is essential for the rational design of more advanced systems.



Scheme 1 General mechanism for cross-coupling reactions catalyzed by transition metals

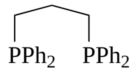
Over the past 30+ years, cross-coupling protocols utilizing a wide variety of metals and metalloids have been studied. However, we will cover only those that have been applied the most often in organic synthesis. Furthermore, the related Heck (*see Heck Reaction*) and Tsuji–Trost reactions, which follow different mechanisms (and hence, do not fall under our more narrow definition), are beyond the scope of this entry.

2 COUPLING OF ORGANIC SUBSTRATES WITH GRIGNARD REAGENTS (*See Grignard Reagents*)

2.1 History and Overview

In 1972, Kumada[5] and Corriu[6] independently disclosed what has come to be known as the Kumada–Corriu protocol for the nickel-catalyzed cross-coupling reaction of Grignard reagents (*see Grignard Reagents*) with organic substrates (equation 2). In a classic example of rational catalyst design, the authors of the first paper showed that the primary side reaction, β-hydride elimination (*see β-Hydride Elimination*) from the intermediate dialkylnickel(II) species, could be minimized if a chelating phosphine were present in the reaction. Thus, using the catalyst $NiCl_2$(dppp) (dppp = diphenylphosphinopropane, (**1**)), viable yields could be obtained even when the Grignard reagent contained β-hydrogens. Furthermore, later studies showed that aryl chlorides provided better results than those obtained with the other halogens, in marked contrast to the trend observed with the corresponding palladium catalysis (vide infra). In fact, despite the vast amount of research performed in this field since 1972, the Kumada–Corriu protocol remains one of the best methods for synthesizing alkylarenes from aryl chlorides.

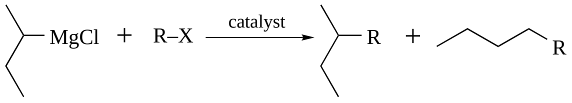
$$R{-}X + R'{-}MgX' \xrightarrow[(-MgXX')]{\text{Ni catalyst}} R{-}R' \qquad (2)$$



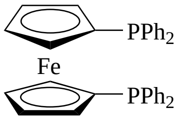
(**1**)

In the following years, a number of researchers reported on the analogous palladium-catalyzed cross coupling of alkenyl and aryl halides with Grignard reagents. The best results were obtained with bromide and iodide substrates, and palladium complexes with triphenylphosphine ligands were typically used as catalysts. In addition to broadening the scope of the reaction to include the other halides, the palladium catalysts also provided for higher E/Z stereoselectivity than what was obtainable with the nickel systems.

One serious drawback for the early nickel and palladium systems was that when secondary alkyl Grignard reagents were employed, a significant amount of 2° to 1° isomerization took place resulting in the competing formation of n-alkyl-substituted by-products (equation 3). Hayashi found that this side reaction could be limited when $PdCl_2$(dppf) (dppf = 1,1′-bis(diphenylphosphino)ferrocene, (**2**)) was used as the catalyst.[7] The authors argued that the superior activity and selectivity for this complex was due to its unusually large P–Pd–P angle of 99°, which served to decrease the C–Pd–C bond angle in the dialkylpalladium intermediate causing an increase in its rate of reductive elimination.



(3)



(**2**)

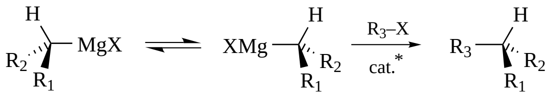
While organic chlorides, bromides, and iodides are still the most common substrates, recently the scope has been expanded to include organic fluorides, nitriles, ethers, triflates, phosphates, iodonium salts, and substrates with various chalconide-leaving groups. Of the different cross-coupling reactions covered in this article, the Kumada–Corriu protocol has been the least reviewed. However, the topic has been covered in recent historical treatments.[3,8,9]

2.2 Recent Improvements in Catalyst Development

Most of the research in terms of methodology improvement has proceeded along three fronts: the development of asymmetric coupling reactions,[10] the use of new nickel and palladium catalysts with specifically designed ancillary

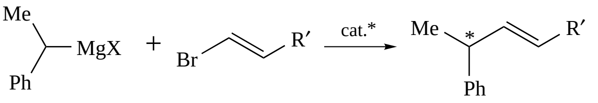
ligands, and the investigation of how different transition metals could be used to catalyze the reaction. While importance of the first area of research is obvious, the second is driven by the tendency of homogeneous nickel and palladium catalysts to decompose during the reactions they mediate, resulting in decreased activity and product contamination.[11] Finally, the expense of palladium and the toxicity of nickel have spurred others to investigate different transition metal alternatives.

There are two primary applications of asymmetric Grignard cross-coupling reactions that researchers have attempted to optimize over the years. The first of these is the reaction of an alkenyl or aromatic substrate with a secondary alkyl Grignard reagent. The challenge in this type of reaction lies in the fact that these Grignard species undergo a rapid racemization; however, with the appropriate asymmetric catalyst, optically enriched cross-coupling products can be obtained (equation 4).

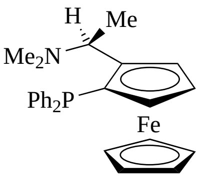


(4)

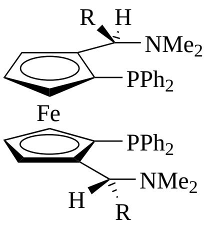
A large fraction of the catalysts investigated for this purpose is on the basis of palladium or nickel complexes with chiral ferrocenylphosphine derivatives. This interest was spurred by the early work of Hayashi and Kumada who achieved the asymmetric coupling depicted in equation (5) ($R' = H$) in 68% ee using phosphine (**3**) to provide chirality at the catalytic center.[10] More recently, Knochel synthesized bisphosphine derivative (**4**) ($R = Ph$) which gave results similar to (**3**) when vinyl bromide was the substrate (equation 5, $R' = H$, 63% ee).[12] However, when the reaction was performed with β-bromostyrene ($R' = Ph$), the enantioselectivity (*see Enantioselectivity*) increased to 93%.



(5)

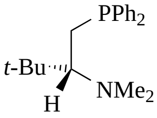


(**3**)

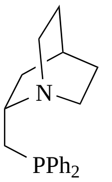


(**4**)

Researchers have also speculated on whether the optical induction provided by (**3**) was because of the ferrocene backbone or to the P–N chelate. Hayashi and Kumada attempted the reaction in equation (5) ($R' = H$) with several β-(dialkylamino)alkylphosphines and found that enantioselectivies as high as 83% could be achieved when the ligands contained bulky groups on the stereogenic carbons (i.e. (**5**)).[10] Another more recent improvement was the development of ligand (**6**), in which the chelating nitrogen atom is itself a stereogenic center. When equation (5) ($R' = H$) was performed with this phosphine and a nickel catalyst, an 86% ee was obtained.[13]

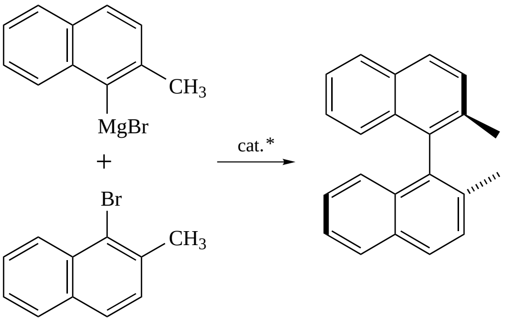


(**5**)

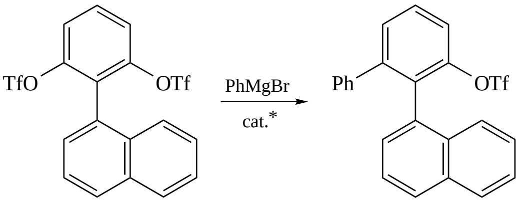


(**6**)

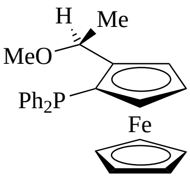
The other primary application of asymmetric Grignard coupling reactions has been in the synthesis of axially chiral binaphthyl and biphenyl derivatives. Hayashi performed a binaphthyl synthesis (equation 6) in 95% ee using a nickel catalyst and ligand (**7**),[10] a P–O chelating analog to (**3**). For a similar synthesis of chiral biaryls (equation 7) ligand, (**8**) was found to yield the most successful results (93% ee).[10]



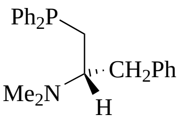
(6)



(7)



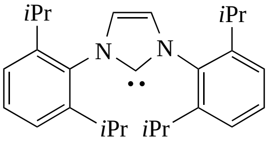
(**7**)



(**8**)

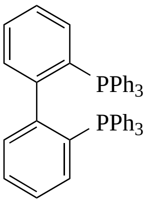
In order to address the issue of phosphine-derived by-products in nickel-catalyzed systems, a number of researchers have investigated the use of alternative ligands to promote cross-coupling reactions. In particular, Herrmann

and coworkers have successfully applied N-heterocyclic carbene ligands (e.g. (**9**)), as well as the commercially available monodentate tri(*tert*-butyl)phosphine, in the nickel-catalyzed Kumada–Corriu protocol.[14] Similarly, Kambe recently reported an alkyl–alkyl Grignard cross-coupling reaction catalyzed by nickel salts in the presence of a butadiene additive.[15]



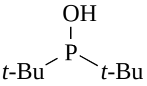
(**9**)

Much of the effort in recent palladium catalyst development has been geared toward improving the activity and selectivity of the original Pd-dppf system. The critical parameter in this regard is believed to be the P–Pd–P bond angle, or phosphine bite angle. In their recent compilation of bite angle effects in homogeneous catalysis,[16] van Leeuwen and coworkers indicated that the optimal values for this parameter were between 96° and 102°. Hayashi recently showed that diphenylphosphinobiphenyl (dpbp, (**10**)) produced results comparable to those generated by dppf, even though the bite angle for this ligand (92°) was less than the optimal range.[17] The authors noted, however, that in the $PdCl_2$ complex with this phosphine, the Cl–Pd–Cl angle (88.2°) was only slightly larger than that for the dppf complex (87.8°), suggesting that this may be the more important parameter for catalyst optimization.



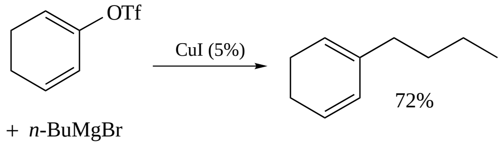
(**10**)

A significant amount of research has also been devoted to the development of phosphine alternatives in palladium catalysis. Investigators have used heterocyclic carbene ligands in a variety of cross-coupling reactions.[18,19] In particular, (**9**) was found to promote the palladium-catalyzed coupling of aryl halides (including chlorides) with aryl Grignard reagents to form substituted biphenyls in nearly quantitative yields. Li has used a combinatorial approach to design phosphinous acid derivatives (e.g. (**11**)) which can be deprotonated in situ to yield electron-rich ligands that are similarly able to activate aryl chlorides during Pd-catalyzed Grignard cross-coupling reactions.[20]



(**11**)

Although the disclosures of Kumada and Corriu are generally regarded as the progenitors of the cross-coupling reaction, these papers were actually preceded by two catalytic systems reported by Kochi. The first of these was a copper catalyzed coupling between alkyl halides and alkyl Grignard reagents.[21] Slight modifications have expanded the scope to include the use of alkyl tosylates, and more recently dienyl triflates, to form 2-substituted 1,3-dienes (equation 8).[22]



(8)

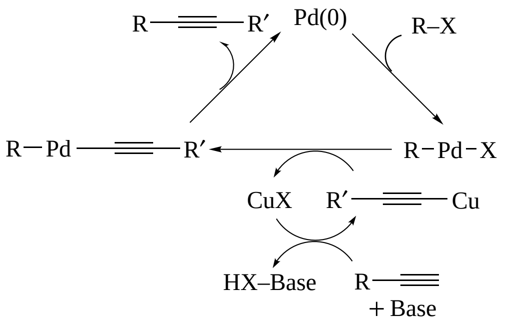
Kochi's other harbinger system was a vinylation of Grignard reagents catalyzed by iron species generated in situ from $FeCl_3$.[23] Despite this early success, iron catalysts for this reaction have received little attention until recently. One problem preventing their use in organic synthesis was that a large excess of halide substrate was required to generate the favorable yields. However, Cahiez spurred the more recent interest by showing that this excess could be eliminated if the reaction were performed in the presence of a dialkyl amide cosolvent (such as DMF or NMP) (equation 9).[24] Fürstner later extended the scope of this reaction to include aryl and heteroaryl chlorides, triflates, and tosylates – without the amide cosolvent.[25] While Kochi proposed a mechanism analogous to Scheme 1, in which the iron shuttles between the $+1$ and $+3$ oxidation states,[26] Fürstner suggested that the active species is an 'inorganic Grignard reagent' $[Fe(MgX)_2]$, and that the cycle proceeds through iron in the 0 and -2 oxidation states,[25] isoelectronic with the proposed intermediates in the traditional nickel and palladium systems.

$$\begin{array}{c} CH_3CH{=}CHBr \\ + \\ n\text{-Octyl-MgBr} \end{array} \xrightarrow[\text{THF–NMP}]{FeCl_3} \underset{88\%}{CH_3CH{=}CH{-}C_8H_{17}} \qquad (9)$$

3 COUPLING OF ORGANIC SUBSTRATES WITH TERMINAL ACETYLENES

3.1 History and Overview

The palladium-catalyzed coupling of organic substrates with terminal acetylenes (equation 10),[27,28] owes its nascence



Scheme 2 Dual cycle mechanism for the Sonogashira protocol

originally to the Stephens–Castro reaction.[29] This procedure, developed in 1963, involves the stoichiometric nucleophilic attack of copper acetylides onto aryl iodide substrates. Twelve years later, two independent reports showed that the related palladium-catalyzed olefination reaction (Heck coupling (*see Heck Reaction*)) could be extended to terminal alkynes, albeit at high temperatures.[30,31] Concurrently, Sonogashira disclosed the standard protocol in which the transformation takes place under much lower temperatures in the presence of a copper(I) cocatalyst.[32] While the mechanism of the copper-free protocols probably involves an alkyne insertion/β-hydride elimination pathway (analogous to the Heck coupling reaction), Sonogashira proposed a dual-cycle mechanism for the copper-assisted reaction involving the traditional cross-coupling steps of oxidative addition, transmetallation, and reductive elimination (Scheme 2).[27]

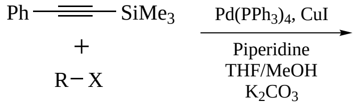
(10)

Unlike other cross-coupling reactions, for which the scope has rapidly expanded in recent years, the range of electrophilic substrates that can be used successfully in the Sonogashira protocol is still rather limited. Vinylic substrates (iodides, bromides, chlorides, triflates, and more recently tosylates) typically yield the best results. For aromatic substrates, iodides and triflates are preferred over bromides, which in turn give far better yields than aryl chlorides. This latter aspect of the reaction is particularly frustrating when one considers the recent advances in the activation of aryl chloride substrates for reactivity in other cross-coupling protocols.[33]

3.2 Methodology Development

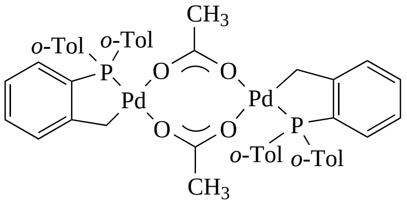
Another serious drawback to the Sonogashira protocol is the occasional occurrence of side reactions. These include oxidative homocoupling of the terminal alkyne coupling partner, exchange of the aryl groups in the $ArPd(PPh_3)_2X$ intermediates, and reductive dehalogenation of aryl halide substrates. Furthermore, the greater reactivity of terminal alkynes relative to acetylene renders the synthesis of monosubstituted alkynes problematic utilizing the original conditions. Fortunately, recent efforts have led to significant improvements in methodology and catalyst development that have addressed many of these issues.

The difficulty in synthesizing monosubstituted alkynes was resolved first through the use of protecting groups. For example, trimethylsilylacetylene can be coupled to aryl halides under the standard conditions, after which removal of the trimethylsilyl group results in the monosubstituted alkyne.[34] This route has since become the standard procedure for the synthesis of the terminal acetylene coupling partners in Sonogashira reactions, as these compounds can be subsequently coupled to form asymmetric alkyne derivatives. Alternatively, this process can be streamlined further through the use of a one-pot procedure (e.g. equation 11).[35] Here, the terminal acetylene is generated in situ and subsequently coupled in the same reaction mixture.



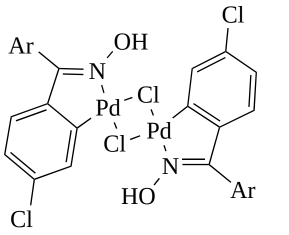
(11)

As has been the case with the other cross-coupling reactions, a great deal of effort has gone into the development and screening of different ligands in order to improve the scope, reactivity, and selectivity of the catalysts used in the Sonogashira protocol. Tri(*o*-tolyl)phosphine has long been a favorite in the related Heck coupling reaction, and palladium complexes of this ligand have also been successfully applied here. Furthermore, the metallacycle (*see Metallacycle*) (**12**) formed from palladium acetate and this phosphine has also achieved high turnovers (as high as 8000) for Sonogashira coupling reactions with aryl bromides.[36] In another recent development, Buchwald and Fu showed that room temperature Sonogashira reactions can be achieved when tri(t-butyl)phosphine-ligated catalysts are used.[37]



(**12**)

The problem of product contamination with phosphine-derived by-products has led others to investigate the use of phosphine alternatives in Sonogashira coupling reactions. N-heterocyclic carbenes (e.g. (**9**)) have found use in a wide variety of cross-coupling reactions,[18,19] including the Sonogashira protocol. Similarly, Nájera showed that oxime



(**13**)

palladacycles (**13**)[38] could successfully catalyze Sonogashira and other coupling reactions.

A number of researchers have tried to tackle catalyst removal/recovery/recycling issues by using systems in which the palladium has been embedded on a solid support. Perhaps the most encouraging example in terms of activation of aryl chlorides is Choudary's heterogeneous layered double hydroxide supported nanopalladium catalyst.[39] This material promotes the coupling of aryl chlorides to phenylacetylene in yields ranging from 60 to 95%.

4 COUPLING OF ORGANIC SUBSTRATES WITH ORGANOZINC REAGENTS

4.1 History and Overview

Building upon the success of the Kumada–Corriu protocol, Negishi and coworkers investigated tandem hydrometallation/cross-coupling methodologies for the stereoselective synthesis of substituted alkenes. The metal that first yielded the sought-after result was aluminum. Hence, the original Negishi coupling entailed a hydroalumination of an alkyne, followed by subsequent coupling of the resulting alkenylalane with an alkenyl halide (equation 12, M = Al).[40] The following year, the authors disclosed an analogous hydrozirconation (*see Hydrozirconation*)/cross-coupling protocol (equation 12, M = Zr),[41] as well as coupling between aryl halides and organozinc reagents (equation 13).[42] Of the three metals, zinc was found to be the most reactive, the most functional group tolerant, and since then the most widely used.[3,43]

(12)

$$\text{R–ZnX} + \text{R}'\text{–X} \xrightarrow{\text{Pd or Ni}} \text{R–R}' + \text{ZnX}_2 \qquad (13)$$

The traditional scope for this reaction involved coupling alkenyl or aryl iodides or bromides with aryl, alkenyl, or alkynylzinc halides. However, recent modifications have allowed the scope to be extended to include additional electrophiles (*see Electrophile*) such as aryl and vinyl chlorides, sulfonate esters, aryl ethers, and substrates with various chalconide-leaving groups. Other improvements on couplings with alkynylzinc nucleophiles have made this reaction a viable alternative to the Sonogashira reaction, particularly for vinyl and aryl chloride substrates. Finally, recent modifications in reaction protocols have led to coupling reactions that can stitch together two sp^3-hybridized carbon centers. While these procedures are air and moisture sensitive, they can be performed in the presence of a wide variety of functional groups on either or both of the coupling partners.

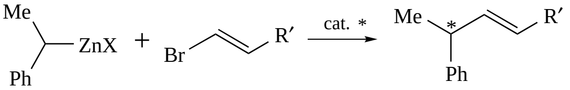
4.2 Methodology Development

The Negishi protocol is relatively free of side reactions, the most prevalent being the competing homocoupling of two substrate-derived groups, and β-hydrogen elimination (*see β-Hydride Elimination*) of alkene from intermediate alkylmetal complexes. Head-to-head comparisons have shown coupling with zinc reagents to be the most active of the commonly used cross-coupling protocols,[43] typically occurring in minutes at room temperature or even below. As a result, many of the catalyst-derived side reactions that can be problematic with other protocols do not compete with the desired coupling process here.

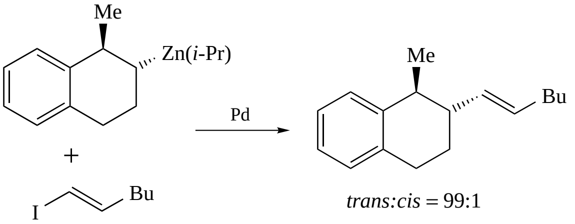
The palladium catalyst used in the original example was $Pd(PPh_3)_2$, formed in situ by treating $PdCl_2(PPh_3)_2$ with diisobutylaluminum hydride prior to adding the reagents. However, simple $Pd(PPh_3)_4$ was later found to yield equivalent results. For typical sp^2–sp^2 coupling procedures, this system is perfectly sufficient. However, for coupling of sp^2 substrates with alkylzinc reagents, palladium complexes with dppf (**2**) were found to be more active and more selective for the desired product.[7] Other phosphines that have seen more recent use include tri(*tert*-butyl)phosphine and tri(cyclopentyl)phosphine, for the coupling of aryl chloride[33] and alkyl halide[44] substrates, respectively. Nonphosphine-based palladium catalyst systems, such as Li's phosphinous acid ligands (e.g. (**11**)),[45] have also been utilized, as have palladacycle (**12**)[36] and ligandless systems without added phosphine.

As was the case with the Kumada–Corriu protocol, a significant amount of research has been devoted to the development of asymmetric Negishi coupling reactions.[10] In fact, for the standard asymmetric coupling reaction (equation 14), the enantioselectivity for the reaction performed with the organozinc reagent (86% ee) was significantly higher than that attained with the Grignard reagent (equation 5, 65% ee). This increased enantioselectivity for zinc relative to magnesium has been seen in other asymmetric coupling reactions,[12] although it is not universal. The best enantioselectivity for this reaction (93%) was realized utilizing the zinc reagent with phosphine (**4**) (R = Me).[10] A significant improvement in the asymmetric Negishi reaction was the discovery that unlike their magnesium counterparts, configurationally stable chiral alkylzinc reagents can undergo

cross coupling with retention of configuration (equation 15).[46]



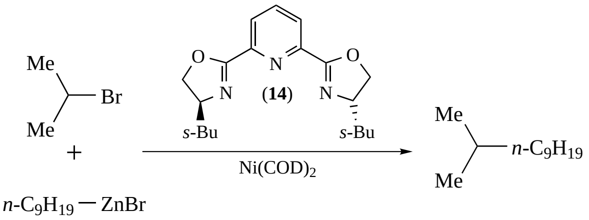
(14)



trans:cis = 99:1

(15)

Another recent improvement to the Negishi protocol has been the extension of the scope to include alkyl substrates. Knochel showed that coupling reactions between alkyl substrates and alkylzinc reagents could be performed if they were run in the presence of an electron-poor alkene such as *p*-trifluoromethylstyrene.[47] The authors suggested that the alkene serves as a π-acid, removing electron density from the catalyst center, and thereby increasing the rate of reductive elimination relative to possible side reactions. Finally, Fu and coworkers approached the problem by screening different catalysts. They noted that a palladium system with the electron-rich tri(cyclopentyl)phosphine ligand was optimal for the coupling of primary alkyl substrates (halides, tosylates),[44] while a nickel system with the ligand Pybox (**14**) worked best for the coupling of secondary alkyl bromides and iodides (equation 16).[48]



(16)

5 COUPLING OF ORGANIC SUBSTRATES WITH ORGANOTIN REAGENTS

5.1 History and Overview

The development of the reaction between an organic electrophile (*see Electrophile*) and an organotin reagent (equation 17)[49–51] was arguably the most significant single step forward in cross-coupling methodology. While organozinc and Grignard reagents are incompatible with acidic and some electrophilic functional groups, organotin reagents show a remarkable functional group tolerance, due largely to the relative nonpolarity of the C–Sn bond. Eaborn set the groundwork for this reaction by showing in 1976 that a group could be transferred from a tin reagent to an organic halide in the presence of a palladium catalyst (equation 18).[52] The first carbon–carbon bond forming reaction involving tin nucleophiles was performed by Kosugi in 1977,[53] a year prior to Stille's first paper on the coupling of acyl chlorides with organotin reagents.[54] Nevertheless, it was Stille who developed the reaction and performed the seminal mechanistic experiments through the 1980s.

$$\text{R–X} + \text{R}'\text{–SnR}''_3 \xrightarrow{\text{catalyst}} \text{R–R}' + \text{X–SnR}''_3 \qquad (17)$$

$$\text{Ar–X} + \text{R}''_3\text{Sn–SnR}''_3 \xrightarrow{\text{Pd}} \text{Ar–SnR}''_3 + \text{X–SnR}''_3 \qquad (18)$$

The traditional scope[55] of the reaction included acyl, aryl, vinyl, benzyl, and allyl substrates with bromide, iodide, and triflate leaving groups. More recently, the scope has been extended to include alkyl halides and substrates with chloride, fluoride, fluorosulfonate, nonaflate (nonafluoro-1-butanesulfonate), and sulfonium salt leaving groups. Even metal halides can be activated during this protocol, opening the door for the formation of carbon–metal bonds mediated by palladium catalysis.[56] Thus, the Kosugi–Stille protocol has come a long way since its early development in the late 1970s. However, it is still not without its problems, and efforts to improve this methodology are continually being pursued.

5.2 Methodology Development

Two of the most significant drawbacks of the Kosugi–Stille protocol are direct consequences of the reaction's sought-after mildness. Often the reactions are quite sluggish, which necessitates that they be carried out at elevated temperatures. Also, the nonpolarity of the C–Sn bond renders the transmetallation step rate determining. Thus, side reactions promoted by RPdL_2X species,[11] the resting state of the triphenylphosphine-based catalysts most commonly used, can have a particularly detrimental effect on the yield and purity of the desired product. Most notable among these are the alkyl–aryl (equation 19, R = alkyl)[57] and aryl–aryl (equation 19, R = aryl)[58,59] exchange reactions. When this occurs during the catalytic cycle, phosphine-derived rather than substrate-derived groups are incorporated into the cross-coupled product mixture. Furthermore, oxidative homocoupling of the tin reagents, participation of the tin-derived dummy ligands (R″ in equation 17), and cine substitution of α-substituted vinyl stannanes are other prevalent side reactions endemic to this protocol.

$$\text{R}-\overset{\text{PAr}_3}{\underset{\text{PAr}_3}{\text{Pd}}}-\text{X} \rightleftharpoons \text{Ar}-\overset{\text{RPAr}_2}{\underset{\text{PAr}_3}{\text{Pd}}}-\text{X} \qquad (19)$$

In order to improve the activity and selectivity of this reaction, a veritable witches brew of additives has been

incorporated into the standard procedure. Chief among these is lithium chloride. Originally, this was employed by Stille in coupling reactions of vinyl triflates in order to prevent the formation of a catalytically inactive Pd species that was observed via ^{31}P NMR. However, the more recent use of LiCl to promote couplings that do not involve triflates[60] suggests that the role of this additive may be a bit more complicated. One possibility is that the chloride coordinates to the Sn, renders it hypervalent (*see Hypercoordination*), and thus, more reactive toward transmetallation.[60] Others have used tetrabutylammonium fluoride in this same capacity, given the known tendency of fluoride to coordinate to tin.

Another common additive is cuprous iodide, the role of which appears to be twofold.[61] Firstly, it provides an alternate pathway involving transmetallation first from tin to copper and then from copper to palladium, both of which appear to be faster than the original tin to palladium process. Secondly, it can act as a scavenger for excess triphenylphosphine, which is known to retard the transmetallation step of this cross-coupling reaction.

One other significant drawback to the Kosugi–Stille protocol is that it generates a stoichiometric amount of a toxic trialkyltin halide by-product that has to be removed from the product mixture. One development geared toward mitigating this problem is Maleczka's tandem hydrostannylation/Kosugi–Stille coupling procedure in which tin is used in catalytic amounts (Scheme 3).[62] Here, the stoichiometric reagents are a vinyl halide and an alkyne, the latter of which is hydrostannylated with trimethyltin hydride to form the vinylstannane. At this point, the cross coupling yields the product and trimethyltin halide, which is subsequently reduced by carbonate and poly(methylhydrosiloxane) (PMHS) back to the tin hydride. By employing this procedure, tin usage can be reduced by 96%.

Some of the most significant improvements in catalyst development were the discoveries of alternative palladium ligands made by Farina in the early 1990s. In particular, tri(2-furyl)phosphine (**15**) and triphenylarsine proved to be far superior to triphenylphosphine when used as ligands in palladium-catalyzed Kosugi–Stille reactions.[63] Perhaps just as importantly, this discovery showed that significant improvements in methodology could be achieved by tailoring the structure of the ancillary ligands bound to the catalytic center. This in turn opened the gates for a flood of research on the synthesis and screening of ligands designed to improve the protocol further. A few notable examples include Elsevier's rigid bidentate imine ligands (**16**),[64] Mathey's tetraphosphole macrocycle (**17**),[65] and Shirakawa's iminophosphine ligands (**18**).[66] Palladacycles such as (**12**),[36] (**13**),[38] and (**19**) have also been successfully applied, the last of which produced turnover numbers as high as 830 000 in the coupling of 4-bromoacetophenone with phenyltributyltin.[67] In terms of activating aryl chloride substrates,[33] trialkylphosphines such as tri(*t*-butyl)phosphine have seen the most success. Recent catalyst systems based upon N-heterocyclic carbene ligands[18,19] have also been applied in the Kosugi–Stille protocol, with (**9**) being successful at promoting the reaction with aryl bromides and chlorides.

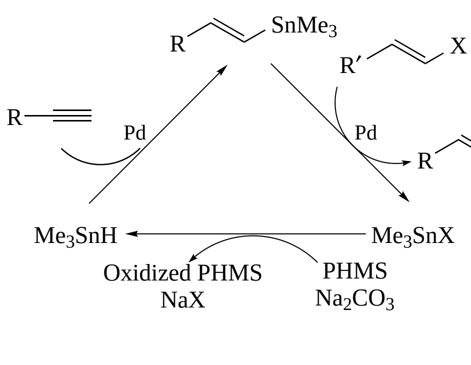

Scheme 3 One-pot tandem hydrostannylation/Kosugi–Stille coupling procedure that is catalytic in tin

5.3 Recent Mechanistic Insights

Of the different cross-coupling protocols, the Kosugi–Stille reaction is the one for which the mechanism has been studied in the greatest detail. Indeed, our basic picture (Scheme 1) for the mechanism of cross-coupling reactions in general is due in no small part to the extensive mechanistic work performed on this reaction by Stille and coworkers through the early 1980s.[55] As of 1993, the least-understood step of the catalytic cycle was the transmetallation reaction. Consequently, most of the recent mechanistic work has been done on this final rate-determining step in the catalysis.

This recent interest was piqued by the observation of Louie and Hartwig[68] that the rate of transmetallation was inversely dependent upon the concentration of added phosphine, suggesting a mechanism involving predissociation of this ligand. This prompted Casado and Espinet to study the kinetics of the coupling reaction between an aryl iodide and vinyltributyltin.[69] A large, negative entropy of activation led them to propose a mechanism involving an associative substitution in which the nucleophile directly replaces the ancillary ligand (Scheme 4). Such a mechanism is analogous to an S_E2(cyclic) substitution in which the electrophilic Pd accepts electrons from the front lobe of the Sn–C bonding orbital (Scheme 5). This implies that a stereogenic carbon bound to tin would undergo transmetallation with retention of configuration, in line with certain examples in the literature. However, other instances have been shown to proceed with inversion of configuration in line with an S_E2(open) mechanism (Scheme 5) in which the electrophilic palladium accepts electrons from the back lobe of the Sn–C bonding orbital. In a later study,[70] Espinet and coworkers showed that the key to this discrepancy was the presence of halide in the coordination sphere of the palladium. When aryl triflates were coupled to tin nucleophiles in the absence of halide, the authors found evidence for an S_E2(open) pathway. However, when LiCl was added to the reaction mixture, the cross coupling reverted to the S_E2(closed) mechanism.

Other efforts in the mechanistic study of the Kosugi–Stille protocol have been geared toward directly observing and/or isolating the transmetallation products. This is a nontrivial undertaking since the subsequent reductive elimination is generally rapid. However, Echavarren and coworkers were able to synthesize complex (**20**) which cleanly transmetallated to complex (**21**), isolation of which was made possible by its reluctance to form the three-membered ring upon reductive elimination (equation 20).[71] Lo Sterzo showed that the transmetallation product formed between the reaction of tributyltinacetylides with metal iodide complex (**22**) could also be isolated and characterized (equation 21).[56] Furthermore, kinetics experiments revealed that this process similarly followed two different pathways analogous to the S_E2(open) and S_E2(closed) mechanisms mentioned above.

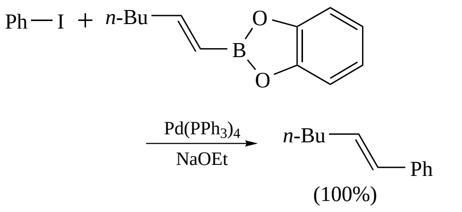
6 COUPLING OF ORGANIC SUBSTRATES WITH ORGANOBORON REAGENTS

6.1 History and Overview

The first example of the use of boron reagents in palladium-catalyzed coupling reactions was supplied in 1975 by Heck, who showed that alkenyl boronic acids could serve as substrates (in lieu of alkenyl halides) in the analogous Heck coupling reaction (*see Heck Reaction*) with alkenes.[72] However, early attempts by Negishi to involve boranes in catalytic cross-coupling reactions were not realized, despite his success at utilizing the analogous aluminum reagents.[40] In 1979, Miyaura and Suzuki noted that the catalytic cross coupling between aryl halide substrates and alkenyl boranes could be achieved if the reaction were run in the presence of a stoichiometric amount of base, such as hydroxide or alkoxide (e.g. equation 22).[73] This procedure, now known as the Suzuki–Miyaura reaction,[74–79] provided the advantages of the Kosugi–Stille protocol, namely, functional group tolerance and mildness of reaction conditions, without its chief

downside, the resulting formation of toxic tin by-products.

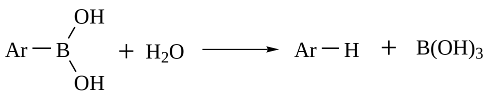


(22)

The traditional scope of this reaction entailed the use of alkenyl, alkynyl, or aryl bromides or iodides coupled with aryl or alkenyl boronic acids or esters. More recently, the range of substrates has been expanded to include aryl chlorides, activated aryl fluorides, and sulfonate esters, as well as iodonium, trimethylammonium, diazonium, and sulfonium salts. Furthermore, the development of bicyclic alkyl boron reagents enabled the transfer of alkyl groups in this reaction.[74] Finally, with new modifications that allow for the coupling of alkyl substrates with β-hydrogens,[80] it is now possible to couple virtually any imaginable combination of organic electrophile and organoboron reagent.

6.2 Methodology Development

The conditions for the traditional methodology involved performing the reactions in an arene solvent (benzene or toluene) along with aqueous base and tetrakis(triphenylphosphine)palladium(0) as the catalyst precursor. However, several side reactions resulting in reduced yield of products can also occur under these conditions. Chief among these is the hydrolytic deboronation of the boron reagent (equation 23), which has long been known to be catalyzed by base and metal cations, such as cadmium, magnesium, and nickel.[81] Aryl–aryl exchange[58,59] between Pd- and P-bound aryl groups can result in phosphine-derived coupling products contaminating product mixtures, particularly when the reaction is performed with electron-rich aryl substrates. Reductive dehalogenation of the substrate and oxidative homocoupling of the boron reagents have also been noted during this protocol.



(23)

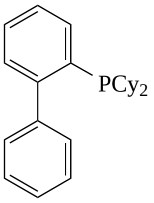
The last two side reactions are fairly easy to control. The reductive dehalogenation appears to be caused by the concomitant oxidation of a primary alcohol (either from the boronic ester or from an alcohol cosolvent).[82] Consequently, it can be minimized simply by utilizing boronic esters from tertiary alcohols (such as pinacol) and by avoiding the use of alcohol cosolvents. Since oxidative homocoupling is facilitated by ambient oxygen, the impact of this side reaction can be reduced by rigorously excluding oxygen from the cross-coupling mixtures. The other two side reactions, however, can be more problematic. Consequently, a great deal of effort has gone into optimizing the various parameters of this protocol (solvent, base, catalyst, etc.) so as to minimize their effect on product yields.

As there is no clear consensus on the best solvent to use, this unfortunately remains a parameter that should be screened for a given reaction. Water-free protocols have been developed, and they can be useful for moisture-sensitive substrates and for minimizing the competing protodeboronation.[82] However, there is evidence that some water is required in order to facilitate the cross coupling,[83] though the water of hydration typically present in the inorganic base appears to be sufficient.[82] Other research has been devoted toward the other extreme, the development of all-aqueous Suzuki–Miyaura reactions.[84] Water-soluble substrates such as carboxylic acids and phenols react cleanly at room temperature, while water-insoluble substrates can be coupled successfully by either increasing the temperature to 100 °C or adding a water-miscible organic cosolvent such as acetone or DMF. Further work has shown that a surfactant can replace the organic cosolvent,[85] and that the higher temperatures can be achieved more efficiently (allowing successful reactions in minutes) through the use of microwave irradiation.[86]

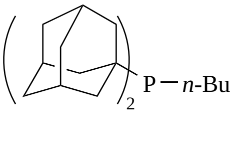
The fact that stronger bases speed up both the coupling and the hydrolytic deboronation means that the choice of base is not always obvious. Although aqueous carbonate is the one most commonly used, stronger alkoxide bases appear to yield the best results for sterically hindered boronic acids.[87] For base-sensitive substrates, bicarbonate can be used successfully when THF is the organic cosolvent.[88] However, this base is less successful when employed with mostly nonaqueous reaction conditions.[83] On the other hand, fluoride, an even weaker base, appears to work well with both aqueous and nonaqueous protocols.[89]

By far the greatest amount of research, in terms of methodology development, has gone into the search for more active and more general catalyst systems that promote fewer side reactions. Early on, researchers noted that the yields of typical Suzuki–Miyaura reactions could be improved by replacing the triphenylphosphine-based catalysts with those using sterically hindered triaryl phosphines such as tris(2-methoxyphenyl)phosphine and tri(*o*-tolyl)phosphine. The success of these systems can be explained by the fact that aryl–aryl exchange is inhibited by steric hindrance close to the metal.[59] More recently, Buchwald and coworkers discovered that electron-rich dialkylphosphinobiphenyl ligands (e.g. (**23**)) could perform nonaqueous Suzuki–Miyaura reactions at room temperature on not only aryl bromide substrates, but with nonactivated aryl chlorides as well.[90] Concurrently, Fu and coworkers showed that simple sterically hindered trialkylphosphines such as tri(*t*-butyl)phosphine and tri(cyclohexyl)phosphine could form highly active catalysts

that also coupled aryl chloride, bromide, and triflate substrates under mild conditions.[91] Of particular import with this system is the phosphine to palladium ratio. Interestingly, the authors noted that Pd[P(t-Bu)$_3$]$_2$ was not as effective as a catalyst formed in situ from Pd$_2$(dba)$_3$ and P(t-Bu)$_3$ with one phosphine per palladium atom. Other bulky trialkylphosphines based upon an adamantane framework (e.g. (**24**)) have been similarly developed and used in Suzuki–Miyaura reactions.[92]

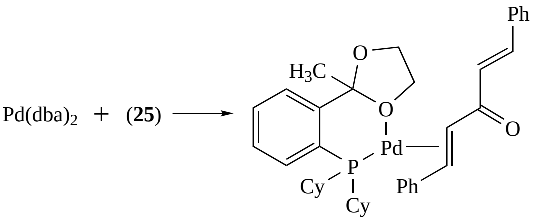


(**23**)

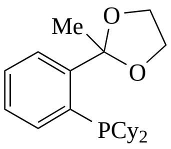


(**24**)

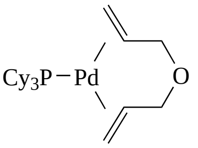
Efforts have also gone toward new strategies to enforce the optimal 1:1 P to Pd ratio. Bei, Guram, and coworkers showed that P–O chelating ligand (**25**) forms a 1:1 P to Pd complex upon reaction with Pd(dba)$_2$ (equation 24).[93] However, the dibenzylidineacetone ligand still present has been shown to hinder the reactivity of palladium toward oxidative addition.[4] In support of this, Beller pointed out that catalyst (**26**) is more active than those formed in situ from the phosphine and Pd$_2$(dba)$_3$.[94] Similarly, Hartwig's Pd(I) dimer (**27**), with one phosphine per palladium and no supporting alkene ligands of any kind, is one of the most active catalysts screened to date.[95]



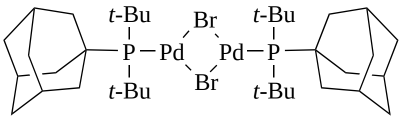
(24)



(**25**)



(**26**)



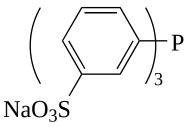
(**27**)

Significant research has also been devoted to extending this electron-rich sterically hindered ligand strategy to nonphosphine-based catalysts. In particular, N-heterocyclic carbene ligands such as (**9**) have seen increasing use in Suzuki coupling reactions of various substrates.[18,19] Li's phosphinous acid catalysts also fall into this category,[45] as do other systems based upon phosphite[67] and diazabutadiene[19] ligands.

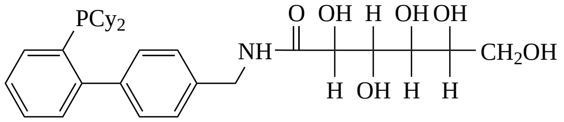
Another strategy for catalyst development was based upon the discovery of Beller and coworkers, that the palladacycle (**12**) could catalyze the nonaqueous Suzuki coupling of aryl bromide and chloride substrates with efficiencies greater than what had been observed up until that time.[96] Since then, palladacycles based upon a variety of functional groups have been developed and screened in Suzuki–Miyaura coupling reactions.[97] Particularly noteworthy is the observation of Bedford and coworkers that the most active catalysts are obtained from single phosphine adducts of these palladacycles.[98] They surmise that the true catalyst is a monoligated Pd–L species formed in situ from the adducts under the reaction conditions. Thus, once again the importance of the proper L:Pd ratio becomes apparent in the optimal catalyst design for this protocol.

Considering all the work that has gone into catalyst development, it is interesting that excellent activities can be obtained when simple palladium salts are used as catalysts. This 'ligandless' methodology for aqueous Suzuki–Miyaura coupling reactions was first disclosed by Bumagin, Bykov, and Beletskaya in the late 1980s, and summarized in a more recent full paper by Bumagin and Bykov.[84] Wallow and Novak demonstrated that simple palladium acetate is significantly more efficient than triphenylphosphine-based catalysts, and that the ligandless methodology works best in water, with a water-miscible cosolvent such as acetone.[99] In terms of how these systems are able to function, Reetz has provided evidence that palladium nanoparticles are responsible for the actual catalytic activity.[100]

In order to address catalyst separation, recovery, and recycling issues, a great deal of work has been devoted toward the development of heterogeneous catalyst systems. One obvious strategy is to exploit the heterogeneity already present in the traditional protocol, that is, to force the palladium to partition into the aqueous phase of the reaction. Genêt recently demonstrated that the water-soluble triarylphosphine (**28**) can promote efficient Suzuki–Miyaura reactions from which it was possible to recycle the catalyst up to three times.[101] Water-soluble versions of the newly developed nonaqueous catalysts have also been investigated. Miyaura demonstrated the effectiveness of a carbohydrate-substituted Buchwald phosphine (**29**),[102] while Shaughnessy has shown the utility of water-soluble versions of hindered, electron-rich trialkylphosphines.[103] Finally, heterogeneous catalysts in the form of, for example, palladium nanoparticles,[104] have also been extensively investigated.



(**28**)



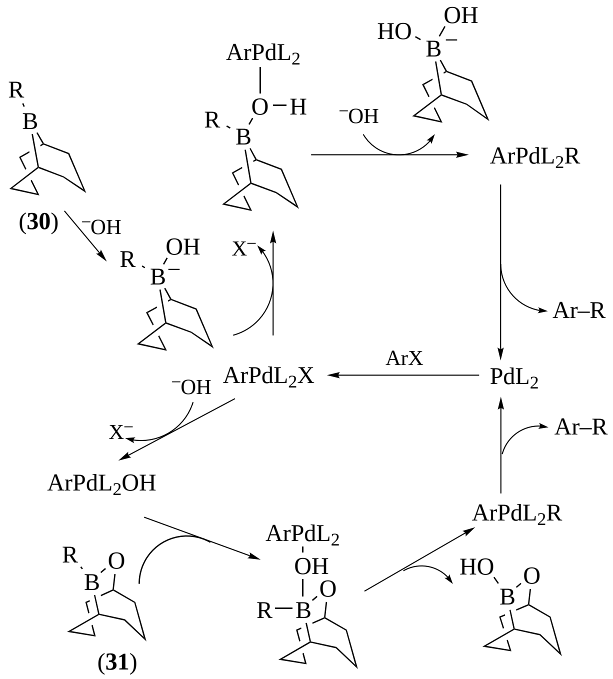
(**29**)

6.3 Recent Mechanistic Insights

Most of the mechanistic work on this reaction has been devoted to determining the role of the base. Its most obvious function would be to complex the Lewis-acidic boron reagent, rendering it nucleophilic and thus activating it toward transmetallation. However, Miyaura, Suzuki, and coworkers noted that an electron-rich tetracoordinate boronate complex was less reactive than a trivalent boronic ester.[105] From this, they surmised that the role of the base was not to activate the boron toward transmetallation, but rather to transform the palladium halide intermediate to the hydroxide or alkoxide species, which would then be more reactive toward boron. However, in a mass spectrometry study of a reaction between a pyridyl halide substrate and an aryl boronic acid, Aliprantis and Canary saw no evidence of palladium hydroxide or alkoxide intermediates, despite observing signals in the mass spectra assignable to every other palladium intermediate of the proposed catalytic cycle.[106]

In a more recent study, Matos and Soderquist noted that trialkylboranes such as (**30**) reacted much more quickly than alkylborinates (e.g. (**31**)),[107] and they explained this with the fact that the former can complex hydroxide, while the latter cannot. This led the authors to speculate that the two boron reagents reacted via two different mechanisms (Scheme 6). For species such as (**30**), which are capable of forming nucleophilic hydroxide complexes, the top cycle is active; while, for species such as (**31**), the bottom cycle – analogous to that proposed by Miyaura and Suzuki – predominates.

To complicate matters further, Smith and coworkers noted that for reactions with arylboronic acid coupling partners, the rate-determining step for aryl bromide substrates was oxidative addition, while for aryl iodide substrates it was transmetallation.[83] Thus, the exact mechanism for a particular coupling reaction depends upon the substrate, the activity of the coupling partner, and doubtless the conditions under which the reaction is performed. Finally, one further observation[107] showed that coupling with chiral alkyl boron reagents proceeds with retention of configuration, suggesting that transmetallation occurs



Scheme 6 Possible mechanistic cycles for Suzuki–Miyaura reactions

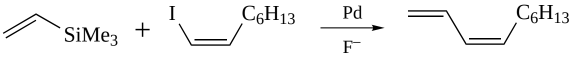
via an S_E2(cyclic) pathway as described above in the Stille–Kosugi protocol.

7 COUPLING OF ORGANIC SUBSTRATES WITH ORGANOSILICON REAGENTS

7.1 History and Overview

The first cross coupling of organosilicon reagents, which in this case were in the form of organopentafluorosilicate salts,[108] was reported by Kumada in 1982. Soon afterwards, Kikukawa[109] and Hallberg[110] independently disclosed the coupling of alkenyltrimethylsilanes with aryl diazonium salts and aryl iodides, respectively. However, these reactions were not stereoselective, leading the authors to postulate a mechanism involving carbometallation (*see Carbometalation*) rather than the transmetallation more typical of cross-coupling reactions. In 1988, Hiyama showed that this transformation could occur under much milder conditions (50 °C) with retention of stereochemistry, when performed in the presence of a source of fluoride (e.g. equation 25).[111] This idea of activating silicon for cross coupling by rendering it pentavalent upon treatment with a base is a central theme to what has become known as the

Hiyama protocol.[112–115]



(25)

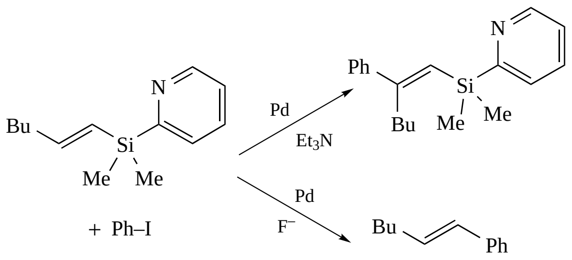
Traditionally, this reaction could be performed on alkenyl, alkynyl, or aryl substrates with iodide, bromide, or triflate leaving groups. However, recent methodology improvements have expanded the scope to include aryl chlorides and nonaflates. Furthermore, with the observation that functionalized alkyl groups can be transferred from silicon,[116] a wide array of cross-coupling procedures can now be performed. Other advantages of this protocol include excellent functional group compatibility, the low cost of the silicon reagents, and the lack of toxic by-products.

7.2 Methodology Development

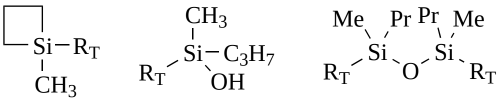
The majority of the methodological improvements to this reaction have been in the development of new organosilane coupling partners. This research was spurred by the discovery that organofluorosilanes (**32**) react more quickly than the nonfluorinated analogs.[112] Interestingly, while monofluorosilane reagents ($n = 2$) work best for the transmetallation of alkenyl groups, aryl silanes require two fluorine atoms ($n = 1$) for effective coupling to occur. The analogous chlorosilanes can also be effective coupling partners, provided that they are treated with fluoride beforehand or used in the presence of hydroxide. A more recent development allows for the coupling of alkyl groups from the silicon.[116] Here three fluorine atoms ($n = 0$) are required to promote the reaction. Similarly, Ito and coworkers disclosed that alkenylalkoxysilanes (**33**) were also effective coupling partners, proving that the electronegative atoms other than halogens could serve to activate the silicon.[117] Shibata[118] and DeShong[119] have since shown that arylalkoxysilanes could be used to synthesize biphenyl derivatives upon coupling with aryl halide substrates.

$R_T{-}SiMe_nF_{(3-n)}$ (**32**) $R_T{-}SiMe_n(OR)_{(3-n)}$ (**33**)

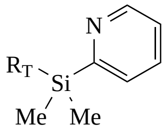
In 1999, Denmark disclosed that silacyclobutane derivatives (**34**) were very effective coupling partners for the transfer of alkenyl and aryl groups.[115] The original theory was that the release of strain energy upon treatment with fluoride to make the silicon pentacoordinate is what made these species so active. However, later studies showed that under the conditions of the cross-coupling reactions, silacyclobutanes formed silanols (**35**) and disoloxanes (**36**), which themselves proved to be efficient transmetallating species. Finally, Yoshida and coworkers have developed the cross-coupling chemistry of 2-pyridylsilane derivatives (**37**).[120] Of interest here is, the fact that conditions can be tailored so as to toggle between either the Heck or Hiyama coupling of these compounds (equation 26).



(26)



(**34**) (**35**) (**36**)



(**37**)

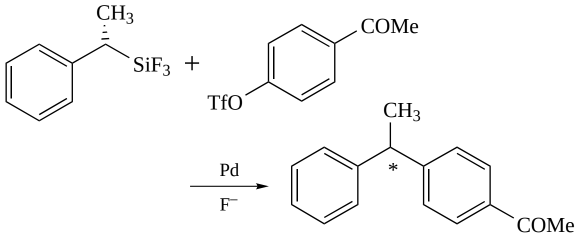
R_T = Group that is transferred to palladium

As was the case with the other coupling protocols, side reactions can limit the yields of the desired products. In particular, reductive dehalogenation of aryl substrates, protodesilylation of the organosilicon reagent, homocoupling of one or both components, cine substitution, and participation of the dummy silicon ligands have all been observed in Hiyama coupling reactions. Again, as with the other protocols, different catalyst systems have been utilized in order to minimize the impact of these competing processes.

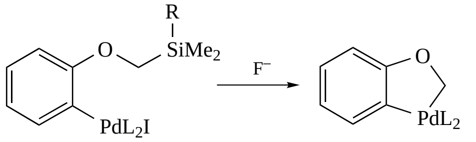
In Hiyama's original publication, the major catalyst system consisted of the allylpalladium(II)chloride without added ligands.[111] Consequently, the majority of the silicon cross-coupling reactions have been performed with this or similar ligandless protocols. However, researchers have occasionally had success in improving the reaction by performing it with added triphenylphosphine, triphenylarsine, triethylphosphite, or tri(*o*-tolyl)phosphine ligands. A more recent development is that aryl chloride substrates can participate if catalyst systems based upon trialkylphosphines, Buchwald's ligand (**23**), or N-heterocyclic carbenes (e.g. (**9**)) are employed.[33]

7.3 Recent Mechanistic Insights

Information on the transmetallation step was obtained by monitoring the coupling of optically active silane derivatives (equation 27).[112] At lower temperatures, the reaction proceeds with the retention of configuration, suggesting an S_E2(cyclic) transition state, while higher temperatures result primarily in inversion, in line with an S_E2(open) pathway. Also, Echavarren and coworkers were able to monitor the transmetallation step directly using their 'frustrated coupling cycle' strategy (equation 28).[121] Intriguingly, the platinum analog transmetallated without the addition of a fluoride activator.



(27)



(28)

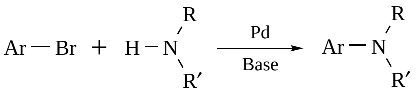
8 CATALYTIC AMINATION OF ORGANIC ELECTROPHILES (*See Electrophile*)

8.1 History and Overview

Arguably the most significant advance of the past 10 years in the field of cross-coupling reactions has been the development of the catalytic amination of organic electrophiles.[122,123] Despite the relative youth of this procedure, its history can be traced back to the turn of the previous century with the venerable Ullmann reaction, which entails heating an amine with aryl halide in the presence of copper powder and base. However, the spark that truly ignited the development of this protocol came in 1983, with Kosugi's coupling of aryl bromides with tin amides (equation 29).[124]

$$\text{Ph–Br} + \text{Bu}_3\text{Sn–NEt}_2 \xrightarrow[\text{[}-\text{Bu}_3\text{SnBr]}]{\text{Pd}} \text{Ph–NEt}_2 \qquad (29)$$

A tantalizing observation made by Kosugi was that triphenylphosphine-based catalysts were far inferior to $PdCl_2$(*o*-tolyl$_3$P)$_2$ for the coupling of aryl halides with tin amides.[124] In 1994, the groups of Buchwald and Hartwig began publishing work in which this catalyst was used as a starting point to improve vastly the scope and utility of this reaction. The true breakthrough came the following year when both groups concurrently disclosed a procedure entailing the direct reaction of an amine with an aryl bromide in the presence of base (sodium *tert*-butoxide[125] or lithium hexamethyldisilazide[126]) and a palladium tri(*o*-tolyl)phosphine catalyst (equation 30). This was a significant improvement in that it provided relatively mild reaction conditions and eliminated the concomitant formation of toxic tin by-products.



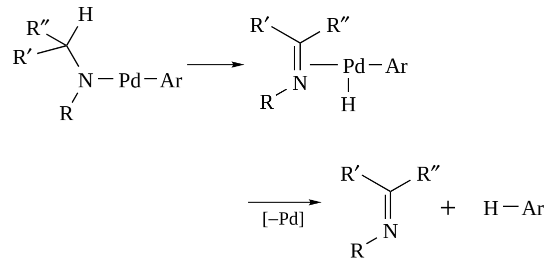
(30)

The original procedure involved the coupling of aryl bromides with secondary amines. However, since then the scope has been expanded to include substrates such as aryl iodides, chlorides, fluorides, triflates, tosylates, nonaflates, iodonium salts, and even boronic acids. While the reaction has not been extensively utilized with vinyl or alkynyl substrates, it can be performed with various heteroaryl halides. Similarly, numerous types of nitrogen-containing coupling partners, including primary amines, imines, various azoles, lactams, and simple amides, can now be used in this reaction.

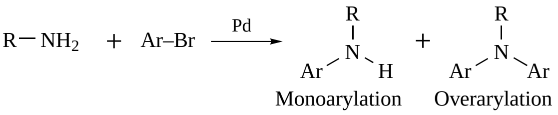
8.2 Methodology Development

Despite the success of the original Hartwig–Buchwald protocol, this procedure was not without its drawbacks. The scope was limited to aryl bromide substrates and secondary amine coupling partners, and the requirement of a strong *tert*-butoxide or amide base meant that substrates with base-sensitive functional groups would not be compatible. While this latter constraint has since been obviated by the discovery that weaker bases such as Cs_2CO_3 can promote the reaction, the extension of the scope has required some sophisticated catalyst development (vide infra).

A second issue is that catalytic aminations are plagued by several notable side reactions. Most prevalent among these is β-hydride elimination (*see β-Hydride Elimination*) of imine from the intermediate Pd-amido complex (equation 31). This reaction also produces a Pd–H species, which can then reduce the substrate to form arene, the generation of which can be considered a second side reaction. Furthermore, aryl–aryl exchange has also been noted in amination reactions, and, for the monoarylation of primary amines, by-products caused by overarylation (equation 32) to form tertiary amines pose an additional difficulty.

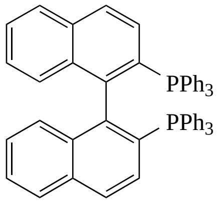


(31)

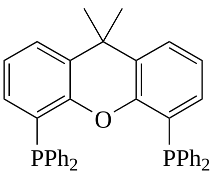


(32)

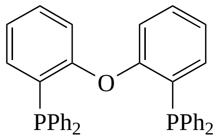
In order to tackle the β-hydrogen elimination problem, researchers took a page from the methodology developed for the Kumada–Corriu protocol. Buchwald and Hartwig concurrently divulged that this side reaction could be minimized when aminations were performed with the chelating ligands BINAP (**38**)[127] and dppf (**2**).[128] These encouraging results then led researchers to experiment with other chelating phosphines, such as Xantphos (**39**),[129] and DPEphos (**40**)[130] which proved to be particularly active. Others have investigated ligands that chelated through atoms besides phosphorus, again with impressive results. In particular, (**7**) was shown to be extremely active and selective for the arylation of acyclic secondary amines,[131] a transformation that had previously proved troublesome.



(**38**)



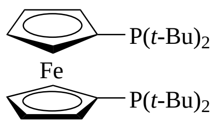
(**39**)



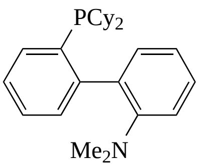
(**40**)

While these investigations were occurring, researchers in Japan showed that sterically hindered electron-rich trialkylphosphines such as tri(*tert*-butyl)phosphine[132] were extremely effective at promoting the amination of aryl halides, including aryl chlorides. Afterwards, Hartwig disclosed that the best activity was obtained when the tri(*tert*-butyl)phosphine to palladium ratio was strictly held to 1:1 (rather than the 2:1 or greater typically seen with other types of phosphines), and that the scope of this catalyst system could be expanded to include the coupling of a variety of aryl halide substrates with various nitrogen coupling partners.[133] This strict ratio can be enforced through the use of Pd(I) dimers such as (**27**), which promote the rapid amination of aryl chlorides and bromides at room temperature.[95]

The next generation of catalysts combined the structural elements discussed in the previous paragraphs. In particular, Hartwig noted that dppf analog (**41**) promoted room temperature amination of aryl bromides and iodides, and elevated-temperature aminations of aryl chlorides and tosylates.[134] Soon afterwards, Buchwald reported similar activity with (**42**), which incorporated chelation through a nitrogen atom.[135] Guram and coworkers also reported effective amination of chloride substrates with (**25**), which similarly promotes chelation through a nearby oxygen atom.[136] A significant step forward was Buchwald's development of phosphinobiphenyl ligands (e.g. (**23**)) which provide for catalytic activity and generality in scope similar to tri(*tert*-butyl)phosphine with the additional advantage of being air stable.[137]



(**41**)



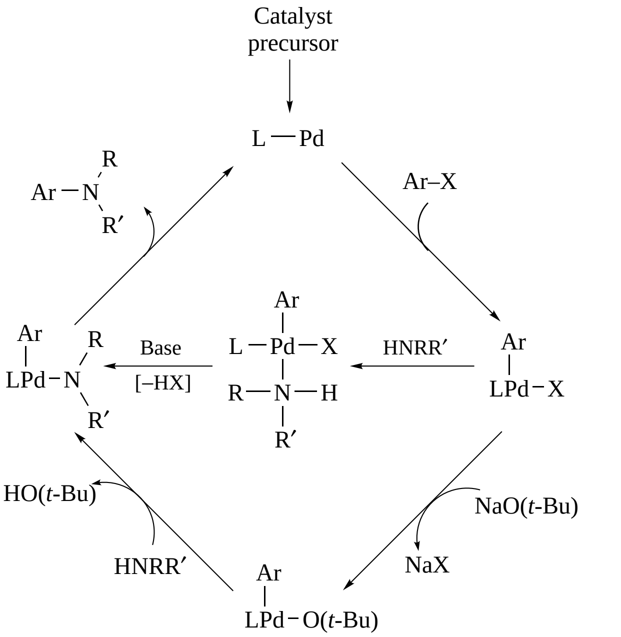
(**42**)

As was the case in the other coupling reactions, nonphosphine-based catalysts have also been applied in amination chemistry. In particular, N-heterocyclic carbenes such as (**9**) have provided successful results for a wide variety of amination transformations.[18,19] Similarly, catalysts based upon phosphinous acid ligands (e.g. (**11**)) have also found success in the amination of aryl chloride substrates.[138]

The amination of aryl chlorides was first accomplished utilizing the palladacycle catalyst (**12**).[139] This initial success spurred a significant amount of research that has gone into the synthesis and study of various palladacycles in order to see if the activity of this type of catalyst could be improved further.[36,97] Recently, systems that consist of a palladacycle plus an added ligand have proven to be some of the most active yet. The theory here is that these species act as precursors to the actual Pd–L catalysts in which, once again, the P:Pd ratio is restricted to its optimal 1:1 value.[98]

8.3 Recent Mechanistic Insights

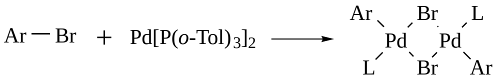
A general mechanism for the palladium-catalyzed amination of aryl halides is presented in Scheme 7.[122] This picture has been developed from studies performed largely upon isolated complexes, with the oxidative addition and reductive elimination steps being investigated in the greatest detail. On



Scheme 7 General mechanism for catalytic amination of organic electrophiles

the face, this process does not seem to be markedly different from the general mechanism cited for carbon–carbon bond forming cross-coupling reactions. However, the fact that many nontraditional catalysts are used for amination reactions suggests that many subtle mechanistic differences, leading to less subtle differences in reactivity, should operate for the different catalyst systems.

For the case of tri(*o*-tolyl)phosphine-ligated catalysts, the upper pathway appears to predominate. Oxidative addition occurs first via loss of a ligand from the bisphosphine precursor to form the oxidative adduct, which exists as a dimer bridged through the halogen atoms (equation 33).[122] This dimer is broken up by amine, the coordination of which to palladium renders its proton acidic. Subsequent deprotonation by base leads to the amido complex, which can then reductively eliminate to form the product. When *tert*-butoxide is used as the base, the rate is limited by formation of and reductive elimination from the amido complex, while for the stronger hexamethyldisilazide, the rate-determining step appears to be oxidative addition.[126]



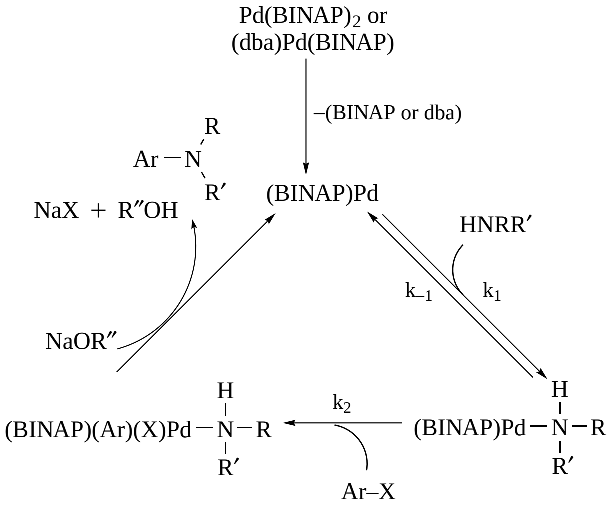
(33)

For the case of chelating phosphines, Hartwig noted that palladium alkoxide complexes can be formed by treatment of the corresponding halides with base, and that amido complexes can, in turn, be formed from the alkoxide.[122] This observation opened the possibility that alkoxide intermediates lie on the catalytic cycle (lower pathway in Scheme 7). Van Leeuwen and coworkers studied the kinetics for the amination of aryl triflates and bromides using different Xantphos catalyst systems.[140] For triflate amination, they found the rate to be first order in amine and *tert*-butoxide, but zero order in aryl triflate. From this, they concluded that a mechanism similar to the upper pathway in Scheme 7 was operating, with the deprotonation of coordinated amine being the rate-determining step. For aryl bromides, however, the rate was dependent on the concentration of *tert*-butoxide, but not amine or aryl bromide. Thus, under these conditions, the lower pathway – with the replacement of halide by *tert*-butoxide as the rate-limiting step – was postulated to be the operating mechanism.

Hartwig and coworkers have studied the amination reaction of aryl halides catalyzed by $Pd(BINAP)_2$ and $Pd(dppf)_2$.[141] They similarly observed kinetics that were zero order in aryl halide; however, their rates were independent of the concentrations of base and amine. From this, they suggested a mechanism in which loss of a chelating ligand (prior to oxidative addition) was the rate-determining step. Furthermore, NMR evidence led them to suggest that $Pd(BINAP)_2$ was the resting state of the catalytic cycle, as predicted from the results of their kinetics experiments. However, in a subsequent paper, they found that the rate did depend upon aryl halide at higher substrate concentrations, suggesting that another mechanism may be operating under these conditions.[142]

More recently, Blackmond, Buchwald, and coworkers investigated the kinetics of catalytic aminations via in situ reaction calorimetry.[143] They maintained that the apparent zero-order kinetics observed by others was in fact caused by an induction period during which the active catalytic species was gradually introduced into the mechanistic cycle. For the case of $Pd(BINAP)_2$, they argued that this complex was external to the catalytic cycle, with the active catalyst being the monoligated species (which enters the cycle via a slow dissociation of BINAP from $Pd(BINAP)_2$). Furthermore, they observed rates that were dependent upon the concentrations of both aryl halide and amine (though not on base), suggesting a mechanism in which amine coordinates to palladium prior to oxidation addition of the aryl halide (Scheme 8).

Others have investigated the kinetics of amination reactions mediated by catalyst systems employing the new electron-rich monodentate ligands. In particular, Hartwig has shown that for catalysis by a 1:1 palladium to tri(*tert*-butyl)phosphine system, a mechanism in which oxidative addition of aryl chlorides follows coordination of base to the palladium competes with the standard nonanionic pathway.[144] Finally, Caddick, Cloke, and coworkers have studied amination reactions of aryl chlorides performed by palladium complexes of N-heterocyclic carbene ligands.[145] They found the rate to be limited by the oxidative addition step, which occurs first through the dissociation of an NHC ligand.



Scheme 8 Modified amination mechanism involving amine coordination prior to oxidative addition

9 APPLICATIONS

Discoveries made in the late 1970s of electrical conductivity in conjugated polymers spawned a monumental interest in the study of these materials, which are ideally suited for synthesis via cross-coupling reactions. Yamamoto was the first to realize this possibility with a regiochemically defined synthesis of poly(*p*-phenylene) formed via the Kumada–Corriu protocol.[146] Since then, various cross-coupling reactions have been applied in condensation polymerization reactions,[147,148] with the Suzuki[149] and Sonogashira[150] protocols gaining the most widespread use.

Cross-coupling reactions have also seen increasing utilization in the synthesis of natural products,[151] as well as in the generation of combinatorial libraries[152] for both pharmaceutical[153] and materials[154] applications. Finally, other reviews note the importance of cross-coupling reactions in the formation of porphyrins[155] as well as in the industrial synthesis of commercial pharmaceuticals[156] and industrial fine chemicals.[157]

10 CONCLUSIONS AND FUTURE OUTLOOK

Given the prolific use of cross-coupling chemistry in such a wide array of applications, it is easy to see that these reactions have matured remarkably from the academic curiosity they were a mere 20–30 years ago. As industry comes to rely more heavily on this chemistry, future developments will doubtlessly be driven by economics. Strategies for catalyst recovery and recycling have been developed, but there is clearly room for improvement. Furthermore, the fact that palladium is one of the most expensive elements in the periodic table will drive the search for systems based upon more abundant metals, an area of research that we are now just beginning to explore. Thus, while our understanding of this chemistry has indeed come a long way, there is still a great deal more to be learned.

Glossary

M41S: A family of mesoporous materials including MCM-41, MCM-48, and MCM-50
MSU-1,2,3,4: Michigan State University no. 1, 2, 3, 4, a series of wormhole mesoporous materials prepared in the presence of nonionic surfactants
Pluronic: polyethylene oxide–polypropylene oxide triblock surfactant, $(EO)_m(PO)_n(EO)_m$, for example, P123 = $(EO)_{20}(PO)_{70}(EO)_{20}$
SBA-x: Santa Barbara no. x, a series of mesoporous materials
Tergitol: alkyl–polyethylene oxide surfactant, $C_nH_{2n+1}(EO)_m$
Triton-X: alkylaryl–polyethyleneoxide surfactant, $C_nH_{2n+1}Ph(EO)_m$

Abbreviations

2D or 3D = 2 or 3 dimensional; 3DOM = 3-dimensional ordered macroporous materials; CMK-1,2, 3 = Carbon mesostructured by KAIST (Korea Advanced Institute of Science and Technology) no. 1, 2, 3; CTAB = Cetyltrimethylammonium bromide, $[C_{16}H_{33}N(CH_3)_3]^+Br^-$; HMS = Hexagonal molecular sieves. ICF-*m* = Inorganic chalcogenide framework, no. *m*; MCF = Mesostructured cellular foams; MCM-41, 48, 50 = Mobil composition of matter no. 41, 48, and 50; MMS = Mesoporous molecular sieves; PCH = porous clay heterostructures; SEM = Scanning electron microscopy; TEM = Transmission electron microscopy; TEOS = Tetraethoxysilane.

1 INTRODUCTION

Porous materials are of great interest because of their wide commercial applications as ion exchangers, adsorbents, and catalysts. There are a variety of porous materials differing in chemical composition, pore geometry and size, and degree of crystallinity. According to the IUPAC definition,[1] porous materials are classified into three groups on the basis of pore size: microporous materials are porous solids with pore size below 2 nm, mesoporous materials are porous solids with pore size between 2 and 50 nm, and macroporous materials are those with pore size larger than 50 nm (Figure 1).

Pores with different sizes show characteristic physical adsorption effects as manifested in the isotherm.[2] The isotherm shows the relationship between the amount of a given gas taken up or released by a solid as a function of the gas pressure under a constant temperature. The type-I isotherm shows a steep increase at very low pressures and a long saturation plateau and is characteristic of microporous materials. The type-IV isotherm exhibits a steep increase at high relative pressure and, in many cases, a hysteresis loop, which is associated with capillary condensation in mesopores.

The development of microporous materials started in late 1940s with the synthesis of synthetic zeolites by Barrer, Milton, Breck, and their coworkers. Some commercially important microporous materials such as zeolites A, X, and Y were made in the first several years of Milton and Breck's work. In the following 30 years, zeolites with various topologies and chemical compositions were prepared, culminating in the synthesis of ZSM-5 and its aluminum-free pure silica form in 1970s. A breakthrough leading to an extension of crystalline microporous materials to nonsilicates occurred in 1982 when Flanigen *et al.* reported the synthesis of aluminophosphate molecular sieves. Since the late 1980s and the early 1990s, crystalline microporous materials have been made in many other compositions including chalcogenides and metal–organic frameworks.

Prior to the 1990s, materials with pore size in the meso range such as silica gels and activated carbons show disordered pore structure with a broad distribution of pore size. In 1992, by using cationic surfactants as template, Mobil scientists

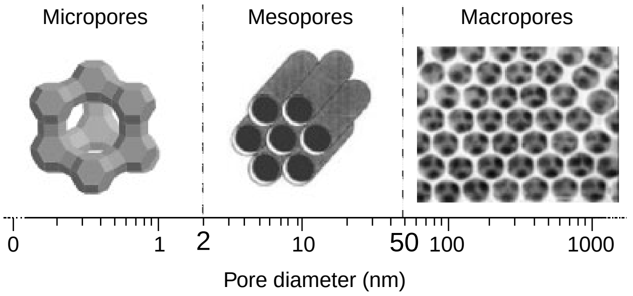

Figure 1 The IUPAC classification of porous materials on the basis of pore diameter

prepared a family of mesoporous silicas (denoted M41S) with hexagonal and cubic symmetry and highly uniform pore sizes ranging from 2 to 10 nm. There has been a widespread interest in ordered mesoporous materials since the discovery of M41S.

Following the discovery of ordered mesoporous materials, the templated approach was also employed for the synthesis of ordered macroporous materials. Macroporous materials with uniform pore sizes are predicted to have useful optical properties and may have applications as photonic crystals with optical band gaps.[3]

This article focuses on ordered mesoporous materials that have undergone a rapid growth in the past decade. For completeness, the concurrent progresses in the areas of crystalline microporous and ordered macroporous materials are briefly described.

2 MICROPOROUS MATERIALS[4]

Microporous materials are formed with hydrated inorganic cations or organic species located within cavities of the extended inorganic or inorganic–organic hybrid host framework. Extra-framework organic species are usually protonated amines, quaternary ammonium cations, or neutral solvent molecules. Dehydration (or desolvation) and calcination are two methods frequently used to remove extra-framework species and generate microporosity.

Even though crystalline microporous materials include those with pore size between 10 and 20 Å (called extra-large pore materials), few of them have a pore size within this range. This limits the applications of microporous materials to small molecules. There has always been a desire to increase the pore size of a crystalline material to more than 10 Å while maintaining adequate thermal or hydrothermal stability required for various applications.[5] Recent advances in chalcogenide and metal–organic framework materials have shown much promise for the preparation of extra-large pore materials.

In addition to the desire for an increase in the pore size, there has been a strong interest in generating multifunctional materials in which crystalline microporosity is integrated with other useful properties such as framework chirality, ferromagnetism, semiconductivity, or ion conductivity.[6]

2.1 Microporous Silicates and Germanates

Microporous materials are typified by natural and synthetic zeolites that are crystalline 3D aluminosilicates with open channels or cages. Synthetic and structural concepts of zeolites have to a large extent shaped the development of microporous materials during the past 50 years. For example, the use of organic structure-directing agents in the synthesis of high-silica zeolites and their all-silica polymorphs contributed to the later discovery of aluminophosphate molecular sieves. A comprehensive review on the synthesis and structure of zeolites and related materials has been given by Dyer and will not be repeated here.[7]

The commercial importance of zeolites has prompted numerous efforts aimed at the synthesis of new microporous materials. One commonly used approach is through the substitution of framework cations (i.e. Al^{3+} or Si^{4+}) in zeolites by other cations such as Ga^{3+}, Ge^{4+}, and P^{5+}. Because of the close resemblance to zeolites, gallosilicates and alumino- (or gallo-) germanates were among the earliest nonzeolite microporous materials being prepared. In general, gallosilicates and alumino- (or gallo-) germanates do not possess framework topologies not previously found among zeolites. However, the recent use of organic structure-directing agents in the synthesis of germanates has resulted in a number of materials with unprecedented framework topologies.[8]

In general, each compositional system has a unique range of the T–O bond length and the T–O–T angle (where T refers to tetrahedral atoms) and has its own preference for certain types of framework topology. For example, structures with strained double four-ring units are more likely to occur as germanates. Another example is the synthesis of UCSB-7. It could be prepared under a variety of experimental conditions as either a gallogermanate or aluminogermanate.[9] However, it has not been prepared as a silicate. It is thus not surprising to find that by incorporating the germanium source into the synthesis mixture of silicates, new microporous materials could be synthesized.[10]

2.2 Microporous Phosphates and Arsenates[11]

The synthesis of aluminophosphate molecular sieves in 1980s represents a breakthrough in the development of microporous materials. Since then, much of the worldwide synthetic efforts have been directed toward nonsilicate microporous materials. Many novel framework topologies could be found with phosphates, and many other elements could be incorporated into phosphates to produce additional new framework topologies or new compositions.

Aluminophosphate molecular sieves, as originally prepared, have a neutral framework and generally require organic amines or alkylammonium cations as extra-framework species. However, it was soon discovered that both Si^{4+} and many metal cations (in particular divalent metal cations) could be incorporated into the aluminophosphate framework to generate a negative framework similar to high-silica zeolites. A complete substitution of Al^{3+} sites by divalent cations such as Zn^{2+} or Be^{2+} gives a series of zinco- or beryllo-phosphates that are similar to low-silica zeolites. The negative framework charge and the associated extra-framework charge-balancing cations are useful for many applications of microporous materials; however, the stability of microporous materials generally decreases with increasing negative charge on the framework.

Of great significance is the synthesis of an extra-large pore microporous material in the aluminophosphate composition. VPI-5, a hydrated aluminophosphate, has a unidimensional channel with a window size formed by 18 tetrahedral cations. At the time of its discovery, the largest window size for zeolites was only 12. Thus, the discovery of VPI-5 inspired new efforts aimed toward the synthesis of extra-large pore microporous materials. Since then, a number of extra-large pore phosphates and silicates have been synthesized. Chalcogenide and metal–organic framework materials offer new promises for the development of extra-large pore materials.

Compared with microporous phosphates, there are few microporous arsenates. The syntheses and structures of arsenates are similar to those of phosphates when divalent metal cations such as Zn^{2+} and Be^{2+} are employed as framework tetrahedral atoms.[12] However, there is very little similarity between alumino- (or gallo-) arsenates and the corresponding phosphates. In the intermediate range where both divalent and trivalent metal cations are present, some similarities between arsenates and phosphates have been observed.[13]

2.3 Microporous Sulfides and Selenides[14,15]

The replacement of framework anions (i.e. O^{2-}) with chalcogens (e.g. S^{2-}) represents a more recent approach for generating microporous materials. The efforts to make microporous chalcogenides began with germanium or tin sulfides. However, germanium or tin sulfides do not form microporous materials similar to all-silica polymorphs of zeolites. It was later found that the incorporation of low-valent cations such as Mn^{2+} into the Ge–S composition helped to generate 3D frameworks.

Three-dimensional sulfide and selenide frameworks have also been made in the indium and gallium chalcogenide compositions. In addition, the incorporation of mono or divalent cations into indium or gallium chalcogenide compositions has produced some new framework chalcogenides often based on the assembly of chalcogenide clusters.

The combination of trivalent (M^{3+}) and tetravalent (M^{4+}) cations in chalcogenides has led to a series of framework chalcogenides, among which the microporous behavior has been demonstrated. The M^{4+} to M^{3+} ratio in these chalcogenides, however, can be much smaller than that in zeolites and so far falls within the range from about 0.21 to 0. Despite the low M^{4+} to M^{3+} ratio, some sulfides in this series possess adequate stability toward ion exchange and thermal treatment. The Cs^{+} exchanged UCR-20GaGeS-TAEA (TAEA = tris(2-aminoethyl)amine) exhibits the type-I isotherm and its pore size is as large as 9.5 Å.[16]

Similar to zeolites, chalcogenides could be prepared with either inorganic or organic cations as extra-framework species. A family of hydrated sulfides and selenides were made recently. These materials, denoted as ICF-*m*, were prepared in aqueous solutions from simple inorganic salts. One of the most interesting properties of these inorganic chalcogenides is fast-ion conductivity at room temperature and moderate to high humidity. In particular, lithium compounds such as ICF-22 and ICF-26 exhibit ionic conductivity significantly greater than previously known crystalline lithium compounds.[6]

2.4 Inorganic–Organic Hybrid Microporous Materials[17]

A rapidly developing field in the microporous materials involves metal–organic framework materials. These materials are prepared by using multidentate organic ligands (e.g. nitriles, carboxylates, amines) to link together metal cations with a low valence (usually divalent cations such as Zn^{2+}). The resulting materials are now called metal–organic frameworks or MOFs.

One promising application of metal–organic frameworks is in the area of gas storage. Several metal–organic framework materials have been found to have a high capacity for methane or hydrogen storage. Through proper design of organic ligands and their assembly with metal centers, noncentrosymmetric or chiral frameworks can be prepared. Moreover, because MOFs generally involve transition metal cations, they open up new opportunities in the design of magnetic microporous materials.

3 MESOPOROUS MATERIALS[18,19]

3.1 Synthesis Pathways and Formation Mechanisms[20,21]

3.1.1 Base Synthesis

The synthesis of ordered mesoporous materials in the past decade greatly expanded the range of ordered porous materials and opened up many new opportunities in the design and applications of materials. Of particular importance is the synthetic methodology that is used for the preparation of these materials. Prior to this, the synthesis of porous materials generally involved the use of individual molecules or hydrated clusters of simple ions. In the synthesis of ordered mesoporous materials, however, it is the assembly of surfactant molecules that directs the condensation of inorganic precursors.

Inspired by the similarity between M41S and surfactant/water liquid crystal phases, Mobil scientists proposed two general pathways (Figure 2).[20,21] The first model suggests that the water-surfactant liquid crystal phase serves as the structure-directing element. This model could not explain observations that surfactant-silicate mesophases could form at surfactant concentration as low as 1%, which is too low to form a liquid crystal phase. The second model suggests that the presence of the silicate somehow mediates the ordering of surfactant micelles into the hexagonal (or cubic Ia3d) arrangement. This model was later further developed by Monnier *et al.* into a more general cooperative assembly mechanism.

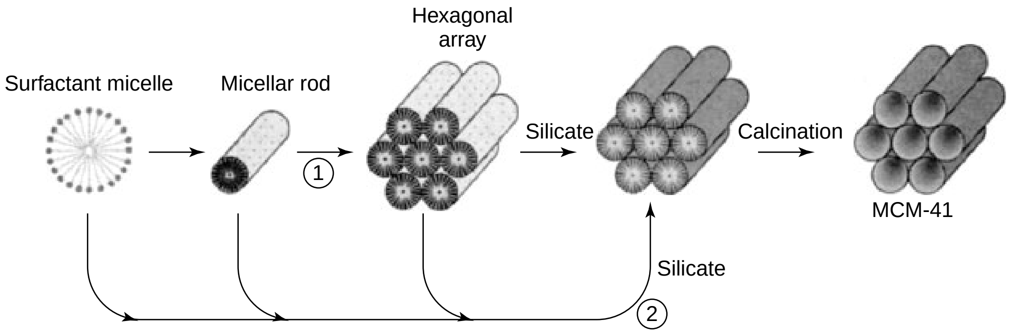

Figure 2 The proposed two possible pathways, (1) and (2), to the formation of MCM-41. (Reprinted with permission from Ref. 21. © 1992 American Chemical Society)

The model by Monnier *et al*. presented a more detailed mechanism by which silicate species can prompt the formation of inorganic–organic composite mesophases.[22] This mechanism suggests that the direct cooperative multidentate binding between cationic surfactants and negatively charged silicate oligomers, preferential polymerization of silicates at the interface, and charge-density matching across the silicate-surfactant interface are crucial factors for the formation of mesophases.

3.1.2 *Acid Synthesis*

The direct interaction between surfactants and inorganic precursors was later found to be not the only pathway for the formation of mesophases. A major discovery following Mobil's work is the synthesis of mesophases through the assembly of cationic inorganic species with cationic surfactants in acidic solutions. Here, the interaction between cationic silica species and cationic surfactant headgroups is suggested to be mediated by halide anions.

The synthetic results under both basic and acidic conditions allowed Huo *et al*. to propose a generalized mechanism[23,24] for the formation of mesostructured inorganic/organic composites. This mechanism involves electrostatic interactions between the inorganic precursor I and the surfactant headgroup S (Figure 3). Both direct and mediated modes are possible between charged inorganic precursors (cationic I^+, anionic I^-) and charged surfactant headgroups (cationic S^+, anionic S^-), resulting in four synthetic routes: (S^+I^-), (S^-I^+), ($S^+X^-I^+$), and ($S^-M^+I^-$). The (S^+I^-) and ($S^-M^+I^-$) routes occur when the base conditions are used, whereas the (S^-I^+) and ($S^+X^-I^+$) routes are associated with the acid synthesis. The discovery of the acid synthesis approach and the four proposed pathways has had a profound impact on the later development of mesoporous materials.

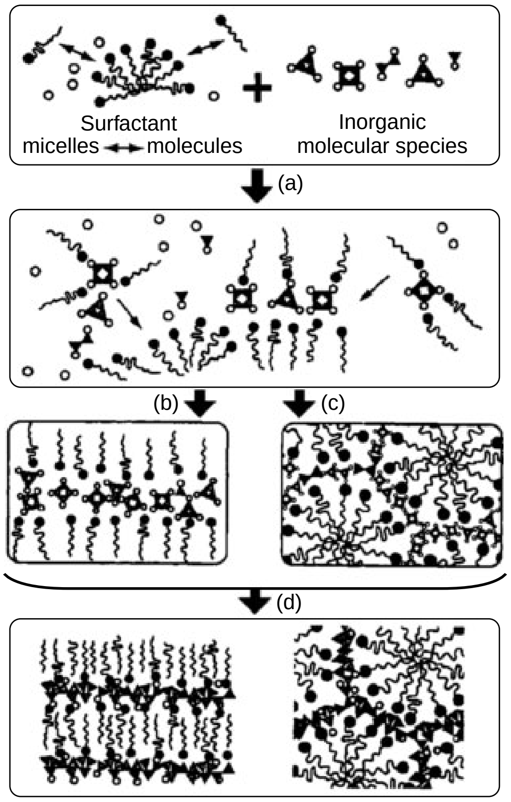

Figure 3 Schematic illustration of interaction between surfactants and inorganic species. (Reprinted with permission from Ref. 24. © 1994 American Chemical Society)

Zhao *et al*.[25,26] greatly extended the utility of the acid synthesis approach when they used amphiphilic triblock copolymers to prepare a series of periodically ordered mesoporous silicas, SBA-*n* ($n = 11$, 12, 14, 15, and 16), with uniform pore sizes well beyond 100 Å. Prior to this work, mesoporous materials with pore size in this range either did not exist or had much lower ordering compared to SBA-*n*. The formation of SBA-*n* from block copolymers was proposed to go through the (S^0H^+) (X^-I^+) pathway in the acidic media involving a combination of electrostatic and hydrogen-bonding interactions.[26] The use of the acidic media

is a major difference between this work and the earlier work by Pinnavaia *et al.*

In the above work by Zhao *et al.*, when the amount of the swelling agent (i.e. 1,3,5-trimethylbenzene) was gradually increased, a structural transition from the hexagonally ordered mesophases into mesostructured cellular foams (MCFs) occurred.[27] The MCFs were made from a system composed of aqueous HCl, triblock copolymer P123, 1,3,5-trimethylbenzene (TMB), and ethanol. Tetraethoxysilane (TEOS) was hydrolyzed at the organic–inorganic interface at the surface of P123-coated TMB droplets in aqueous HCl to form hydrophilic cationic silica species that subsequently condensed around the organic assemblies. The MCFs possess uniform spherical cells with controllable diameter ranging from 24 to 42 nm, depending on the amount of TMB and aging temperature.[28]

3.1.3 Neutral Synthesis

Pinnavaia *et al.*[29] used neutral alkylamines as templates to form disordered mesoporous silica, named hexagonal molecular sieves (HMS). The S^0I^0 formation mechanism was proposed between neutral amine micelles (S^0) and neutral inorganic precursors (I^0). The interactions between S^0 and I^0 were assumed to be hydrogen bonding. The resulting HMS has a 'worm-like' pore structure, with thicker framework walls and smaller X-ray scattering domain sizes compared to M41S.

Mesoporous silica could also be prepared using nonionic amphiphilic surfactants (N^0)[30] with a polyethylene oxide (PEO, EO_n) hydrophilic headgroup. Through the proposed neutral N^0I^0 assembly pathway, worm-like disordered mesoporous silica or amorphous silica are formed using nonionic PEO surfactants or triblock copolymers. The low structural order may be related to the absence of sufficiently strong electrostatic or hydrogen-bonding interactions.

The above N^0I^0 pathway was later modified by Pinnavaia *et al.* by introducing small metal cations ($M^{n+} = Li^+$, Co^{2+}, Ni^{2+}, Mn^{2+}, and Zn^{2+}) into the assembly process, affording mesoporous silica with improved structural order.[31] This approach was denoted $(N^0M^{n+})I^0$, wherein hydrogen bonds were formed between cationic metal complexes containing nonionic $R(EO)_nH$ surfactants (N^0) and the neutral inorganic precursors (I^0). Electrostatic forces were enhanced through the complexation of small M^{n+} cations by the EO groups of N^0. As summarized in Table 1, various types of interactions between the organic surfactants and the inorganic precursors, including electrostatic charge matching (S^+I^-, S^-I^+, $S^+X^-I^+$, and $S^-M^+I^-$), H-bonding (S^0I^0 and N^0I^0), covalent interactions or their combination ((S^0H^+) (X^-I^+) and $(N^0M^{n+})I^0$), may play significant roles in the formation of mesostructured materials.

3.1.4 Ligand-assisted Templating Mechanism

Antonelli and Ying prepared hexagonally packed mesoporous niobium oxide (2D-hexagonal, *p*6m), named Nb-TMS1, using alkyl amines as the structure-direct agent.[32] A new mechanism called 'ligand-assisted templating' (LAT) was suggested. The proposed mechanism involves direct covalent interactions between the Nb alkoxide precursor and the amine ligand through the N–Nb bond prior to the hydrolysis and condensation of the preformed alkoxide-surfactant precursor. After removal of the surfactant by extraction, mesostructures are retained. This approach provides control of mesostructured phases by simple adjustment of the metal/surfactant ratio, resulting in a family of mesoporous transition metal oxides ('$P6_3/mmc$' hexagonal Nb-TMS2, cubic *Pm*3*n* Nb-TMS3, and lamellar Nb-TMS4).[33]

3.1.5 Direct Liquid Crystal Templating Mechanism[34]

Mesoporous materials described so far are prepared under surfactant concentrations that are generally too low to form long-range ordered lyotropic liquid crystal phases in a surfactant/water system. The coorganization between inorganic and organic species is prompted by various forms of interfacial interactions, and in general, the stronger the interaction, the more ordered the resulting mesophases.

Mesoporous materials can also be prepared at high surfactant concentrations at which long-range liquid crystals can form even in the absence of inorganic precursors. Attard *et al.* demonstrated this approach by using the liquid crystal phases of the nonionic surfactants such as octaethylene glycol monododecyl ether ($C_{12}EO_8$) or octaethylene glycol monohexadecyl ether ($C_{16}EO_8$) as templates. This synthesis approach is reminiscent of pathway 1 of the original liquid crystal templating mechanism for MCM-41 proposed by Mobil scientists.

In Attard's approach, tetramethylorthosilicate (TMOS) was hydrolyzed and condensed in the aqueous domain of the liquid crystal phase at pH of about 2, leading to mesostructured hexagonal, cubic, or lamellar silica. Methanol from the hydrolysis of TMOS destroys the long-range order of the liquid crystal; however, upon the removal of methanol, the lyotropic liquid crystal is restored and serves as the template phase for the further condensation of silicates. The resulting pore system replicates the shape of the lyotropic mesophase, so this process is also termed 'nanocasting'.

Feng *et al.* prepared a series of periodically ordered mesoporous silica by using high concentrations of triblock copolymers in multicomponent ternary (surfactant/cosurfactant/water) and quaternary (surfactant/cosurfactant/oil/water) systems.[35] One key feature to Feng's approach is that methanol is removed under vacuum prior to the mixing between silicate precursors and surfactants. Thus the lyotropic liquid crystal phase, once formed, maintains its long-range ordering throughout the whole silicate condensation process. The removal of methanol prior to mixing with surfactant/cosurfactant/oil is also advantageous because the presence of surfactant, cosurfactant, or oil could make the

efficient removal of methanol difficult. The use of cosurfactants and oils provides additional variables for the control of a number of structural features of resulting mesophases including pore size and wall thickness.

During the direct liquid crystal templating, the condensation of inorganic precursors occurs in the aqueous domain of preformed lyotropic liquid crystals. With this approach, the interaction between inorganic precursors and surfactant headgroups could disrupt the long-range order of liquid crystals and should therefore be minimized. For silicates, performing reactions at pH of about 2, which is the isoelectric point of silicates, helps to reduce such interaction.

3.1.6 Evaporation-induced Self-assembly (EISA)

Brinker *et al.* developed a simple evaporation-induced self-assembly (EISA) process that allows the rapid production of patterned porous or nanocomposite materials in the form of films, fibers, or spheres.[36] Starting from a homogeneous solution of soluble silica and surfactant below the critical micellar concentration, evaporation of ethanol increased surfactant concentration, driving self-assembly of silica-surfactant micelles and their further organization. By adjusting the initial alcohol/water/surfactant molar ratio, 2D hexagonal, cubic, 3D hexagonal, and lamellar silica-surfactant mesophases could be made.

3.2 Structure[37]

The pore structure, such as pore geometry and pore size, of mesoporous materials is one of the key parameters for practical applications, especially those dependent on size and shape selectivity and ready access to porosity. Considerable efforts have been devoted to control the pore structure of mesoporous materials.

3.2.1 Pore Geometry Control

The pore geometry is associated with the symmetry of mesophases and can be ill defined when the ordering of the mesophases is very low. However, highly ordered mesophases can be prepared under a variety of experimental conditions. By tuning synthetic parameters, it is possible to control the topological features of resulting mesophases. The original Mobil work led to the synthesis of a 2D ordered hexagonal

phase with unidimensional channels ($p6$m) and a 3D ordered cubic phase with 3D bicontinuous channels (Ia3d). The use of the acidic medium and the surfactant $C_{16}H_{33}N(C_2H_5)_3^+$ or $C_{16}H_{33}N(C_2H_5)(C_5H_{10})^+$ (cetylethylpiperidinium) allowed Huo *et al.* to discover a new cubic phase (Pm3n), SBA-1.[24] In addition, SBA-2[38] (acid synthesis) and SBA-7[39] (base synthesis) with previously unknown pore structure were also prepared by using divalent quaternary ammonium surfactants with the general formula $C_nH_{2n+1}N(CH_3)_2(CH_2)_sN(CH_3)_3{}^{2+}$ (denoted C_{n-s-1}, $n = 12, 13, 16, 18, 20$, $s = 2, 3, 6$). Two new cubic mesoporous silica SBA-11 (*Pm*-3*m*) and SBA-16 (*Im*-3*m*) have been synthesized by Zhao *et al.* from $C_{16}EO_{10}$ and $EO_{106}PO_{70}EO_{106}$,[26] respectively, in addition to SBA-12 that is similar in structure to SBA-2.

The use of surfactant molecules with different charges and geometrical features is an effective way to control the structure of mesophases. According to the cooperative self-assembly formation mechanism, inorganic species interact with surfactant micelles at the interface through electrostatic interaction or hydrogen bonding. So phase transitions are expected to be associated with changes in the curvature of interface. In classical micelle chemistry, micellar organization is related to the local effective surfactant packing parameter, $g = V/a_0l$, where V is the total volume of the hydrophobic chains, a_0 is the effective headgroup area at the micelle surface, and l is the kinetic surfactant tail length. The expected mesophase depends on the value of g (Table 2). Huo *et al.* first applied this concept to explain and predict product structure and phase transition.[38,40]

Other factors that affect the structure of mesophases include the concentration ratio between surfactants and inorganic precursors. For example, MCM-41 was prepared at a $C_{16}H_{33}(CH_3)_3N^+$/Si ratio of less than 1. As the $C_{16}H_{33}(CH_3)_3N^+$ /Si ratio increases beyond 1, the cubic phase (Ia3d) can be produced. Similarly, Nb-TMS1 ($p6$m), Nb-TMS2 ($P6_3/mmc$), Nb-TMS3 (*Pm*-3*n*), and Nb-TMS4 ($p2$) were prepared at various surfactant to Nb ratios.[33]

3.2.2 Pore Size Engineering

Surfactant Chain Length. Under comparable reaction conditions, the pore size generally increases with the chain length of surfactants. For example, when quaternary ammonium surfactants (C_nTMABr) with different alkyl tails ($n = 8, 9, 10, 12, 14$, and 16) were used, the pore size of resulting materials increased from 18 to 37 Å with the increase in the chain length.[21]

Table 2 Different g values and related mesophases

g	Mesophase	Space group	Examples
<1/3	3D hexagonal	$P6_3/mmc$	SBA-2
1/3	Cubic	*Pm*3*n*	SBA-1
1/3–1/2	2D hexagonal	*p*6*m*	SBA-3, MCM-41
1/2–2/3	Cubic	*Ia*3*d*	MCM-48
>1	Lamellar	*p*2	MCM-50

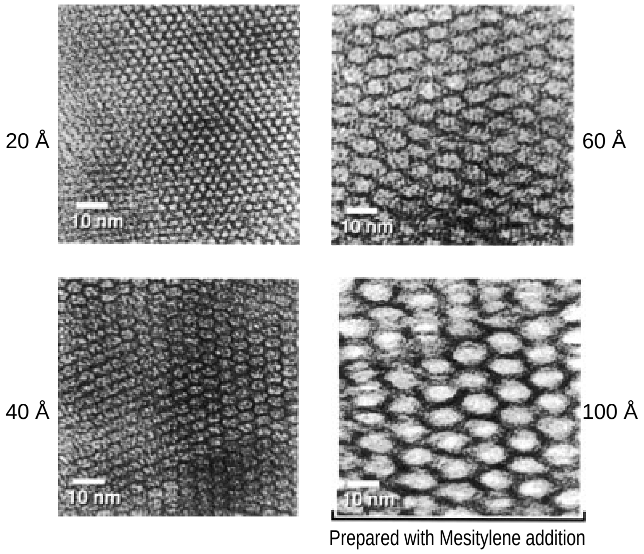

Figure 4 TEM images of MCM-41 with different pore sizes up to 100 Å. (Reprinted with permission from Ref. 21. © 1992 American Chemical Society)

Addition of Swelling Agents. In Mobil's original work on M41S, 1,3,5-TMB was used as the swelling agent to increase the pore size of mesoporous materials. By adjusting the TMB/C_{16}TMABr ratios, the pore size of MCM-41 was enhanced up to 100 Å (Figure 4). Other aromatic hydrocarbons, alkanes, and amines have also been used as pore expanders. Owing to their hydrophobicity, organic auxiliaries can be incorporated into the core of micelles to increase the size of micelles. The increase in the pore size of resulting mesophases is related to this phenomenon.

Temperature[41]. The N^0I^0 synthetic pathway can be used to control the pore size by choice of the assembly temperature. In the case of MSU-1 silica assembled with Tergitol 15-S-12, pore size increases from 21 to 45 Å when the synthesis temperature is increased from 25 to 65 °C. With increasing temperature, PEO segments of the surfactant become more hydrophobic, thus decreasing the size of hydrophilic headgroups and, consequently, enlarging the diameter of hydrophobic core, which determines the pore size. The hydrogen bonding between the shortened hydrophilic PEO segments of surfactants and inorganic species, which is related to the wall thickness, can become weaker at elevated temperatures. This mechanism is supported by the evidence of a decrease in the wall thickness accompanied by an increase in the pore size.

Postsynthesis Treatment[42]. As-synthesized mesoporous silica can contain a significant concentration of the OH^- group, particularly if made at low synthesis temperatures and in short times, and their pore size can be modified by the postsynthesis treatment. Tailoring the pore size through this method is commonly achieved by hydrothermal restructuring of as-synthesized materials at a higher temperature. A gradual pore size expansion to about 70 Å was observed by treatment of as-made MCM-41 in the mother liquid at 150 °C for a period of 1 to 10 days.[43] Huo and coworkers found that the pore size of MCM-41 could be enlarged by hydrothermal treatment of the predried, as-made samples at 100 °C, affording high-quality materials with the pore size up to 60 Å.[24]

Water is thought to enter the pore space to solvate the silicate framework, surfactants, and their counterions, leading to silica dissolution, transport, and redeposition. It is shown that the hydrothermal restructuring process is very sensitive to both the temperature and the duration. While an excessive hydrothermal treatment can cause dramatic decreases of pore volumes and surface areas, neutral amines and alkenes generated in situ by the decomposition of some quaternary ammonium surfactants can act as swelling agents. The water-amine postsynthesis treatment provides further support for the swelling effect of neutral amines. Sayari *et al.* reported pore size expansion by up to threefold when as-synthesized MCM-41 was treated in aqueous emulsions of an appropriate long-chain amine, such as *N*,*N*-dimethylhexadecylamine (DMHA).[44] An unprecedented enlargement of pore size (from 31.5 to 250 Å) and pore volume (from 0.85 to 3.31 $cm^3\ g^{-1}$) was achieved by hydrothermal treatment in the presence of dimethyldecylamine (DMDA).[45]

3.3 Composition

3.3.1 Silica and Doped Silica

A large variety of mesoporous silica has been prepared. These mesoporous silicas differ in a number of features including space group symmetry, degree of ordering, pore size and wall thickness, and degree of polymerization. As shown in Table 3, these differences are generated by a number of synthetic factors such as pH, types of surfactants, and auxiliary reagents such as oils and inorganic ions. Many different names exist for mesoporous silica, and these different names designate materials prepared under specific conditions used by different individual research groups.[46–52]

Numerous efforts have been spent on doping silica with other elements, most of which are transition metal elements. In many cases, the goal of these syntheses is to introduce or enhance acidic or redox catalytic activity into mesoporous silica. Depending on the individual element and synthetic procedures, the doping level spans a wide range of values from about 5 to over 3000 for the Si/dopant molar ratio.[54]

3.3.2 Phosphates

Because of the similarity between aluminophosphate and silica molecular sieves, the synthesis of mesoporous silica was soon followed by the efforts aimed toward the synthesis of mesoporous aluminophosphates. Both lamella and hexagonally ordered aluminophosphate mesostructures have been prepared.[55,56]

Recently, Zhao *et al.* proposed that the interaction between two or more inorganic precursors, guided by ‘acid–base pair’ principles, plays an important role in the formation of ordered multicomponent mesoporous structures, in particular phosphates.[57] They suggested that to form multicomponent mesoporous materials, stable pairs of different species during nucleation are necessary. The larger the acidity or alkalinity difference between the metallic and nonmetallic precursors, the more likely that the pairs will form. No extra acid or base is required to adjust the pH of the synthesis system. This method is particularly effective for metal phosphates. A series of mesoporous materials including TiPO, ZrPO, AlPO, NbPO, and CePO were prepared by using this approach.

3.3.3 Metal Oxides

Mesoporous metal oxides encompass a variety of chemical compositions. In general, these compositions are not as stable as mesoporous silica, or they are not as ordered as silica. However, the combination of mesoporosity with other unique properties afforded by these compositions (e.g. semiconductivity, redox activity) has inspired considerable efforts in the synthesis of these mesostructured materials. In the study of synthetic pathways for the formation of mesoporous materials, Huo *et al.* reported a series of mesostructured oxides based on Sb, W, and Al and so on. by using cationic or anionic surfactants.[24] Another significant progress in the templated synthesis of mesoporous oxides was reported by Yang *et al.* when they used block copolymers to synthesize a range of mesoporous oxides including TiO_2, ZrO_2, HfO_2, Nb_2O_5, Ta_2O_5, WO_3, Al_2O_3, SiO_2, and SnO_2.[58] Yang’s approach is also applicable to the synthesis of mixed oxides such as Al_2TiO_y and $ZrTiO_y$. The following gives a discussion of some selected mesoporous oxides.

Titania. Mesoporous TiO_2 is very attractive because of the excellent photocatalytic activity associated with TiO_2. Among the three crystalline polymorphs of titania (anatase, rutile, and brookite), anatase is the most suitable phase for photocatalysis because of its large band gap and suitable redox potential. The early attempts to prepare mesoporous titania used surfactants with phosphate headgroups, and the resulting mesophases contain phosphate groups even after calcinations.[59,60] Phosphorus-free mesoporous titania was reported by Antonelli by using dodecylamine.[61] Using block copolymers, Yang *et al.* reported the synthesis of

Table 3 A summary of various silicate mesophases

Name	Mesophase	Space group	Surfactant	Pathway
MCM-41[20,21]	Hexagonal	*p*6*m*	alkylammonium, e.g. CTAB	S^+I^-
MCM-48[20,21]	Cubic	*Ia*3*d*	alkylammonium, e.g. CTAB	S^+I^-
MCM-50[20,21]	Lamellar	*p*2	alkylammonium, e.g. CTAB	S^+I^-
MSU-1[30]	Wormhole/disordered		Tergitol, e.g. $C_{11-15}EO_9$	S^0I^0
MSU-2[30]	Wormhole/disordered		Triton-X, e.g. C_8PhEO_8	S^0I^0
MSU-3[30]	Wormhole/disordered		Pluronic, e.g. $EO_{13}PO_{30}EO_{13}$	S^0I^0
MSU-4[30]	Wormhole/disordered		Tween	S^0I^0
MSU-G[46]	3D vesicular	L_3	gemini diamines, e.g. $C_{10}H_{21}NH(CH_2)_2NH_2$	N^0I^0
HMS[29]	Wormhole/disordered		amines, e.g. C_8NH_2	N^0I^0
SBA-1[24]	Cubic	*Pm*-3*n*[51]	alkylammonium	$S^+X^-I^+$
SBA-2[38]	3D hexagonal	$P6_3/mmc$	divalent quaternary ammonium	S^+I^-
SBA-3[20]	hexagonal	*p*6*m*	quaternary ammonium (acid synthesis)	$S^+X^-I^+$
SBA-4[39]	lamellar	*P*2		base
SBA-5[39]	cubic	*R*3*c*		base
SBA-6[39]	cubic	*Pm*-3*n*[51]	$18B_{4\text{-}3\text{-}1}$ gemini[a]	base
SBA-7[39]	3D hexagonal	$P6_3/mmc$		$S^+X^-I^+$
SBA-8[53]	2D rectangular	*cmm*	cationic bolaform[b]	S^+I^-
SBA-11[26]	cubic	*Pm*3*m*	alkyl-polyethylene oxide, e.g. $C_{16}EO_{10}$	$(S^0H^+)(X^-I^+)$
SBA-12[26]	3D hexagonal	$P6_3/mmc$	alkyl-polyethylene oxide, e.g. $C_{18}EO_{10}$	$(S^0H^+)(X^-I^+)$
SBA-14[26]	cubic	*Pm*3*n*	alkyl-polyethylene oxide, e.g. $C_{12}EO_4$	$(S^0H^+)(X^-I^+)$
SBA-15[25,26]	2D hexagonal	*p*6*m*	block copolymer, e.g. $EO_{20}PO_{70}EO_{20}$	$(S^0H^+)(X^-I^+)$
SBA-16[26]	cubic	*Im*-3*m*[51]	block copolymer, e.g. $EO_{106}PO_{70}EO_{106}$	$(S^0H^+)(X^-I^+)$
FDU-1[47]	cubic, caged	*Fm*3*m*[52]	$EO_{39}BO_{47}EO_{39}$	$(S^0H^+)\ (X^-I^+)$
KIT-1[48]	disordered		$[C_{16}H_{33}N(CH_3)_3]^+Cl^-$	S^+I^-
FSM-16[49]	layered		$[C_{16}H_{33}N(CH_3)_3]^+Cl^-$	sheets folding
PCH[50]	layered		intercalated quaternary ammonium and neutral amine	gallery-templated

[a]Gemini surfactant 18B4-3-1 = $C_{18}H_{37}OC_6H_4OC_4H_8N(CH_3)_2C_3H_6N(CH_3)_3Br_2$. [b]Bolaform surfactant $(CH_3)N–(CH_2)_n–O–(C_6H_4)_2–O–(CH_2)_n–N(CH_3)_3Br_2$, $n = 4, 6, 8, 10, 12$.

2D hexagonal titania from $EO_{20}PO_{70}EO_{20}$ and cubic titania (*Im*3*m*) from $EO_{75}BO_{45}$.[58]

Very recently, mesoporous TiO_2 with anatase, rutile, bicrystalline mixture (anatase and rutile) with controlled phase composition, and tricrystalline mixture (anatase, rutile, and brookite) were reported by using triblock copolymer as template and $TiCl_4$ as precursor.[62] The resulting crystalline titanias are thermally stable and have high surface area and large pore size up to 16 nm.

Zirconia. Mesoporous zirconia was first reported by Knowles and Hudson[63] with cationic alkyltrimethylammonium surfactants.[64] Starting from zirconium sulfate or propoxide, Schüth[65] and Ciesla *et al.*[66] synthesized hexagonal mesoporous zirconia using alkyltrimethylammonium surfactants as templates. Reddy and Sayari[67] obtained hexagonal or lamellar phases of mesostructured zirconia using quaternary ammonium surfactants and acidified primary alkylamine, respectively. Mesoporous zirconia has also been synthesized with amphoteric[68] and anionic[69,70] templates.

In a detailed study,[71] mesostructured zirconia has been prepared by using various amphiphilic surfactants with different headgroups (anionic and nonionic) and different tail lengths (1–18 carbons) as templates. Removal of surfactants leads to the loss of structural order and a decrease of the surface area. However, the presence of phosphates and sulfates in the walls may improve the stability.

Alumina. Mesoporous aluminas with high surface area are of great interest because of their potential use as catalysts and catalyst supports. The first successful synthesis of mesoporous aluminas was reported by Bagshaw and Pinnavaia through N^0I^0 assembly process.[72] Aluminas accessible through this route (designated as MSU-X aluminas) have wormhole pore structures with surface area around 400 to

$500\,m^2\,g^{-1}$. Similar wormhole mesoporous aluminas were also prepared using cationic[73] or anionic[74] surfactants as templates.

Mesostructured alumina with hexagonal structure can be synthesized in the presence of sodium dodecyl sulfate (SDS), but it was not stable upon surfactant removal.[75] Thermally stable mesoporous alumina has been obtained by using triblock copolymer as templates in ethanol solution. Most alumina mesophases consist of amorphous or semicrystalline framework. Recently, Pinnavaia and coworkers developed a novel three-step assembly method to prepare mesostructured alumina with framework walls composed of crystalline, lathlike γ-Al_2O_3 nanoparticles.[76,77]

3.3.4 Carbons[78]

Porous carbonaceous materials are important in many application areas because of their remarkable properties, such as high surface areas, chemical inertness, and good mechanical stability. Carbon molecular sieves that are amorphous and microporous are commercially important for the separation of nitrogen from air, and activated carbons with a wide pore size distribution are also useful adsorbents for various applications.

Recently, there has been an increasing interest in the synthesis of ordered mesoporous carbons,[79] since such materials are very promising as adsorbents, catalyst supports, and electrochemical double-layer capacitors.[80,81] Ordered mesoporous silicas have been shown as suitable templates to prepare periodic mesoporous carbons with various pore shapes and connectivity. The synthesis procedure involves impregnation of the mesoporous silica with an appropriate carbon precursor, carbonization of carbon source, and subsequent removal of silica using an aqueous solution of HF or NaOH.[78]

Ryoo *et al.* reported the first ordered mesoporous carbon, CMK-1, using cubic MCM-48 as template and sucrose as carbon source.[79] CMK-1 exhibited a highly ordered cubic structure, as confirmed by transmission electron microscopy (TEM). However, x-ray powder diffraction patterns indicated that CMK-1 underwent a structural transformation upon the silica removal due to the two disconnected porous systems separated by the silica wall.[82,83]

Similarly, cubic SBA-1 and disordered HMS have also been used as templates to prepare periodic mesoporous carbons (designated as CMK-2[79] and SNU-2[84] respectively). On the other hand, MCM-41 that has a hexagonal structure with unidimensional channels was found unsuitable as the template for the preparation of mesoporous carbons. Using SBA-15 as a template resulted in the first-ordered mesoporous carbon, designated as CMK-3,[85] which is exactly an inverse replica of the silica template. Although SBA-15 possesses the hexagonal mesostructure ($p6m$) similar to MCM-41, the microporosity[86] or the mesotunnels[87] within the silica walls could be responsible for the successful replication of ordered CMK-3.[88] Recent work on periodic mesoporous carbons includes improving structural integrity and thermal stability,[89] developing a low-cost synthesis route,[90] controlling the pore diameters,[91] and preparing carbons with graphitic pore walls.[92]

3.3.5 Periodic Mesoporous Organosilicas (PMOs)

Periodic mesoporous organosilicas (PMOs) are a new kind of organic–inorganic hybrid materials. However, unlike hybrid mesoporous materials made by grafting organic groups on the pore surface, PMOs contain organic groups as an integral component of silica-based framework.[93–95] The synthesis of PMOs involves the hydrolysis and condensation of tailor-made bridged organosilica precursor $((R'O)_3Si)_nR$ ($n = 2$ or 3, $R' =$ methyl or ethyl) in the presence of surfactant assemblies. The surfactant templates can be removed by solvent extraction or ion exchange. Essential to the synthesis of PMOs is the design and selection of the organosilica precursors. Various synthetic routes, such as Grignard, alcoholysis, hydrosilation, Pd-catalyzed Heck coupling, hydroboration, lithiation, and silylation of halides have been applied to prepare the molecular poly(trialkoxysilyl)organic precursors.[96] So far, various organic groups (Figure 5) including methane, ethane, ethylene, and benzene have been integrated into the framework of PMOs.[96,97] Since the first three contributions to PMOs were reported in 1999, some new synthetic strategies have been developed for the preparation of PMOs, resulting in many mesophases including wormhole structures,[95] cubic structures,[98] 2D hexagonal structures similar to MCM-41[93] or SBA-15,[99] and a 3D hexagonal structure with unknown space group.[94] One of the most intriguing successes is the report of a 2D hexagonal mesoporous benzene-silica with a crystal-like wall structure, exhibiting structural periodicity with a spacing of 7.6 Å along the channel direction.[100]

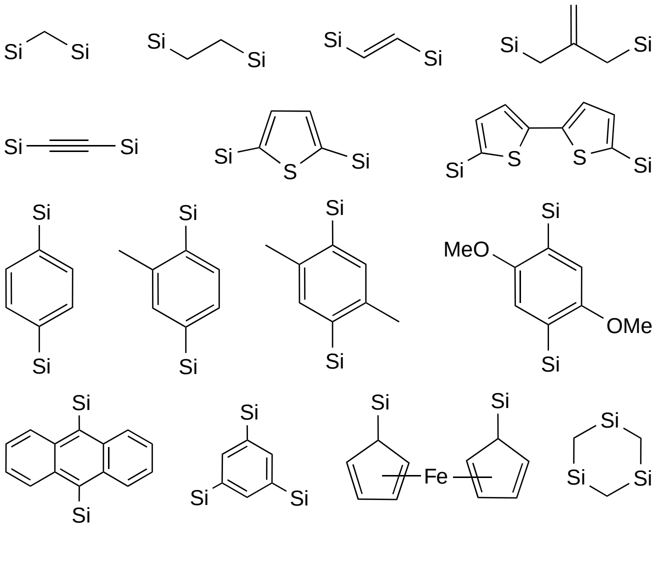

Figure 5 Examples of organic and organometallic bridging groups that have been incorporated into PMOs

Advantages[101] of PMOs include homogeneous distribution of bridged organic groups with high and tunable concentrations, large free void space, and consequently easily accessible functional groups. PMOs are expected to provide interesting electronic, optical, magnetic, catalytic, and mechanical properties.[96,101,102]

3.3.6 *Chalcogenides*

Germanium Sulfides. Metal chalcogenides are among the earliest nonoxide mesostructured materials being studied.[15] Because of the similarity to silicates, germanium or tin chalcogenides have received considerable attention. Through the room temperature reaction of aqueous solutions of $Na_4Ge_4S_{10}$ with solutions of various surfactant alkyltrimethylammonium bromide salts, Kanatzidis *et al.* prepared several surfactant-inorganic phases with the general formula of $[C_nH_{2n+1}N(CH_3)_3]_4Ge_4S_{10}$ ($n = 12$, 14, 16, and 18).[103] All four phases contain unconnected $[Ge_4S_{10}]^{4-}$ clusters and are fully crystalline with the space group P−1, unlike a typical amorphous mesoporous solid.

Ozin *et al.* subsequently prepared hexagonal mesostructured germanium sulfides by using low-valent metal cations such as Co^{2+}, Ni^{2+}, Cu^{+}, and Zn^{2+} to connect $[Ge_4S_{10}]^{4-}$ clusters around cetyltrimethylammonium bromide (CTAB).[104] This approach is similar to the synthesis of microstructured $[(CH_3)_4N]_4Mn[Ge_4S_{10}]$. However, Ozin's approach used formamide as the solvent instead of water.

Mesostructured germanium sulfides containing wormhole-like pores were prepared by Kanatzidis *et al.* by using divalent metal cations such as Zn^{2+}, Cd^{2+}, Hg^{2+}, Ni^{2+}, and Co^{2+} in aqueous medium with cationic surfactants $[C_nH_{2n+1}N(CH_3)_3]Br$ ($n = 12$, 14, 16, and 18). A hexagonally ordered mesostructured manganese germanium sulfide was prepared under hydrothermal conditions with Mn^{2+} as the linking agent and mesityltrimethylammonium surfactant.[105] New hexagonally ordered mesophases could also be made by using Pt^{2+} as the linker in the presence of alkylpyridinium surfactants $[C_nH_{2n+1}NC_5H_5]Br$ ($n = 12$, 14, 16, 18, 20, and 22).[106]

In addition to divalent metal cations, trivalent and tetravalent cations (i.e. In^{3+}, Ga^{3+}, Sb^{3+}, and Sn^{4+}) were also effective as linking agents to organize $[Ge_4S_{10}]^{4-}$ clusters to form hexagonally ordered mesostructures.[107,108] In this case, cetylpyridinium bromide was used as the surfactant, and formamide served as the solvent. The mesophases made with Ga^{3+} and Sb^{3+} showed intense visible photoluminescence at 77 K.

In all the above cases, metal cations are used as linking agents to connect together $[Ge_4S_{10}]^{4-}$ clusters. It can be envisioned that it might also be possible to employ metal clusters to link $[Ge_4S_{10}]^{4-}$. One such cluster is the biologically relevant cubane Fe_4S_4. Starting from $K_4Ge_4S_{10}$ and substitutionally labile $[Fe_4S_4Cl_4]^{2-}$ clusters, a novel hexagonally ordered mesostructured sulfide built from both $[Ge_4S_{10}]^{4-}$ and $[Fe_4S_4Cl_4]^{2-}$ clusters was synthesized from a formamide solution containing the surfactant cetylpyridinium bromide.[109]

Tin Sulfides. Kessler *et al.* reported a crystalline phase synthesized from $SnCl_4$, Na_2S, and dodecylamine in the ethanol-water system at room temperature. This new tin sulfide has the formula of $(C_{12}H_{25}NH_3)_4[Sn_2S_6]\cdot 2H_2O$, and the $[Sn_2S_6]^{4-}$ dimers are formed by two edge-sharing $[SnS_4]$ tetrahedra.[110] Hexagonally ordered mesostructured tin sulfides were synthesized by Kanatzidis *et al.* by linking $[Sn_2S_6]^{4-}$ clusters with metal cations (i.e. Zn^{2+}, Cd^{2+}, Ga^{3+}). These photoluminescent mesophases were made in the presence of cetylpyridinium surfactant in the formamide solution under basic conditions and are semiconductors in the energy range from 2.5 to 3.1 eV.[111]

Germanium Selenides. Mesostructured germanium selenides are chemically and structurally similar to the corresponding sulfides. By following strategies similar to those developed for sulfides, Kanatzidis *et al.* have prepared a series of mesostructured germanium selenides. By using Zn^{2+}, Cd^{2+}, Hg^{2+}, Ni^{2+}, and Co^{2+} to link $[Ge_4Se_{10}]^{4-}$ clusters, mesostructured germanium selenides with wormholes were prepared in the presence of cationic surfactants $[C_nH_{2n+1}N(CH_3)_3]Br$ ($n = 12$, 14, 16, and 18).[112] Hexagonally mesostructured selenides were prepared by linking $[Ge_4Se_{10}]^{4-}$ clusters with Pt^{2+}, Sb^{3+}, Sn^{4+} or Fe_4S_4 clusters as linker agents and cetylpyridinium as the surfactant.

Tin Selenides. A series of mesostructured tin selenides were prepared by Kanatzidis *et al.* by linking $[SnSe_4]^{4-}$ anions with divalent metal cations.[113] These materials have the general formula of $(CP)_{4-2x}M_xSnSe_4$, where CP is cetylpyridinium; $1.0 < x < 1.3$; M = Mn, Fe, Co, Zn, Cd, and Hg. The d-spacing for the lowest peak ranges from 35 to 40 Å, and the pore arrangement based on wormhole, hexagonal, and cubic types has been observed. These phases are medium band gap semiconductors with band gap varying from 1.4 to 2.5 eV.

In addition to $[SnSe_4]^{4-}$ anions, $[Sn_2Se_6]^{4-}$ dimers could also form mesophases in combination with Pt^{2+} in the presence of long-chain pyridinium surfactants (C_nPyBr, $n = 18, 20$).[114] In this case, the cubic symmetry with the space group Ia-3d was preferred. The surfactant molecules could be ion-exchanged reversibly and without loss of the cubic structure and particle morphology. This Pt−Sn−Se phase has a low-energy band gap of 1.7 eV.

Similar to germanium sulfides or selenides, $[Sn_4Se_{10}]^{4-}$ adamantine clusters also exist and have been found to form mesostructured semiconductors with Pt^{2+} when templated by the lyotropic liquid-crystalline phase of alkylpyridinium surfactant $[C_{16}H_{33}NC_5H_5]Br$. This mesophase designated as $C_{16}PyPtSnSe$ has a band gap of 1.5 eV.

Other Chalcogenides. In addition to germanium (or tin) sulfides and selenides, mesostructured chalcogenides have also been made in other compositions. For example, Stupp *et al.* prepared hexagonally ordered mesostructured CdS by reacting H_2S with cadmium salts within the ordered environment of the preformed liquid crystal mesophase.[115] The mesophase was formed using oligoethylene oxide oleyl ether ($C_{18}H_{35}(OCH_2CH_2)_{10}OH$) mixed with an equal volume of aqueous 0.1 M Cd^{2+} salt. The symmetry and long-range order of the liquid crystal are preserved during the precipitation of the inorganic–organic mesophase.

3.3.7 Metals

By using preformed lyotropic liquid crystals of nonionic surfactants, Attard and coworkers have prepared mesostructured Pt and Sn.[116–118] This methodology can be applied to other elements such as Se and Te or metal alloys such as Pt–Ru or Pt–Pd.[119–121] The ordered mesostructured metals can be obtained by either chemical or electrochemical reduction of metal salts that are dissolved in the aqueous domain of lyotropic liquid crystals formed from oligoethylene oxide nonionic surfactants. The pore diameter can be tuned by the length of the alkyl chain of the surfactants, and the topology of metallic mesophases can be controlled by the symmetry of lyotropic liquid crystals.

The chemical reduction method generally produces mesostructured metals with granular morphology. The mesostructures of the metals formed by this method are casts of the structures of the liquid crystals used in the syntheses. During this process, the product is formed in the aqueous domain of the preorganized liquid crystals without disrupting the long-range ordering of the liquid crystals.

The electrochemical reduction method can produce mesostructured metals in the form of thin films. By electrodeposition of plating mixtures made from appropriate salts, mesostructured metal films can be produced on the electrode surface with high surface areas and good mechanical and electrochemical stability. The ability to produce ordered mesostructured metal films may lead to new types of electrode materials for applications such as batteries, fuel cells, and sensors.

3.4 Morphology Control

Mesoporous materials were originally synthesized in irregular bulk or powder forms, which could limit their applications in separation, optics, electronics, and so on. Thus, it is highly desirable to produce mesoporous materials with controllable macroscopic forms. So far, mesoporous materials have been synthesized in a variety of forms including thin films, spheres, fibers, monoliths, rods, single crystals, and nanoparticles. The acidic synthetic route ($S^+X^-I^+$) developed by Huo *et al.* appears to be the most appropriate for the morphological control of mesostructures.

3.4.1 Thin Films

The interests in thin films of silica-surfactant mesostructured materials arise from their potential applications in membrane-based separations, sensors, heterogeneous catalysis, and microelectronics.[122] Thin films of mesoporous silicas were first prepared by spin-coating an aqueous mixture of surfactants and prehydrolyzed silica precursors on a substrate followed by drying.[123,124] In addition to the spin-coating method, supported films can also be made by directly growing on substrates[125,126] or by dip-coating.[127,128] The film growth is generally faster by spin- or dip-coating. Free-standing films can be grown at liquid–vapor (e.g. water–air)[129,130] and liquid–liquid (e.g. oil–water) interfaces.[131] In addition to mesostructured silica, thin films of mesostructured titania,[132] zirconia,[133] tin oxide,[134] and organosilica[135] have also been successfully achieved.

3.4.2 Spheres

The use of emulsion biphase chemistry allows the preparation of both hollow[136] and hard[137] mesoporous silica spheres. Through a modified Stöber method,[138] spherical mesoporous silicas with particle sizes ranging from submicrometers to micrometers ($\sim 2\,\mu m$) have been achieved.[139,140] Recent efforts have focused on control of the size and monodispersity. Ward and coworkers have achieved highly monodisperse mesoporous silica spheres with controllable particle size by EISA of precursor microdroplets produced by a vibrating orifice aerosol generator (VOAG).[141] Pseudomorphic transformation of preformed amorphous silica spheres to MCM-41 has demonstrated another promising way for the control of the size and morphology.[142]

3.4.3 Monoliths

There is an increasing interest in transparent monoliths with periodic mesoporous structures due to their potential applications in optics. Using the direct liquid crystal templating approach, Feng *et al.* prepared monolithic mesostructured silica templated by microemulsion liquid crystals.[143] By adjusting the synthetic composition, many different highly ordered mesophases, such as cubic spherical micellar $Im3m$, 3D hexagonal $P6_3/mmc$, bicontinuous cubic $Ia3d$, and primitive-centered cubic $Pn3m$, were obtained.[144] Careful control of evaporation of the solvent by a thin layer of mineral oil also helped the preparation of crack-free monoliths.[145]

3.4.4 Fibers

Early attempts to prepare mesoporous silica fibers employed mechanical drawing[146] or emulsion biphase chemistry.[147] The latter method resulted in fibers with a

single-crystal-like mesostructure where the pore channels run circularly around the fiber axis.[148] Recently, Stucky and coworkers reported a simple one-phase route to mesostructured fibers.[149] The most intriguing aspect of this route is that the internal architecture of such nanofibers can be readily controlled via the synthesis.

3.5 Structural Stability

For applications of mesoporous materials, their structural stability is among the most important considerations and has therefore been studied extensively. Cassiers and coworkers[150] systematically investigated the thermal, hydrothermal, and mechanical stabilities of the most well-known mesoporous silicas. They found that the thermal stability is strongly dependent on the silica source and the wall thickness. M41S materials prepared with fumed silica show higher thermal stability than those made from TEOS. Transformation of layered silicates to mesoporous silica allows the resulting porous clay heterostructures (PCH) and FSM-16 to possess more condensed and ordered walls than M41S materials. It is well known that SBA-15 consists of thicker walls, and is thus expected to exhibit good thermal stability. The following stability trend has been observed by Cassiers *et al.*: MCM-41 (fumed silica), MCM-48 (fumed silica), KIT-1 (colloidal silica) > SBA-15(TEOS) > FSM-16 (layered silicate), PCH (layered silicate) > MCM-41 (TEOS), MCM-48 (TEOS), HMS (TEOS).

The hydrothermal stability is mainly dependent on the wall thickness and the degree of polymerization. KIT-1 and SBA-15 are highly resistant to hydrothermal treatment due to their highly polymerized and thicker walls. Under mild steaming conditions, the pore structure might lead to different hydrothermal stability for materials with comparable wall thickness. Cubic MCM-48 exhibits less structural degradation than the hexagonal mesoporous materials. A complete hydrothermal stability order reported by Cassiers *et al.* is as follows: KIT-1 > SBA-15 > MCM-48 (fumed silica and TEOS), PCH > FSM-16, MCM-41 (fumed silica and TEOS), HMS.

Unlike the thermal and hydrothermal stabilities, the mechanical stability seems less dependent on the nature of mesoporous materials. All materials gradually collapse with the increase of pressure, accompanied with the decrease of surface area and pore volume.[151] Recent studies show that cubic SBA-1 and MCM-48 are more mechanically stable than hexagonal mesoporous materials such as MCM-41 and SBA-15.[152] Hydrolysis of Si–O–Si bonds by water adsorbed onto the silanol groups under compression was found as the main reason for mechanical instability.[153] Organically functionalized materials are more hydrophobic than unmodified counterparts, and thus show enhanced mechanical stability due to the water repelling ability.[154]

3.6 Application

Since the discovery of ordered mesoporous materials, researchers have explored many possible applications that can take advantage of the unique compositional or structural features of mesoporous materials. In addition to applications in traditional areas such as catalysis, separation, and ion exchange, new applications that might involve mesoporous materials include stationary phases in HPLC, bio and macromolecular separations, low dielectric constant materials, enzyme immobilization, optical host materials, templates for fabrication of porous carbons, and reactions in confined environments.

3.6.1 *Catalysis*[155,156]

The potential application in catalysis is one of the most important uses of ordered mesoporous materials. Mesoporous materials can be used as catalysts in either acid or redox catalysis. To help increase acidity, trivalent cations such as Al and B are often incorporated into siliceous mesoporous framework to generate more acid sites. The acidity can also be generated by dispersing heteropoly acids or by grafting organic functional groups onto the surface of mesoporous solids. Many modified MCM-41 type materials have been found to be catalytically active in selected acid-catalyzed processes, However, owing to their disordered framework, mesoporous materials have only moderate acidity. And this limits their applications in petroleum refining and fine chemical synthesis.

For redox catalysis, efforts have been spent on preparing transition metal modified mesoporous materials. These materials are capable of extending the catalytic oxidation chemistry to large molecules. The selective catalytic activity has also been demonstrated, for example, in the oxidation of aromatic compounds by using titanium-containing mesoporous silica (Ti-MCM-41 and Ti-HMS).[157]

In addition to their direct use as catalysts, mesoporous materials are also useful as catalyst supports because of their high surface area, high thermal stability, and low cost. Extensive studies have been done on the preparation and catalytic activity of metals (e.g. Pt, Pd, Ru, Cu) and metal oxides (e.g. TiO_2, VO_x, ZrO_2, Fe_2O_3) supported on ordered mesoporous materials. The impact of mesoporous materials has also been felt in organometallic chemistry, as shown by a new series of composites being made by functionalizing mesoporous materials with organometallic compounds.[158]

3.6.2 *Environmental Remediation and Separation*

Removal of heavy-metal ions has been a major focus in environmental remediation and cleanup. Various materials, such as activated charcoal, clays, silica gels, and ion-exchange resins have been used as adsorbents. Functionalized mesoporous silicas have recently proved to be a promising or even better alternative.[159,160] Mercier *et al.* prepared a

highly effective Hg^{2+} adsorbent by grafting thiol moieties to the framework walls of mesoporous silica, denoted MP-HMS.[159] Because of the uniform and large pore structure, MP-HMS showed an improved access of guest species to the binding sites along with a high loading capacity of 310 mg g^{-1} (1.5 mmol g^{-1}), compared to those made from disordered porous materials, such as silica gel. Concurrently, Feng and coworkers reported a similar heavy-metal ion adsorbent by modifying large-pore MCM-41 with a cross-linked monolayer of mercaptopropylsilane with thiol terminal groups.[160] The resulting adsorbent, functionalized monolayers on mesoporous supports (FMMS), was extremely effective for the removal of Hg^{2+} and other heavy-metal ions. The high relative surface coverage of monolayers (up to 76%) led to a remarkable adsorption capacity of 505 mg g^{-1} for Hg^{2+}. To simplify the synthesis procedure, Mercier *et al.* developed a one-step method by cocondensation of TEOS with 3-mercaptopropyltrimethoxysilane in the presence of surfactants.[161]

Unlike the previously studied mercaptopropyl ligand, the thiourea ligands are expected to have weaker bonding to mercury ions in comparison to thiol group, which should facilitate the adsorbent regeneration.[162] A good example is large-pore MCM-41 grafted with 1-allyl-3-propylthiourea,[163] which could be conveniently regenerated under mild conditions. Recent work in this area has focused on the improvement of mercury adsorption capacity. A logical strategy to increase capacity is the use of multifunctional ligands.[162] Grafting of (1,4)-bis(triethoxysilyl)propane tetrasulfide onto the surface of SBA-15 has led to an adsorbent with an unprecedented loading capacity of 13.5 mmol Hg^{2+} g^{-1}.[164] Functionalized mesoporous silicas for the removal of other metal ions, such as Pb^{2+}, Cu^{2+}, and Zn^{2+}, have also been reported.[165]

3.6.3 *Chromatography*

Commercial chromatography silica stationary phases were prepared by the polymerization induced colloidal assembly (PICA) method,[166] subsequently exhibiting an interparticle (textural) pore structure with moderate surface area (100–550 $m^2\,g^{-1}$) and broad pore-size distribution. Ordered mesoporous silicas show a high surface area up to 1600 $m^2\,g^{-1}$ coupled with tunable and uniform pore size arising from intraparticle (structural) porosity, and are thus expected to provide superior chromatographic performance as stationary phases. MCM-41 was first tested as chromatographic matrix for normal-phase high-performance liquid chromatography (HPLC)[167] and size-exclusion chromatography.[168] The most intriguing advantage of MCM-41 is the ability to separate different types of analytes (basic, acidic, and neutral) with good column efficiency within reasonable analysis times.[167] Gallis *et al.*[169] used acid-prepared mesoporous spheres (APMS) to separate ferrocene from acetylferrocene by normal-phase flash liquid chromatography, exhibiting better separating ability (e.g. longer retention time, higher selectivity) than commercial silicas. Similar results have also been obtained in normal-phase, reversed-phase, and chiral HPLC based on APMS and spherical MCM-48.[170,171] Boissiere and coworkers[172] used MSU-1 spheres to separate polycyclic aromatic hydrocarbons (PAHs) by normal-phase HPLC. Separation of biomolecules was accomplished on spherical SBA-15 by reversed-phase HPLC.[173] In comparison to their applications in HPLC, there are only few efforts to use mesoporous silicas in gas chromatography (GC).[174]

4 MACROPOROUS MATERIALS

4.1 Synthesis

Ordered macroporous materials can be templated by colloidal crystals or emulsions. In comparison to microporous and mesoporous materials, the synthesis strategy of macroporous materials is relatively simple.

4.1.1 *Colloidal Crystal Templating*

A general three-step procedure[175,176] for the formation of macroporous materials by colloidal crystal templating is illustrated in Figure 6. In the first step, monodispersed colloidal spheres assemble into ordered 3D or sometimes 2D arrays to serve as templates. Secondly, the voids of colloidal crystals are filled by precursors that subsequently solidify to form composites. Finally, the original spheres are removed, creating a solid framework with interconnected voids, which faithfully replicate the template arrays.

Latex and silica spheres are the most commonly used templates for the colloidal crystal assembly, because they are highly monodisperse and commercially available. Many crystallization methods have been used to form close-packed structures, including sedimentation, centrifugation, filtration, convective deposition, slit filling, and pressing. All these methods result in polycrystalline domains, usually with face-centered cubic (fcc) packing or randomly stacked hexagonal close-packed planes (rhcp), affording 26-vol% void space. Sometimes colloidal crystals are sintered or annealed to increase their stability and ensure interconnection.

The design of the interstices filling in colloidal crystals with appropriate media and subsequently fluid–solid transformation is central to the whole synthesis. Fluid precursors in the voids of crystal arrays can solidify by polymerization[177] and sol-gel hydrolysis.[178] More recently, many methods[179] have been developed including salt precipitation and chemical conversion, chemical vapor deposition (CVD), spraying techniques (spray pyrolysis, ion spraying, and laser spraying), nanocrystal deposition and sintering, oxide and salt reduction, electrodeposition, and electroless deposition.

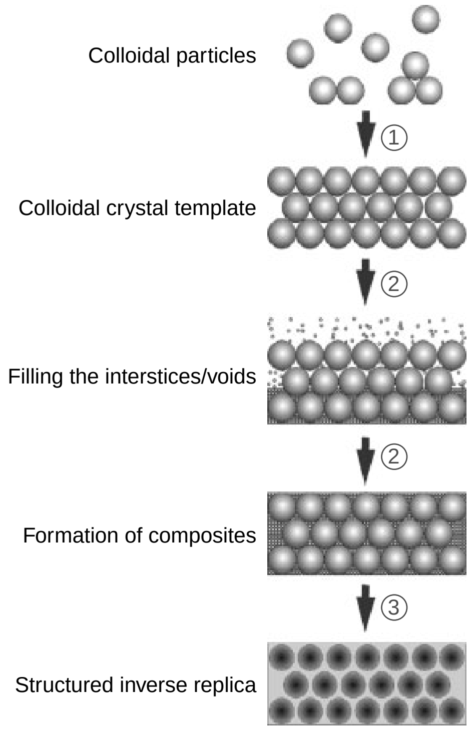

Figure 6 A schematic of the general procedure for preparing ordered macroporous materials by colloidal crystal templating. (1) Assembly of colloidal particles to form colloidal crystal template; (2) Filling the interstices/voids with precursors to form composites; and (3) Removal of templates. (Reprinted from Ref. 175, © 2000, with permission from Elsevier)

Templates should be removed from the composites to yield porous structures. Polymer templates can be removed by calcination, by dissolution with appropriate solvents, or by photo degradation, while silicas are eliminated by dissolution in aqueous HF or NaOH solution.

4.1.2 Emulsion Templating[180,181]

Imhof and Pine have demonstrated that a highly uniform dispersion of emulsion droplets can serve as templates to prepare macroporous materials of titania, silica, and zirconia. In their work, treatment of polydisperse emulsions by shearing and/or fraction resulted in uniform emulsion droplets around which alkoxide precursors are deposited through a sol-gel process. Subsequent drying and heat treatment yielded solid materials with spherical pores left behind by the emulsion droplets (see Figure 7). Macroporous materials templated by emulsion droplets possess highly uniform pores in a wide range from 50 nm to 10 μm, unlike those prepared by colloidal crystal templating whose pore sizes are within 100 to 1000 nm. The materials can be adjusted with any desired porosity up to 90%.

4.2 Composition and Wall Structures

A summary of ordered macroporous materials with different compositions is given elsewhere.[182,183] Many compositions have been made, ranging from oxides,[177] polymers,[184] and carbons,[185] to semiconductors[186] and metals.[187] The wall structures of macroporous materials can be amorphous, crystalline, with mesopores or micropores, organically modified, or with surface catalysts.[188]

4.3 Applications

Because macroporous materials have 3D periodicity on a length scale comparable to the wavelength of visible light, 3DOM materials have potential use as photonic crystals.[183] Other potential applications include catalysts, bioglasses, sensors, and substrates for surface-enhanced Raman scattering spectroscopy (SERS).[176,179]

5 HIERARCHICAL POROUS STRUCTURES

Hierarchical porous materials are solids that are ordered at different length scales. Materials with multiple porosities are of high interest for applications in catalysis and separation, because these applications can take advantages of different pore structures. For example, microporous–mesoporous composites have shown superior catalytic activities by the combination of strong acidity from zeolites with high reactant or product mobility due to large uniform mesopores.[189] Several approaches have been reported on the design and synthesis of hierarchical porous materials, as discussed below.

5.1 Multiple Templating

As discussed previously, organic molecules, supramolecular micelles (or liquid crystals), and colloidal crystals (or emulsions) are employed as templates to prepare microporous, mesoporous, and macroporous materials, respectively. Combining different templates into one synthesis is expected to generate hierarchical porous materials. Yang *et al.* have demonstrated a simple procedure to fabricate hierarchical ordered oxides (silica, niobia, and titania) by concurrently or sequentially combining latex sphere templating, cooperative assembly, and micromolding using polydimethylsiloxane (PDMS) stamps (Figure 8a).[190] In their work, the PDMS mold with micrometer-scale patterns was placed on a substrate, creating accessible channels between the mold and the substrate in which the latex spheres organized into a close-packed array. The voids of the array were filled with a sol-gel block copolymer precursor solution. After sufficient time for cross-linking and polymerization, the mold was removed and the organic templates were eliminated by calcination. The resulting materials exhibited surface patterns of macroporous structures with mesoporous walls (Figure 8, b–e).

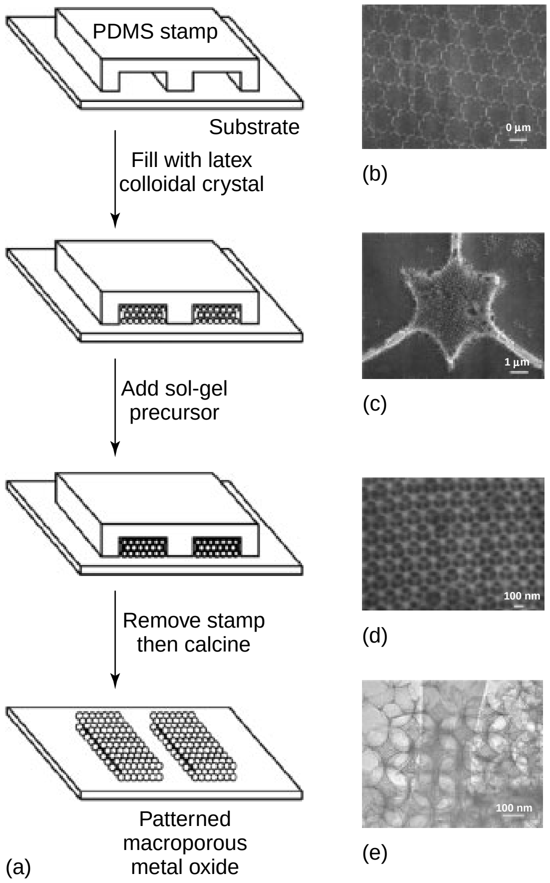

Figure 8 Schematic of the fabrication of hierarchical ordered oxides (a) (Reprinted from Ref. 179, © 2001, with permission from Elsevier) scanning electron microscopy (SEM) images (b, c, d), at different magnifications, of hierarchical ordered mesoporous silica display a high-quality surface pattern (~1000 nm), which is made up of a macroporous (~100 nm) framework of cubic mesoporous silica (~11 nm), as shown in TEM image (e). (Reprinted with permission from P. Yang *et al.*, *Science*, 1998, **282**, 2244)

Stein and coworkers have synthesized a macroporous silicate with zeolitic microporous frameworks by a 'dual templating' method using latex spheres and tetrapropylammonium hydroxide.[191] Similarly, in situ or simultaneous synthesis of macroporous silica with mesoporous wall[192] and micro/mesoporous composites[193] has been reported in the presence of appropriate dual templates. Microporous/mesoporous materials can also be prepared by a two-step synthetic process, where mesoporous materials are synthesized first, followed by transformation of amorphous mesopore walls into a microporous crystalline (or semicrystalline) phase. Huang *et al.* prepared a MCM-41/ZSM-5 composite containing interconnected mesopore and micropore.[194] Trong On *et al.* demonstrated a general method for the preparation of large-pore mesoporous materials with semicrystalline zeolitic frameworks, involving a templated solid-state secondary crystallization of zeolites from amorphous mesopore walls.[195] Unlike the previous work, Goto and coworkers described a 'reversed' two-step approach to prepare microporous/mesoporous composites using zeolites as the silica-alumina source for mesoporous materials.[196]

5.2 Assembly from Building Blocks

Colloidal zeolites have been used as building blocks to fabricate hierarchical porous materials. Infiltrating ethanol sol of zeolite nanoparticles into an ordered array of polystyrene spheres resulted in macroporous zeolites, which involves a self-assembly process.[197] After ethanol evaporation, zeolite nanoparticles were aggregated by capillary forces. High concentration of external silanol groups favored the formation of hydrogen bonds between particles and eventually Si–O–Si bonds after calcination. The method has been further developed to produce transparent and self-standing zeolite membranes with controlled mesoporosity.[198] Concurrently, the preformed zeolite-coated polystyrene spheres have been

used as building blocks to assemble hierarchical materials with ordered nano, meso, and macroporosity.[199] The core-shell building blocks were fabricated through a 'layer-by-layer' method[200] by alternate adsorption of zeolite nanoparticles and positively charged macromolecules onto latex spheres. This allows the wall thickness of the resulting macroporous monoliths to be fine-tuned by the layer numbers.

5.3 Bulk Dissolution and Structural Rearrangement

The strategy of this method is to utilize the inherent porosity of bulky substrates in the construction of hierarchical structures by incorporating additional pore systems. Diatoms are unicellular algae whose walls are composed of silica with an internal pore diameter at submicron to micron scales. Zeolitization of diatoms, in which zeolite nanoparticles are dispersed on the surface of diatoms followed by a hydrothermal conversation of a portion of the diatom silicas into zeolites, resulted in the formation of a micro/mesoporous composite material.[201] Similarly, wood has also been used as a substrate to prepare meso/macroporous composites and meso/macroporous zeolites. After the synthesis, wood is removed by calcination.[202]

Glossary

Assembly descriptor: a formula-like notation that expresses the number of binding sites and the topicity of molecular building units
Default structures: high-symmetry structures that are ubiquitous for all building blocks with a particular symmetry and coordination number
Double molecular box: molecular architecture that resembles two cubes (or boxes) fused at one corner
Functional materials: molecular materials that are designed to perform specific function(s)
Isoreticular structures: a series of molecular architectures with identical network topologies but with different functionalities and dimensions
Linkers: a molecular component that acts as a bridge between molecular entities
Metal-organic-framework (MOF): three-dimensional architectures composed of metal ions and organic ligands
Molecular loop: dinuclear molecules with two bridging ligands with an approximate geometry resembling that of a loop
Octahedral SBU: a octahedral molecular building block whose geometry plays a decisive role in determining the three-dimensional structure of the solid
Paddlewheel: dinuclear metal complexes with four bridging ligands arranged in a paddle-wheel fashion
Secondary building unit (SBU): molecular fragment that is not necessarily an isolable entity but is rather a principle building block of an architecture and that determines the topology of the three-dimensional structure
Single-molecule-magnets: molecules that have the ability to be magnetized when a field is applied and exhibit slow paramagnetic relaxation; the effect is due to an individual molecule rather than to a long-range ordering as in bulk magnets
Square SBU: a molecular fragment with the shape of a square whose geometry plays an important role in determining the three-dimensional structure of the solid
Supramolecular: assembly of molecules of higher complexity than the molecules themselves, held together and organized by means of intermolecular noncovalent interactions

Abbreviations

4,4′-H_2bpy = 4,4′-bipyridinium di-cation; BINAP = Binaphthalene; bpm = bis-(1-pyrazolyl)methane; bptz = 3,6-bis-(2-pyridyl)tetrazine; bpy = Bipyridine; bpym = Bipyrimidine; BU = Building units; Cp = Cyclopentadienyl; *p*-cymene = 4-Isopropyltoluene; DABCO = 1,4-diazabicyclo [2.2.2]octane; DaniF = N,N'-di(p-anisyl)formamidinate; dmpby = 5,5′-dimethyl-2,2′-bipyridine; dbbpy = di-t-butyl-bipyridine; DMF = N,N'-dimethylformamide; DMSO = Dimethyl sulfoxide; dppm = Bis-diphenylphosphinomethane; dppp = Diphenylphosphinopropane; ESI-MS = Electrospray ionization mass spectroscopy; en = Ethylenediamine; Et = Ethyl; H_2BDC = 1,4-benzenedicarboxylic acid; BDC = 1,4-benzenedicarboxylate; *fac* = Facial; Hbim = 2,2′-biimidazolate; impy = 2-(2-pyridyl)-4,4,5,5-tetramethyl-4,5-dihydro-1H-imidazolyl-1-oxy; MOF = Metal-organic framework; MOP = Metal-organic polyhedron; OTf = Triflate ion; PB = Prussian blue; phen = Phenanthroline; Ph = Phenyl; Py = Pyridine-based ligand; SBU = Secondary building unit; tacn = 1,4,7-triazacyclononane; tbp = Trigonal-bipyramidal; tmphen = Tetramethylphenanthroline; triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane.

1 INTRODUCTION

The self-assembly (*see Self-assembly*) of metal cations (*see Cation*) with multidentate ligands (*see Ligand*) results in the formation of a variety of inorganic architectures. Given that a range of products is possible for the same combination of starting materials, it is remarkable that the molecular self-assembly generally favors one particular architecture over the others. This situation is even more favored when the chemistry involves labile (*see Labile*) metal–ligand interactions that allow for healing of defects throughout the reaction profile. Although the outcome of

these self-assembly processes is often unpredictable, the formation of one product in high yield typically can be rationalized on the basis of the interplay between kinetic and thermodynamic factors.

The field of inorganic supramolecular chemistry is motivated, to a large extent, by a desire to prepare new types of functional materials, but the research area also has contributed a great deal to fundamental coordination chemistry as well. This short review is dedicated to highlighting key advances in this area with an emphasis on novel structures. The article is organized according to broad categories of bridging ligands (*see Bridging Ligand*) that have been used to prepare self-assembled inorganic architectures. The terms 'self-assembly' and 'self-assembled structures' include molecular metallomacrocycles, cages/clusters, hydrogen-bonded networks as well as oligomers and polymers.

2 CLASSIFICATION OF STRUCTURE

Self-assembly of ligands with metal ions has led to the isolation of a wide variety of molecular architectures of which discrete two- and three-dimensional structures (metallocyclic polygons and polyhedra) constitute a significant proportion. As their approximate molecular symmetries resemble regular polygons, they are referred to as molecular triangles, squares, pentagons, hexagons, cubes, and so on. An early attempt to develop a notation for describing the building blocks that lead to particular geometries was introduced by Peter J. Stang[1] and later modified by G. F. Swiegers.[2] The assembly descriptor nomenclature employs a formula-like notation to describe the number of binding sites and the topicity of the building blocks involved in the formation of a particular structure. Advantages of this notation are the efficient identification of acceptor(metal)–donor(ligand) combination that is required for the formation of a particular product and the rapid comparison of compounds of different structures. A consideration of the basic manner in which building blocks combine aids in the conceptual development of new architectures. The usefulness of the assembly descriptor notation system is illustrated by the following example. The symbol A^{3a} indicates an 'angular' building block with 'three' identical 'acceptor' sites, with the 'linear' unit having two different 'donor' sites symbolized as L^{1d1d}. An assembly consisting of two A^{3a} and three L^{1d1d} units, as shown in Scheme 1, is given the description $A_2{}^{3a}L_3{}^{1d1d}$. Examples of self-assembled $A_4{}^{1a1d}$ and mixed-assembled $A_2{}^{2a}A_2{}^{2d}$ structures are complex (**1**) and (**2**) respectively. Clearly these descriptors provide valuable information, at a glance, about the building units and their modes of binding in the self-assembled architectures.

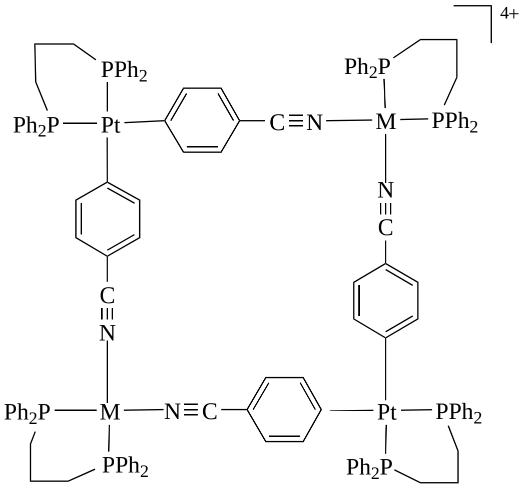
3 N-HETEROCYCLES AND RELATED LIGANDS

Multidentate ligands derived from pyridine have been widely used for the assembly of transition metals (*see*



M = Pt, Pd

$A_2^{2a}A_2^{2d}$

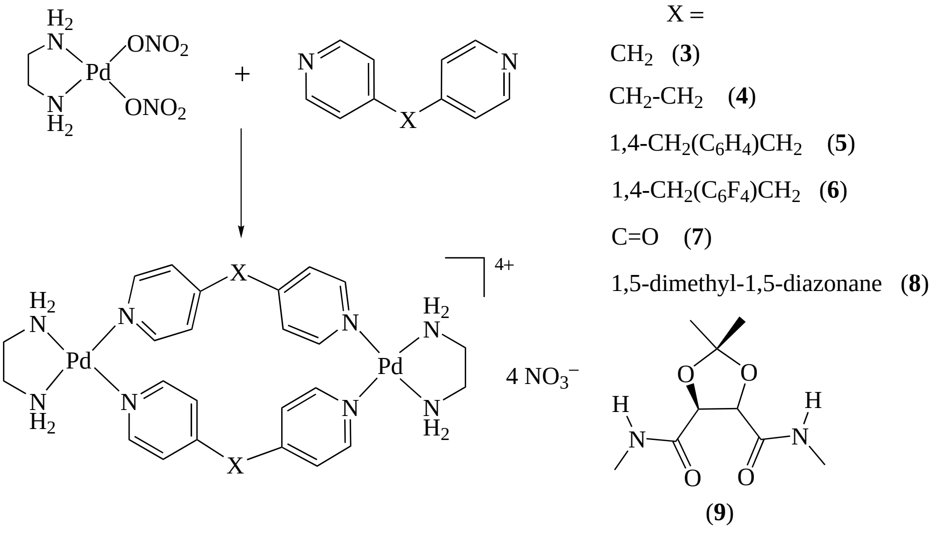
(**2**)

Transition Metals) into oligomers as well as polymers (*see Polymer*). The use of bridging ligands to connect metal precursors that possess capping ligands has produced a large number of discrete molecular structures of varying shapes and sizes. Pioneering work in this area by Fujita[3] and Stang[4] involved the synthesis of specialized ligands and tailored metal precursors, and their subsequent self-assembly into cyclic molecules. Companion spectroscopic and structural studies of the resulting inorganic architectures and investigations of the reaction dynamics led to a comprehensive body of work that has inspired many others to explore the field of inorganic supramolecular chemistry.[5] The following sections describe various structures that have appeared in the literature over the years and that serve to illustrate the rich variety of molecular species that can be accessed by this chemistry. An examination of this body of work provides valuable insight into the topologies of the molecular components that are required for the construction of molecular architectures of particular sizes, shapes and dimensions.

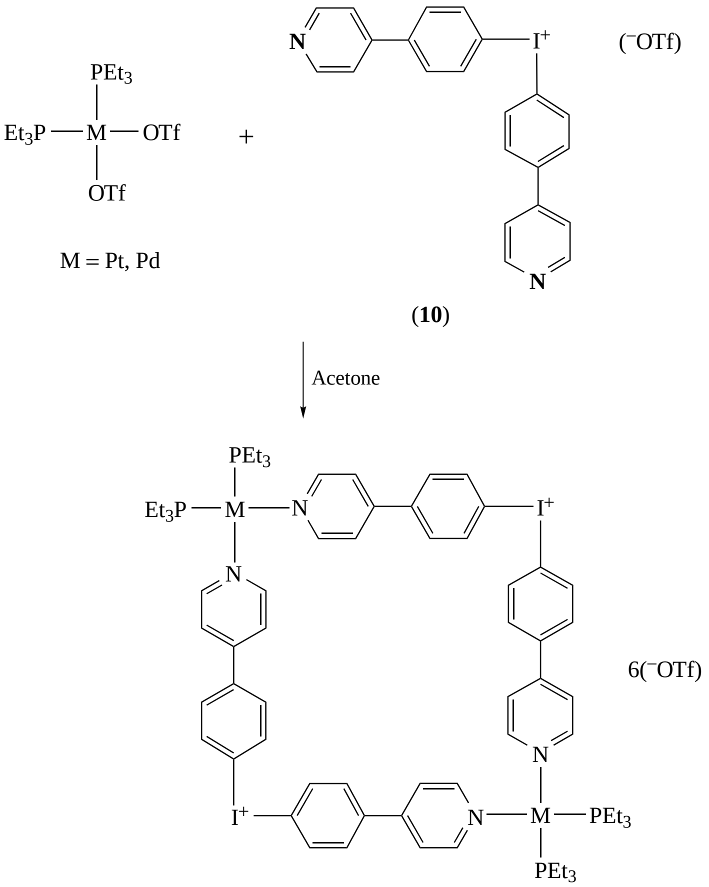
3.1 Dinuclear (*see Dinuclear*) Macrocycles

Reactions of (en)Pd(ONO_2)$_2$ (en = ethylenediamine) with bidentate ligands (*see Bidentate Ligand*) of the type Py-X-Py (Py = a pyridine-based ligand) produce the dinuclear metallomacrocycles (**3–7**) (Scheme 2).[6] As indicated, the organic linker can be varied to generate a host of structures upon coordination to the Pd(II) complex. The ability of these metallocyclophanes to encapsulate organic guests was investigated; for example, the fluorinated macrocycle (**6**) is capable of recognizing electron-rich (*see Electron Rich Compound*) aromatic species such as napthalene in aqueous solutions.[7] The introduction of diazacycloalkanes or chiral (*see Chiral*) groups into the organic backbones yields the analogous metallomacrocycles (**8**)[8] and (**9**)[9] respectively.

In a similar manner, reactions of bis-(triethylphosphine)-M(II)-bis-triflates with bis-pyridine ligands provide access to dinuclear metallomacrocycles. The reaction of equimolar amounts of (Et_3P)$_2$M(II)(OTf)$_2$ (OTf = triflate ion) (M = Pt, Pd) with bis-heteroaryl-iodonium triflate (**10**) yields the molecular squares (**11**) and (**12**) respectively (Scheme 3).[10]

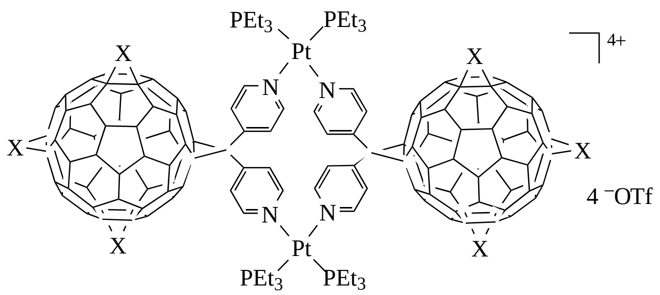


Scheme 2



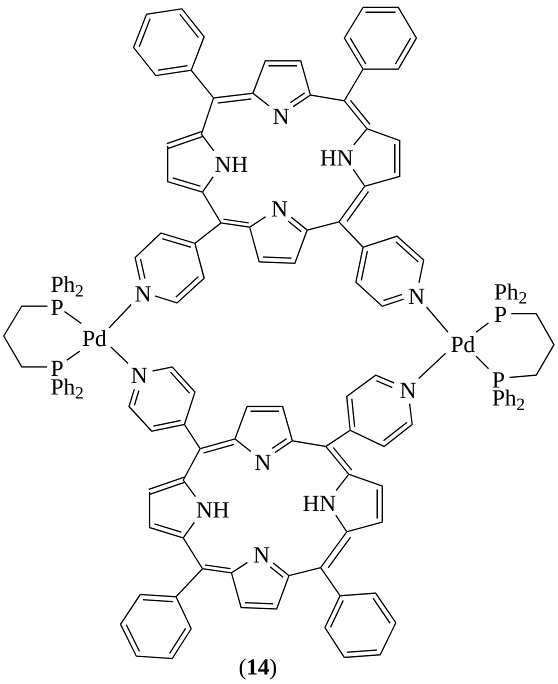
Scheme 3

The solid-state structure of (**12**) reveals that it consists of a planar, rhomboidal molecule with N–Pd–N angle of 84° and a C–I–C corner angle of 99°. Bis-pyridine ligands can be varied in numerous ways to yield a variety of diverse structures; these include macrocycles containing bis-pyridine functionalized C_{60} molecules (**13**)[11] and the bis-pyridine incorporated porphyrin compound (**14**).[12]



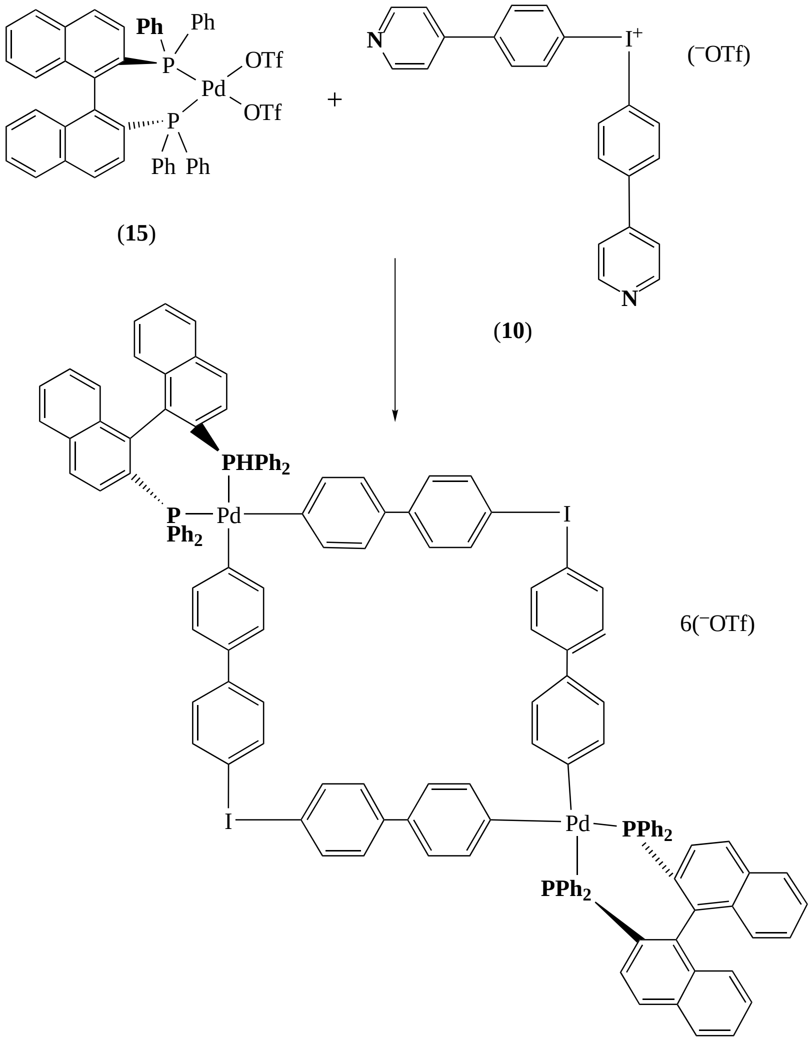
(**13**)

X = $C(CO_2Et)_2$



(**14**)

Diphosphine ligands have also been employed as site-protecting groups. Chirality (*see Chiral*) was introduced to the chemistry by using phosphine-modified binapthalene (BINAP) ligands. In this manner, the chiral molecular square (**16**) was prepared by the reaction of (**15**) with (**10**) (Scheme 4).[13] The induced chirality is entirely due

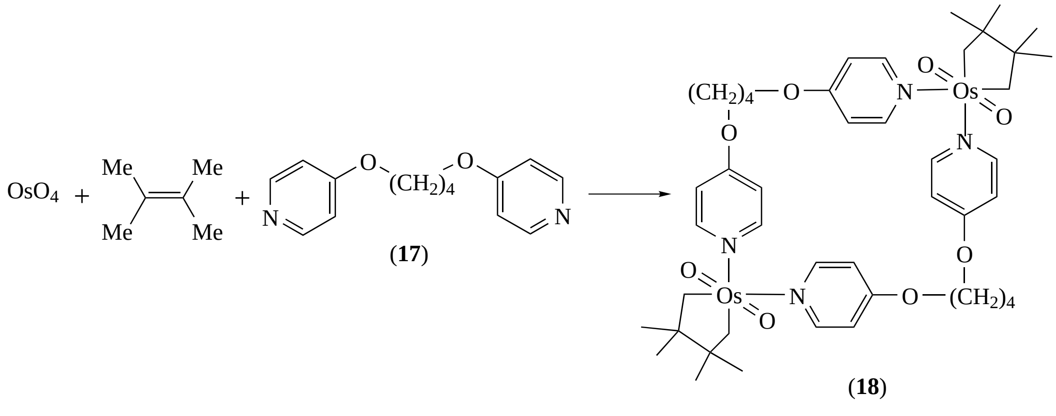


(**15**)

(**10**)

(**16**)

Scheme 4



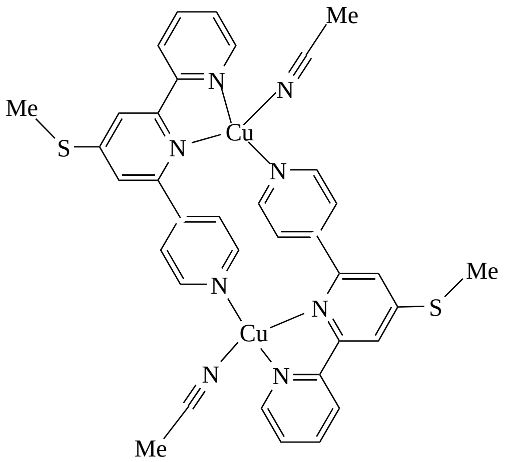
(**17**)

(**18**)

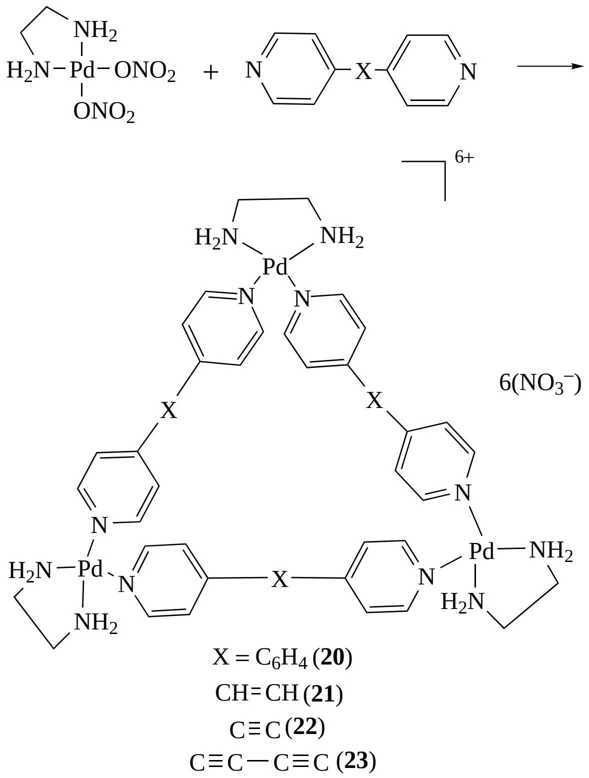
Scheme 5

to the BINAP ligand rather than to the symmetry of the overall molecule.

Relatively few dinuclear metallomacrocycles with metal ions other than Pd(II) or Pt(II) are known. Among the reported examples is the neutral macrocyclic structure (**18**)[14] isolated from the reaction of OsO_4, 2,3-dimethyl-2-butene and the bis-pyridyl ligand (**17**) (Scheme 5). The self-assembly of a tetrahedral (*see Tetrahedral*) Cu(I) salt with 4-thiomethyl-6-(3′-pyridyl)-2,2′-bipyridine leads to the dinuclear metallomacrocycle (**19**).[15] Mass spectroscopic and single-crystal X-ray studies confirmed the composition of the complex. Use of the acetate salt of Cd(II) yields a similar macrocycle but with each metal atom having an irregular octahedral (*see Octahedral*) geometry consisting of bidentate acetate ligands with methanol molecules occupying the additional coordination sites.



(**19**)



Scheme 6

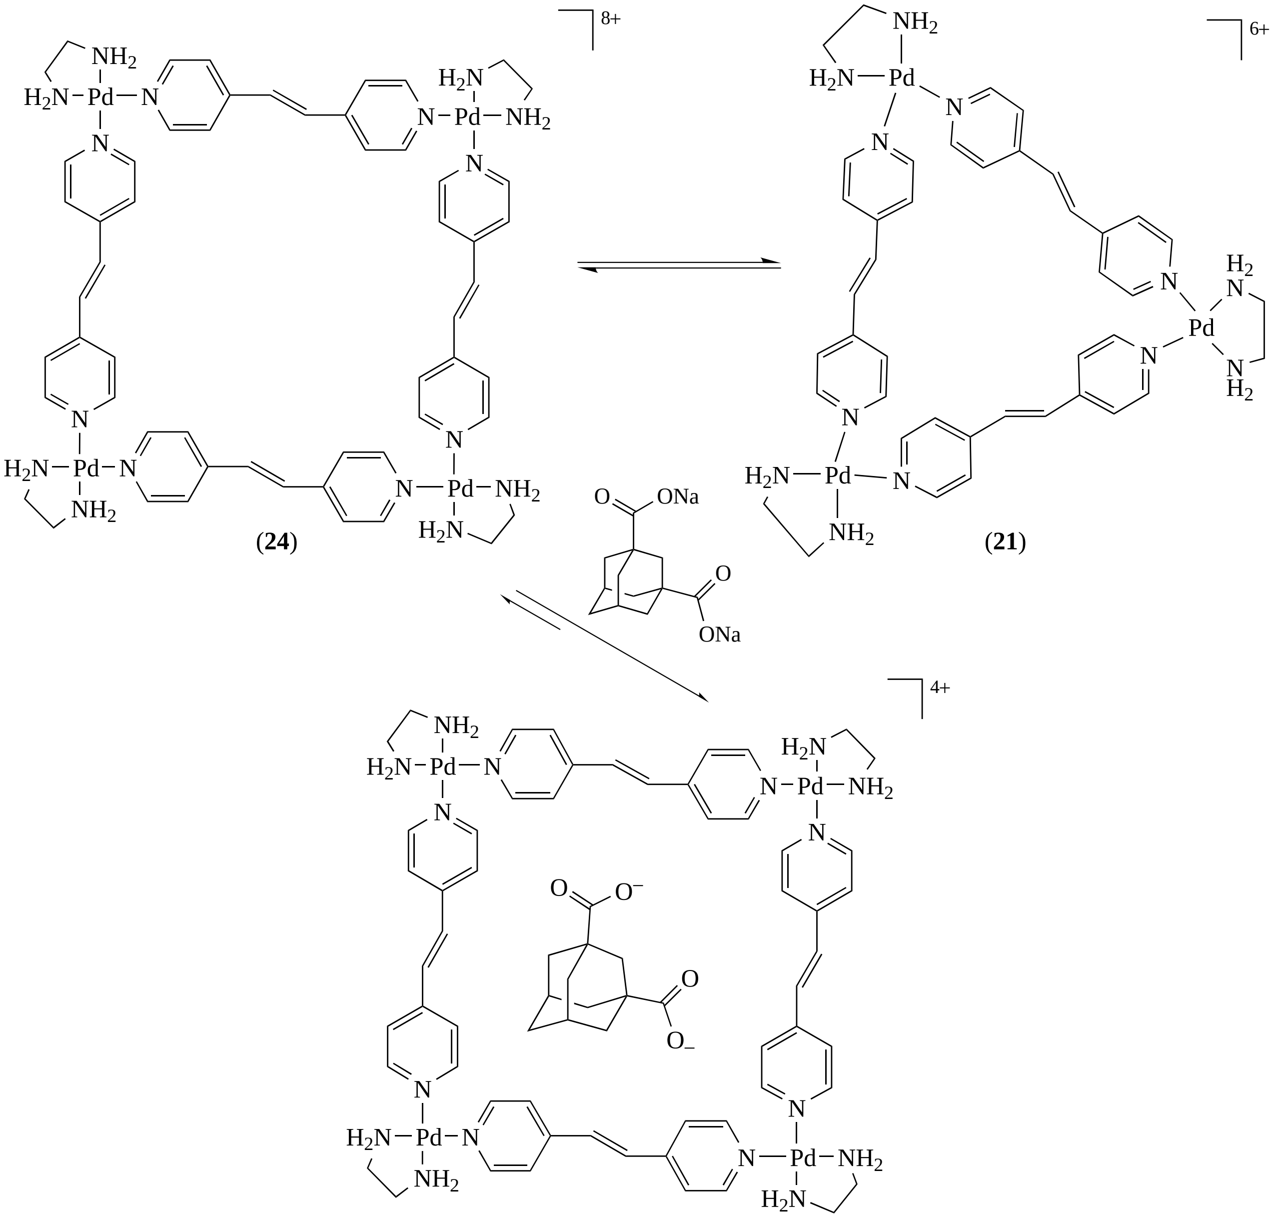
3.2 Molecular Triangles and Trinuclear Macrocycles

Molecular triangles are less well-known as compared to dinuclear and tetranuclear structures. Fujita and coworkers isolated a series of triangles (**20–23**) by reacting linearly disposed bis-heteroaryls with $(en)Pd(ONO_2)_2$ (Scheme 6).[16] These molecular triangles are in equilibrium with the corresponding molecular squares, and the composition varies depending on the flexibility of bridging ligands, the protecting groups on the metal ions, the solvent, and concentrations and identities of potential templates. Electrospray ionization mass spectroscopic (ESI-MS) studies on solutions of (**21**) indicated an equilibrium mixture with the corresponding square (**24**). The results of ^{1}H NMR studies performed on this system revealed that, at moderate concentrations, the square is the major product whereas at low concentrations the formation of the triangle is favored. Oligomers were noted to form at very high concentrations. Addition of di-sodium salts of 1,3-adamantanedicarboxylic acid in water to the equilibrium mixture shifts the equilibrium to the square structure with the anionic guest being located inside the cavity of the square (**25**) (Scheme 7).[17]

It is reasonable to expect that the use of rigid 60° angular building blocks with 180° linear linking units would provide triangular structures. Indeed, this has been demonstrated by the self-assembly of 4,7-phenanthroline and the linear phenyl-bridged bis-palladium complex, which yields the triangle (**26**).[18]

A trinuclear metallomacrocycle (**27**) has been synthesized using 2,2′-bipyrazine and $(en)Pt(ONO_2)_2$.[19] The solid-state structure of (**27**) reveals that the two pyrazine rings of the bipyrazine ligand are twisted with respect to each other, which is an essential ingredient for the formation of the triangle. Subsequent addition of $(en)Pd(ONO_2)_2$ to the molecular triangle leads to a hexanuclear complex in which Pd(II) ions are coordinated to the free 2 and 2′ nitrogen atoms of bipyrazine. Rotation about the C–C single bond allows for chelation to other metal ions and thereby provides access to Pt_6, Pd_6 and Pt_3Pd_3 triangles.[20] Interestingly, the corresponding Pd complex forms a mononuclear chelating bipyrazine complex, which illustrates the unpredictable nature of these reactions.

The high-yield synthesis of a luminescent trinuclear structure (**28**) in which deprotonated benzimidazole acts as the

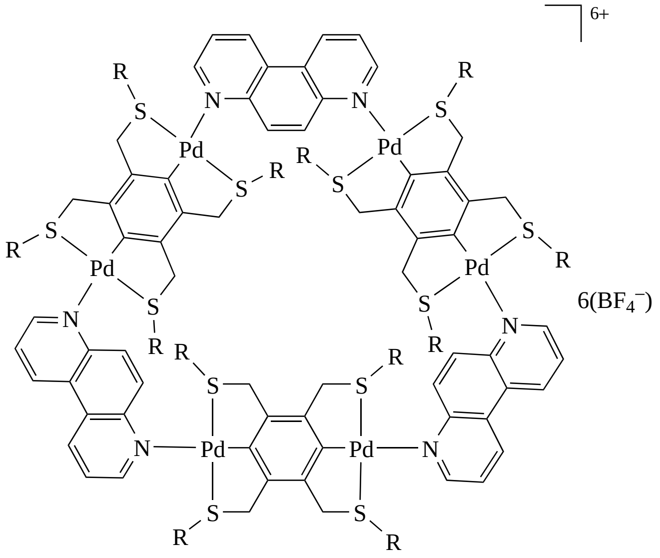


Scheme 7

bridge between cyclometallated Pt(II)-2-(2-thienyl)pyridine units has been reported.[21] The three Pt atoms in this structure occupy the corners of a triangle and the three imidazole ligands span the edges. The N–Pt–N angles at the vertices are close to 90°, which is larger than the expected angles for trinuclear cyclic systems with rigid linkers. Flexible linkers such as 1,2-bis-(3,5-dimethylpyrazol-1-yl)ethane (**29**) also form trinuclear metallomacrocycles with $PdCl_2$. For example, in complex (**30**), the ligand coordinates to *trans*-$PdCl_2$ and is highly strained (Scheme 8).[22] Interactions between methylene protons (of the ligand) and the palladium and chloride ions presumably increase the overall stability of the trimeric structures.

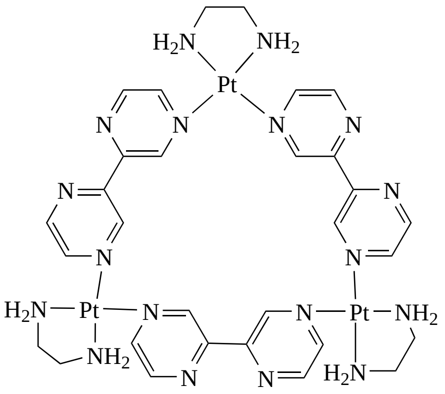
3.3 Molecular Squares and Tetrameric Structures

Among the various polygonal assemblies that inorganic architectures can adopt, molecular squares are the most common. This fact can be attributed to the tendency of transition metals to form cis complexes with L–M–L bond angles of 90° and to the widespread availability of linear-bridging ligands. In this vein, Stang and coworkers

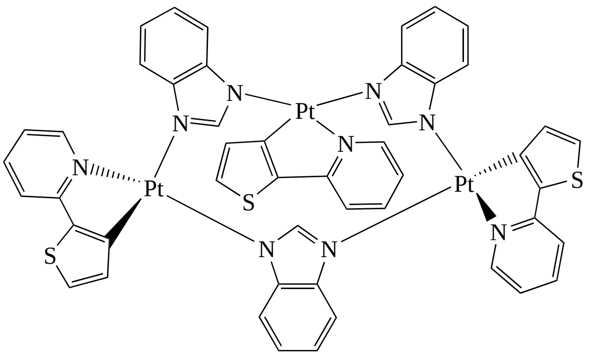


R = *n*-Bu, Ph

(**26**)

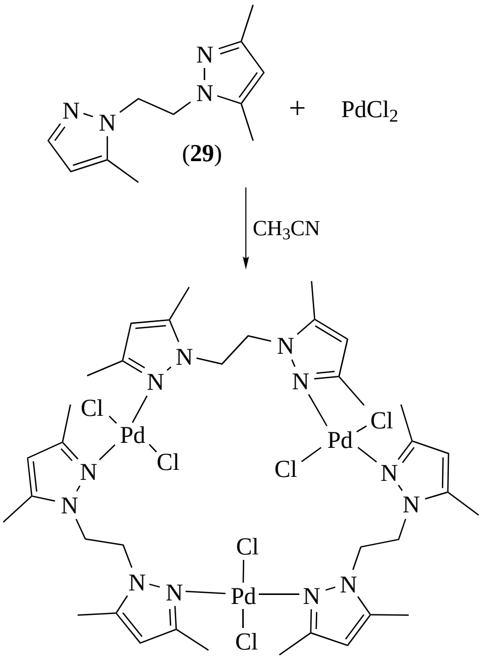


(**27**)



(**28**)

have used Pt and Pd phosphine-containing precursors as the vertices and 4,4′-bipyridine ligands as the edges for the assembly of squares. Reactions of $(Et_3P)_2M(OTf)_2$ (M = Pd, Pt) with equimolar amounts of linearly disposed



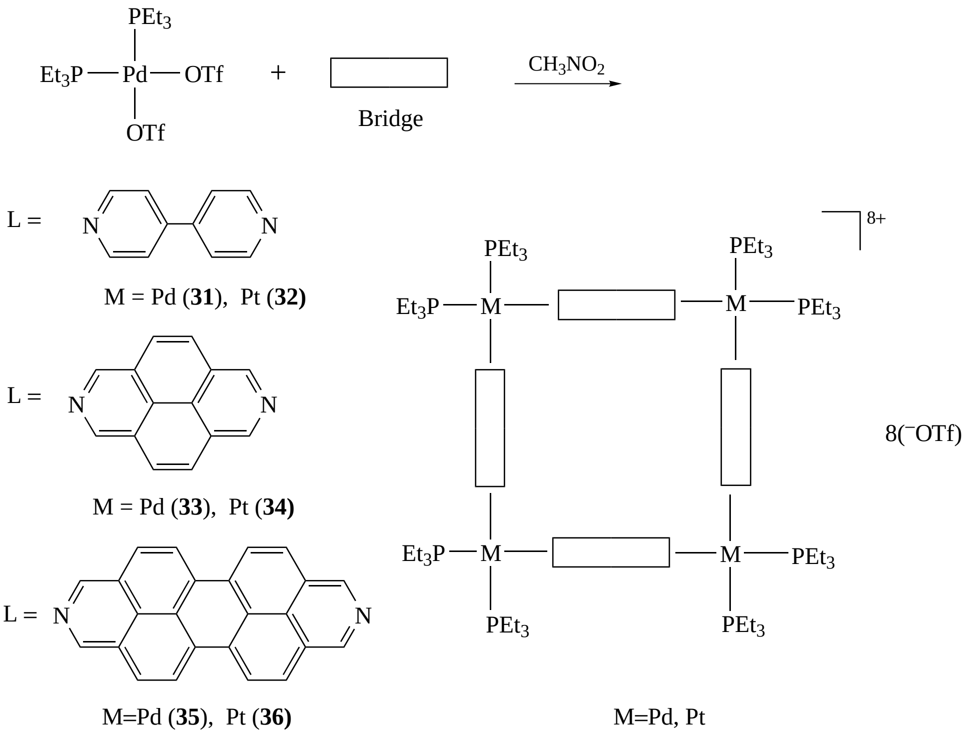
(**30**)

Scheme 8

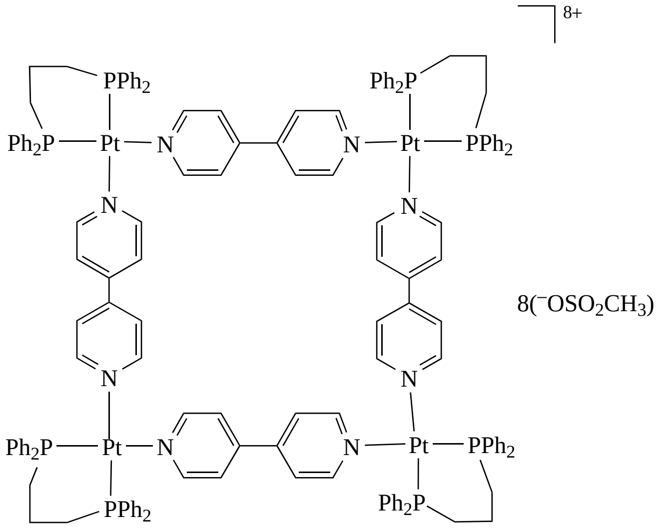
N-aryl ligands yield molecular squares (**31–36**) with varied cavity sizes (Scheme 9).[23] Bis-phosphine ligands also have been used to block the cis positions of square-planar Pt(II) and Pd(II) complexes. Reactions of (dppp)Pt(II)$(OTf)_2$ (dppp = diphenylphosphinopropane) with 4,4′-bipyridine in chlorinated solvents provide the molecular square (**37**)[24] in which the metal ions occupy the corners and the organic ligands span the edges. The diagonal and edge-to-edge metal–metal distances are approximately 15 Å and 11 Å respectively.

Fujita *et al.* pioneered the use of bis-amine ligands in molecular square chemistry. A typical metal precursor that has been used is (en)Pd$(ONO_2)_2$. A quantitative yield of the molecular square (**38**) was obtained from the reaction of (en)Pd(II)$(ONO_2)_2$ with 4,4′-bipyridine (Scheme 10).[16,25] Molecular structure of the resulting 8×8 Å^2 square was established by NMR spectroscopy, mass spectrometry (*see Mass Spectrometry*), and single-crystal X-ray diffraction (*see X-ray Diffraction*) studies. Although the Pd(II) complex produces molecular squares almost exclusively, the Pt(II) analog yields a mixture of oligomers. With heating, the thermodynamically favored square molecules were found to be the predominant products.

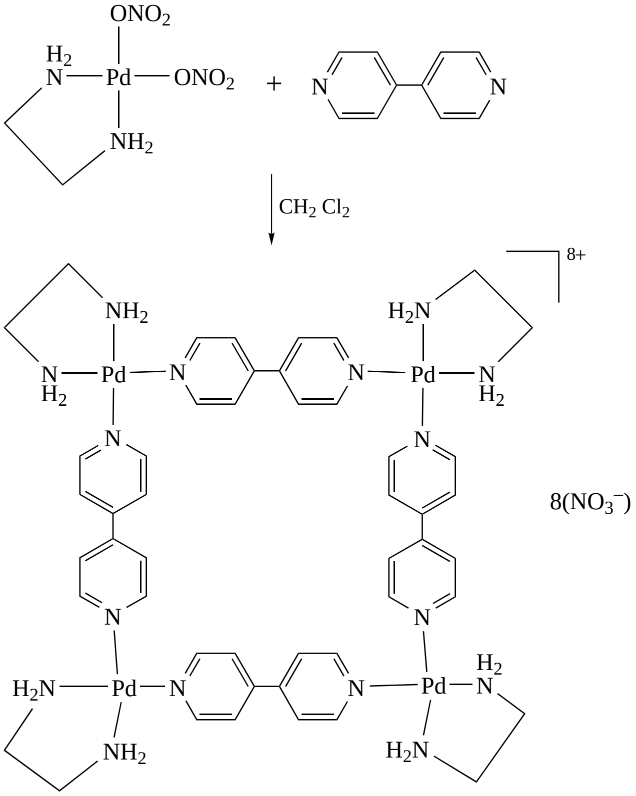
The aforementioned examples primarily involve the use of bis-heteroaryl ligands. Transition metal complexes with appended N-donor ligands, however, can also act as donor ligands for metal acceptors. The organometallic complex (*see Organometallic Complexes*) (**39**) reacts with $(Et_3P)_2Pd(OTf)_2$ to afford the heterometallic square (**40**) (Scheme 11).[26] The



Scheme 9



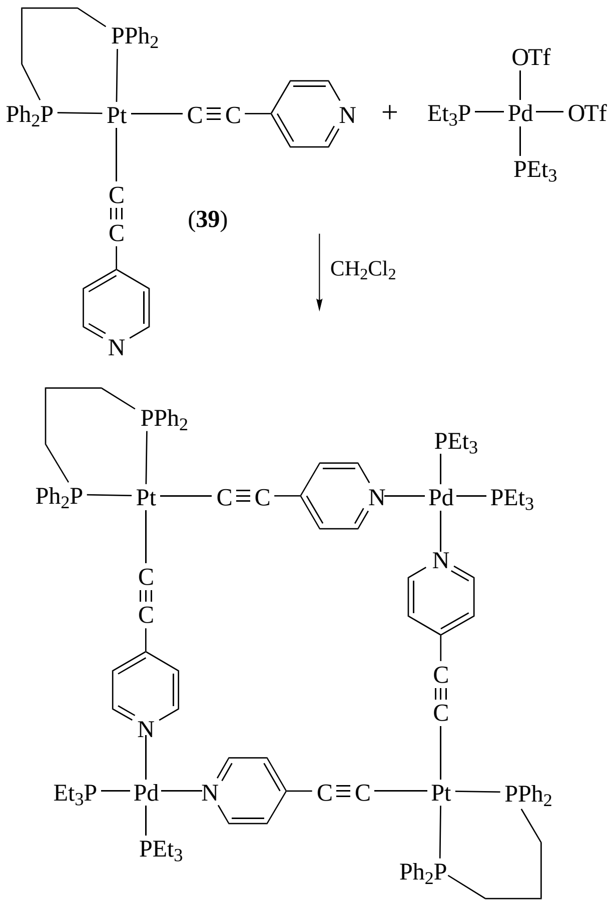
(**37**)



(**38**)

Scheme 10

acetylene units along the edges of the square are capable of binding to soft-metal ions as evidenced by the existence of the silver complex (**41**), whose identity has been established by NMR spectroscopy and mass spectrometry.[27] Dissolution of (**41**) in solvents that contain molecules such as pyrazine, phenazine, and so on results in the formation of host–guest complexes (Scheme 12). The solid-state structure of the square with the phenazine guest, (**42**), has been established.[28] The

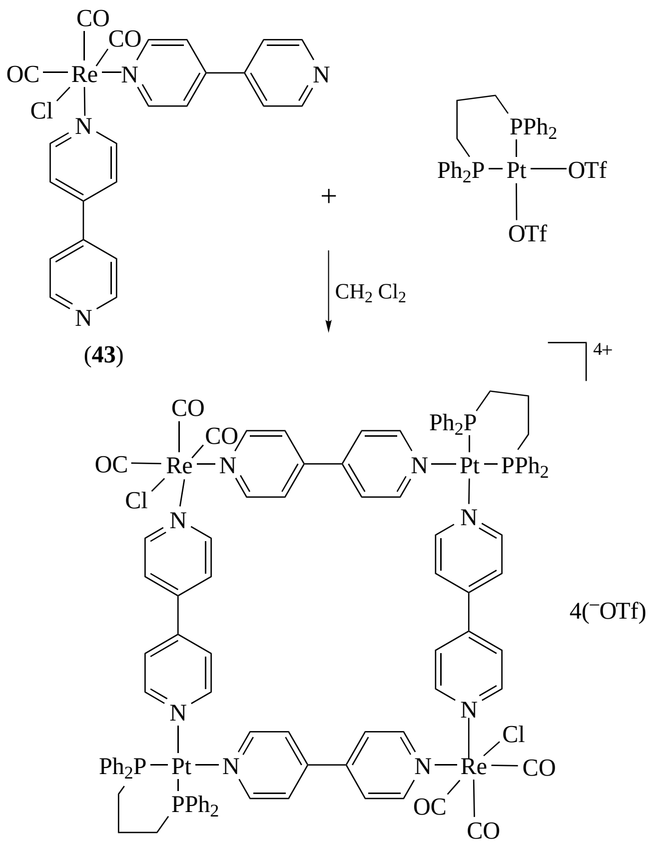


(39)

(40)

Scheme 11

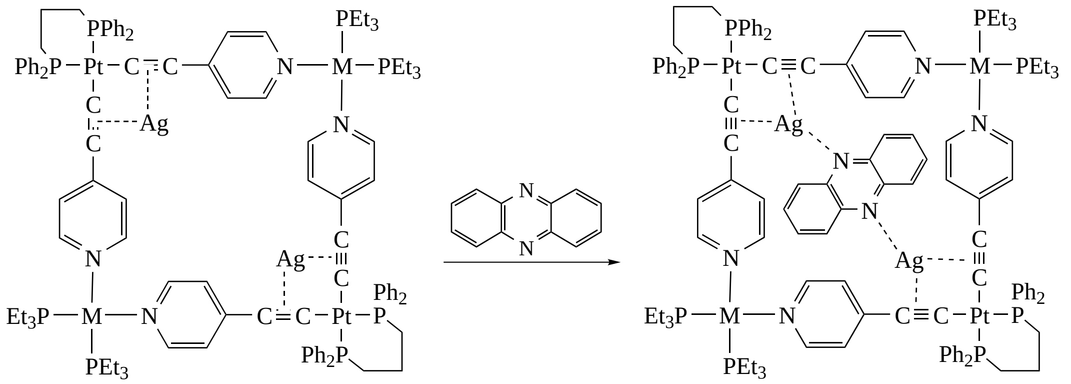
phenyl rings of the host molecule are nearly in the same plane, with the phenazine guest being orientated orthogonal to the rings. The interatomic distances confirm that each Ag^+ ion is π-coordinated to alkyne groups and further linked to N-atoms of phenazine. Structure (**43**) is another example of a transition metal complex that behaves as a ligand. Reaction of (dppp)Pd(OTf)$_2$ with (**43**) gives the heterometallic, luminescent (*see* ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds***) molecular square (**44**) in high yields (Scheme 13).[29] This



(43)

(44)

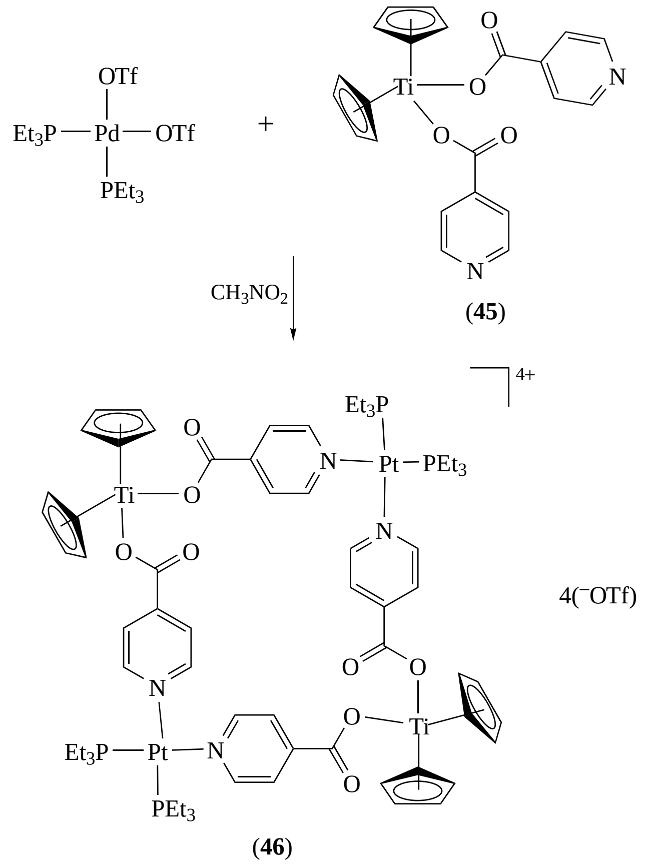
Scheme 13



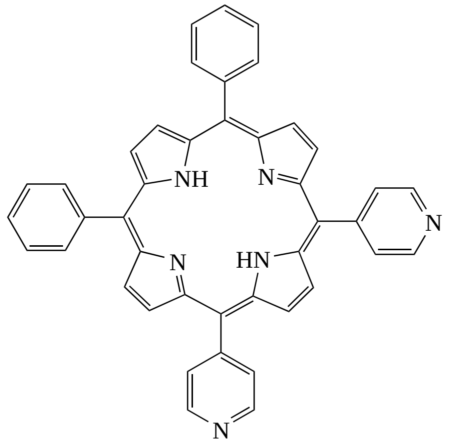
(41)

(42)

Scheme 12



Scheme 14



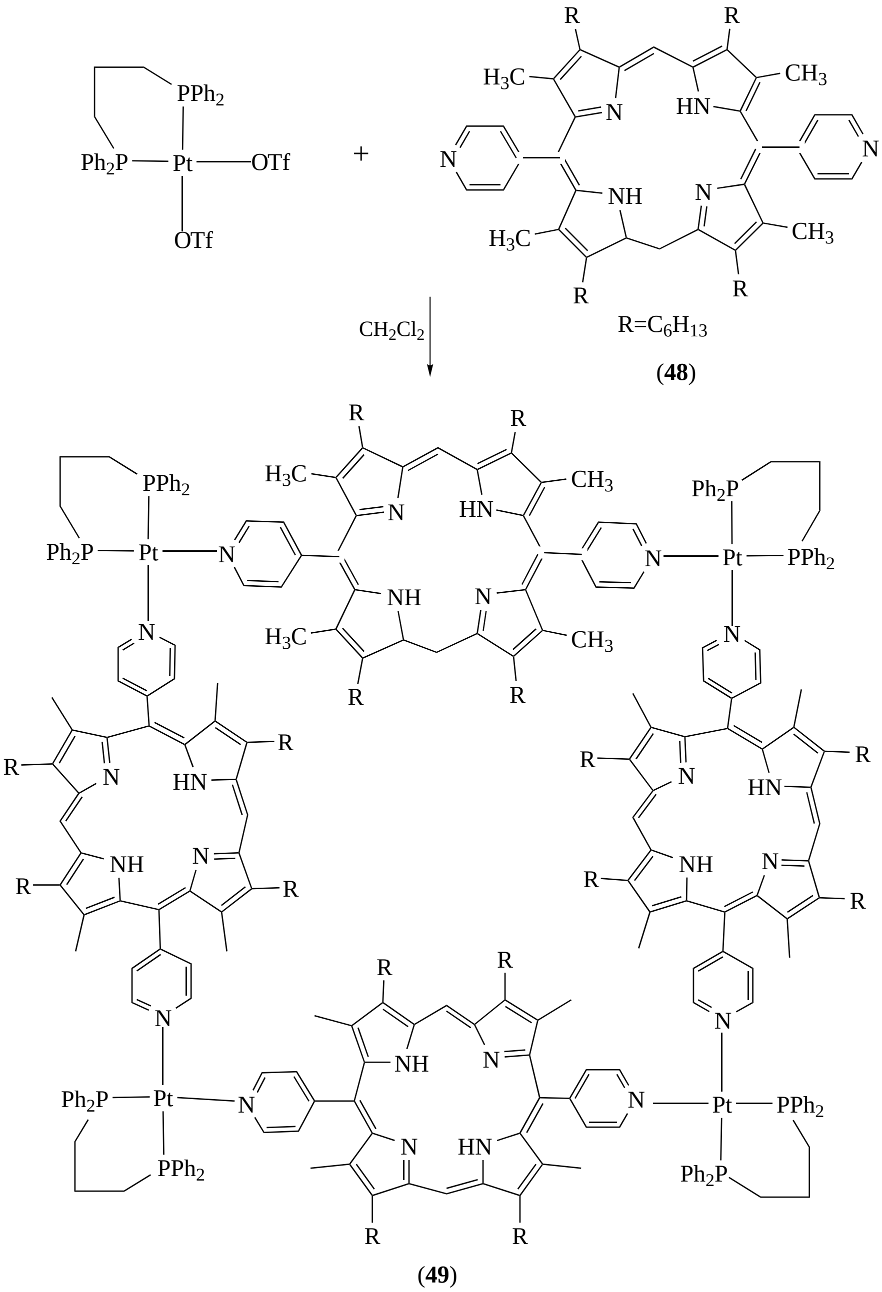
(**47**)

chemistry allows for the investigation of the self-assembly process by photophysical methods. The early transition metal complex (**45**) has been incorporated into a molecular square by an elegant design (Scheme 14). Interaction of (**45**) with $(Et_3P)_2Pt(OTf)_2$ in nitromethane produces the molecular square (**46**).[30] This orange compound was characterized by mass spectrometry, and exhibits a prominent doubly charged molecular ion peak.

Porphyrin (*see Porphyrin*) molecules containing peripheral pyridine groups act as corners or 180° linkers depending on the positions of the pyridyl donor atoms. Reaction of (dppp)Pd$(OTf)_2$ with (**47**) yields the molecular square (**14**)[12] while a larger square (**49**)[31] was obtained by employing a modified porphyrin (**48**) in which the two pyridine units are trans to each other (Scheme 15). The results of these reactions demonstrate that the ability of the molecular components to act as corners or linkers depends on their topologies. Bis-pyridyl-porphyrin (**47**) reacts with *cis*- and *trans*-$(PhCN)_2PdCl_2$ to yield the molecular squares (**50**) and (**51**), respectively, with varied dimensions.[32] These squares have been characterized by NMR spectroscopy and mass spectrometry combined with UV-visible spectroscopy (*see UV–Visible Spectroscopy*) and vapor-phase osmometry.

Two remarkable structures (**52**) and (**53**) have been prepared with '(dppp)M' (M = Pt(II), Pd(II)) corners and a ligand based on perylene-bis-imide.[33] This square is exceptionally large with a diagonal M–M distance of 3.4 nm. An interesting aspect of this molecule is that the organic ligands retain their photophysical and electrochemical properties in the complex. Another nanoscale platinum macrocycle (**55**) that has been reported consists of Pt(II) corners (**39**) and Pt(II) linkers (**54**) (Scheme 16).[34] It was noted that the formation of these squares is concentration dependent, and that the monomer is favored at lower concentrations. At higher concentrations, the tetramer is the main product, and, in the limit of high concentrations, polymer formation dominates.

Self-assembly of labile transition metal ions with N-based multidentate ligands produces metallocyclophanes as in the case of the reaction of (**56**) with $Ni(NO_3)_2$ in water to yield the tetranuclear Ni_4L_4 complex.[35] Recrystallization of this compound from DMSO (dimethyl sulfoxide) in the presence of excess $NaClO_4$ produced crystals that contain one nitrate anion (*see Anion*) inside the square cavity of Ni_4L_4 square. The seven perchlorate anions are located in the interstices of the structure. In this context, the role of anions in the self-assembly of metallocyclophanes is being investigated by Dunbar and coworkers with 3,6 bis-(2-pyridyl)tetrazine (bptz). Reaction of the acetonitrile solvated complexes $M(II)(CH_3CN)_6(X)_2$ (M = Ni, Zn; X = BF_4^-, ClO_4^-) with bptz leads to high yields of the compounds (**57–60**) (Scheme 17). The X-ray and solution NMR studies confirm the location of one anion inside the cavity of the $[M_4(bptz)_4]^{8+}$ unit. The structure of $[\{Ni_4(bptz)_4(CH_3CN)_8\}\subset ClO_4]$ in (**58**) and $[\{Zn_4(bptz)_4(CH_3CN)_8\}\subset BF_4]$ in (**59**) is shown in Figure 1.[36] The coordination geometry (*see* ***Coordination Numbers & Geometries***) around each M(II) ion is distorted octahedral, with four sites being occupied by two different bridging bptz ligands and the two remaining sites being occupied by acetonitrile solvent molecules.

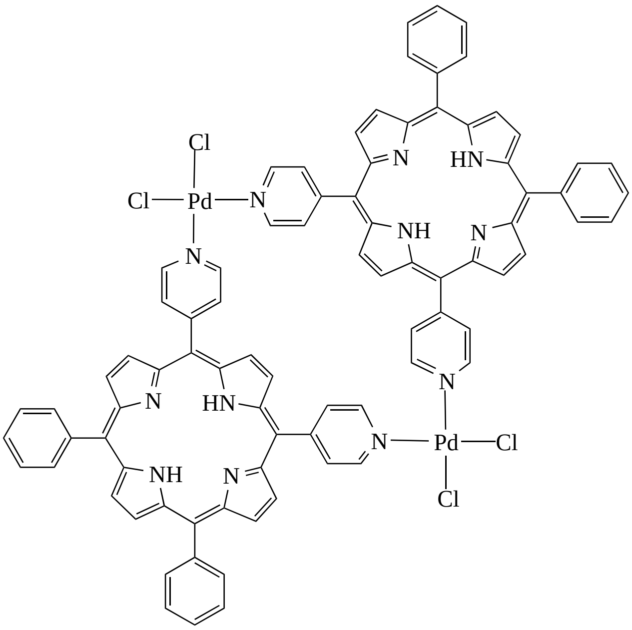


(49)

Scheme 15

3.4 Molecular Pentagons

Pentagons based on metal-coordination complexes (*see Coordination Complexes*) are quite rare. The first example was reported by Lehn and coworkers who reacted (**61**) with $FeCl_2$ in ethylene glycol at 170°C to produce the pentagon (**62**) in nearly quantitative yield (Scheme 18). An X-ray structural determination confirmed that the molecule is a pentagon with a chloride anion tightly bound within the central cavity. The encapsulated chloride was said to be essential for the formation of the pentagon.[37] Reaction of (**61**) with $FeSO_4$ under identical conditions followed by precipitation with NH_4PF_6 produced the hexameric structure (**63**) in high yield (Scheme 19).[38] Evidence of the nuclearity was confirmed by ESI-MS. Dunbar and coworkers reported a molecular pentagon $Ni_5(bptz)_5(CH_3CN)_{10}(SbF_6)_{10}$ (**64**) from the reaction of $Ni(CH_3CN)_6(SbF_6)_2$ with bptz (Scheme 20). An X-ray structure and a mass spectrometric study confirmed the pentagonal structure of $\{Ni_5(bptz)_5(CH_3CN)_{10}\}\subset SbF_6$ (Figure 2). The templating (*see Templating*) effect of the $[SbF_6]^-$ anion in stabilizing the pentagon has been established.[39] Reactions between Ni(II) ions and bptz in the

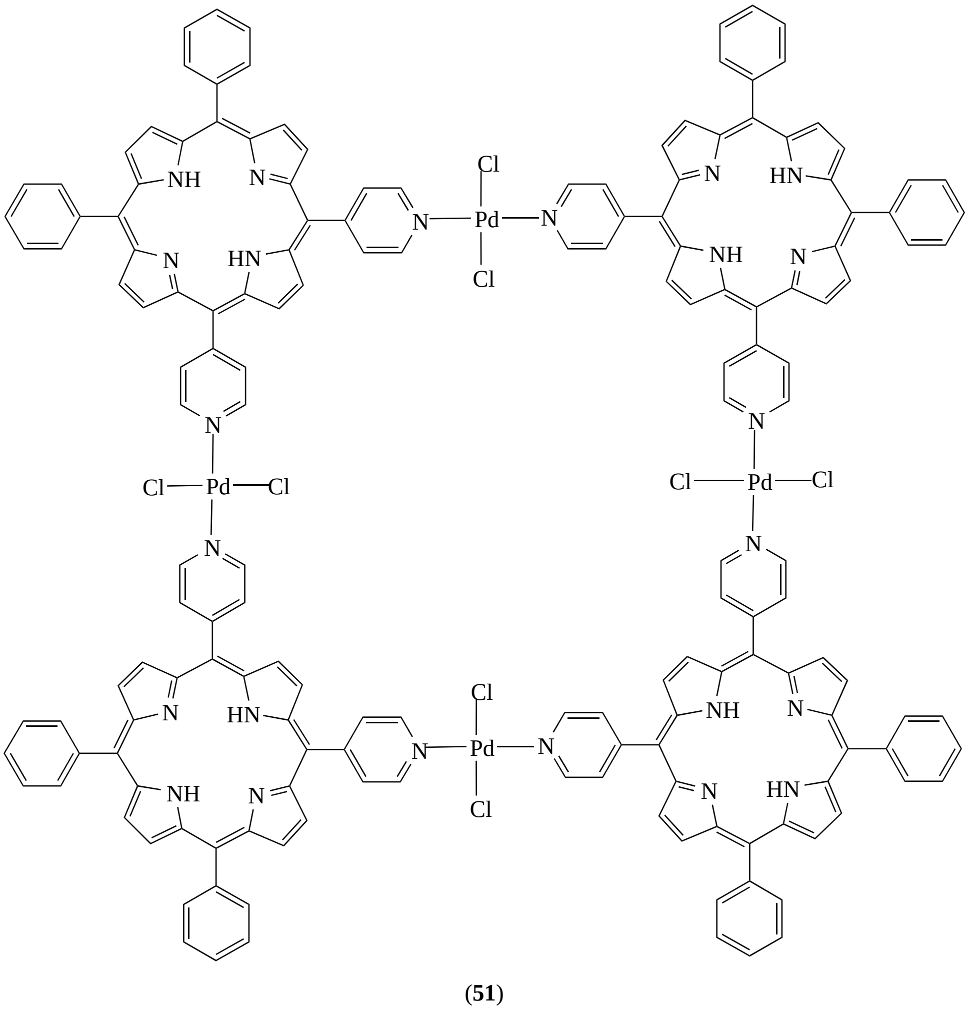


(**50**)

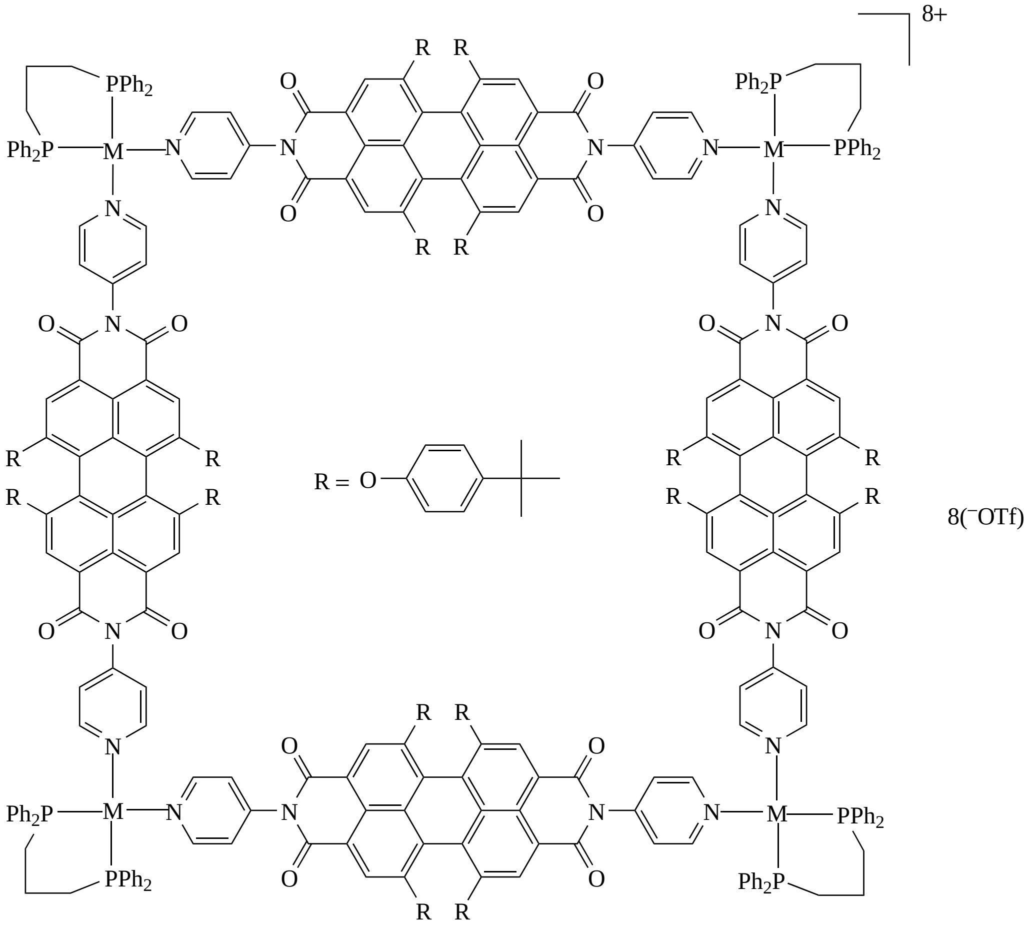
presence of smaller, tetrahedral anions such as $[BF_4]^-$ or $[ClO_4]^-$ lead to the formation of molecular squares under identical conditions.

4 CYANIDE (*See Cyanides*)

The cyanide ligand forms linear bridges and imparts relatively strong electronic and magnetic coupling between metal centers. Metal-cyanide chemistry has been investigated for many years,[40] with the most well-known compound in the family being Prussian blue (PB *see Prussian Blue*), $Fe_4[Fe(CN)_6]_3 \cdot nH_2O$, which was discovered by the German artist Diesbach in 1704. PB has been used in many applications over the years including as a pigment in the manufacture of inks and paints. Prussian blue is readily prepared by the addition of $[Fe(II)(CN)_6]^{4-}$ to Fe(III) ions in aqueous solution. The PB family of compounds exhibit defective face-centered cubic frameworks with cavities capable of encapsulating small molecules or charge balancing ions. The different distribution of the vacancies leads to various space group modifications



(**51**)



M = Pd (**52**)
Pt (**53**)

depending on the crystal growth conditions. The extent of deviation for Prussian blue ranges from a high-symmetry cubic space group (Fm3m) with a random distribution of vacancies occupied by water molecules to a lower-symmetry Pm3m space group with an ordering of the defects. These compounds are typically extremely insoluble, and the 'soluble forms' of PB are, in fact, colloidal suspensions with various degrees of potassium content.

The Prussian blue analogs $M^cM^a[M^b(CN)_6]\cdot nH_2O$ (M^c = K^+, Cs^+ etc.; M^a and M^b = transition metal ions) comprise a family of complexes, many of which exhibit high-magnetic-ordering temperatures. Modification of the PB compounds with the aim of reducing the complexity and dimensionality of the network structure has been achieved by using metal precursors with some of the coordination sites blocked by capping ligands. This chemistry has been fueled by the recognition that large-spin paramagnetic molecules can exhibit slow paramagnetic relaxation or single-molecule magnetic behavior.[41] Researchers are using convergent precursors to favor the deliberate formation of molecular architectures such as squares, cubes, and so on. Unlike the extensive use of square-planar (*see Square Planar*) transition metal ions such as Pd(II) and Pt(II) with the N-heterocyclic based ligands described earlier, molecular components for these magnetic materials consist of six-coordinate transition metals with unpaired electrons. It is necessary to protect four coordination sites at the metal ion to access molecular squares or two-dimensional, infinite networks. In a similar manner, three sites can be capped for accessing three-dimensional structures such as cubes. A number of precursors with two accessible sites available for coordination that have been structurally characterized in recent years include $[M(bpy)_2(OTf)_2]$ (2,2′-bpy = 2,2′-bipyridine) (M = Mn(II) (**65**), Co(II) (**66**)), $[Ni(bpy)_2(H_2O)_2](OTf)_2$ (**67**) and $[Mn(2,2'\text{-}bpym)_2(H_2O)_2](BF_4)_2$ (bpym = bipyrimidine) (**68**). The two cyanide ligands in $[Mn(bpy)_2(CN)_2]$ (**69**) are in cis positions and act as donors to other metal ions.[42]

Slow addition of $Zn(bpy)_2Cl_2$ to an aqueous solution of $K_3[Fe(CN)_6]$ results in the formation of the trinuclear structure $[\{Zn(bpy)_2(H_2O)\}_2\{Fe(CN)_6\}]Cl$ (**70**).[43] An X-ray structure revealed that two $[Zn(bpy)_2(H_2O)]$ units are coordinated to a central $[Fe(CN)_6]^{3-}$ unit in a trans fashion.

The coordinated water molecule is stabilized by hydrogen bonding to a CN^- ligand of $[Fe(CN)_6]^{3-}$. The complex $[Zn(phen)_3]_2[\{Zn(phen)_2\}_2\{Fe(CN)_6\}_2]$ (**71**) was obtained from the reaction of $[Zn(phen)_2(NO_3)_2]$ with $[Fe(CN)_6]^{3-}$, which contains a central bimetallic $[Zn_2Fe_2]$ square unit.[43] The $[Fe(CN)_6]^{3-}$ units reside at opposite vertices of the square with the other two vertices being occupied by Δ and Λ $[Zn(phen)]^{2+}$ units. Similar molecules are accessible with

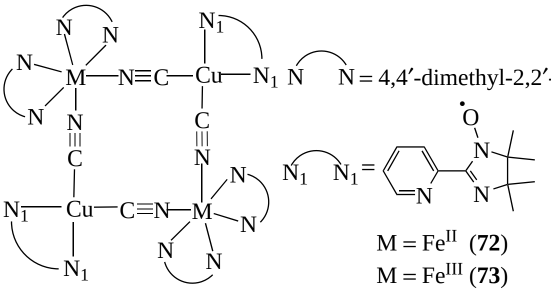
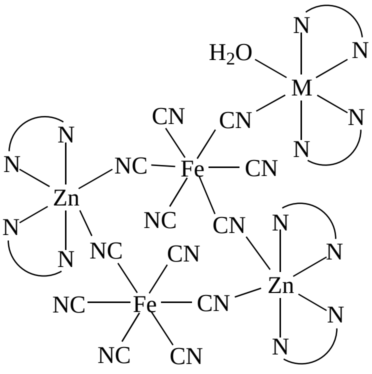
bipyridyl ligands. Oshio and coworkers reported Fe(II)/Cu(II) and Fe(III)/Cu(II) squares based on metal–cyanide complexes (*see* ***Cyanide Complexes of the Transition Metals***). Reactions of $Fe(dmbpy)_2(CN)_2$ or $[Fe(dmbpy)_2(CN)_2](NO_3)$ (dmbpy = 5,5′-dimethyl-2,2′-bipyridine) with $[Cu(ClO_4)_2]$ and imply (impy = 2-(2-pyridyl)-4,4,5,5-tetramethyl-4,5-dihydro-1H-imidazolyl-1-oxy) yield (**72**) and (**73**), respectively.[44]



N N = 4,4′-dimethyl-2,2′-bipyridine

M = Fe^{II} (**72**)
M = Fe^{III} (**73**)

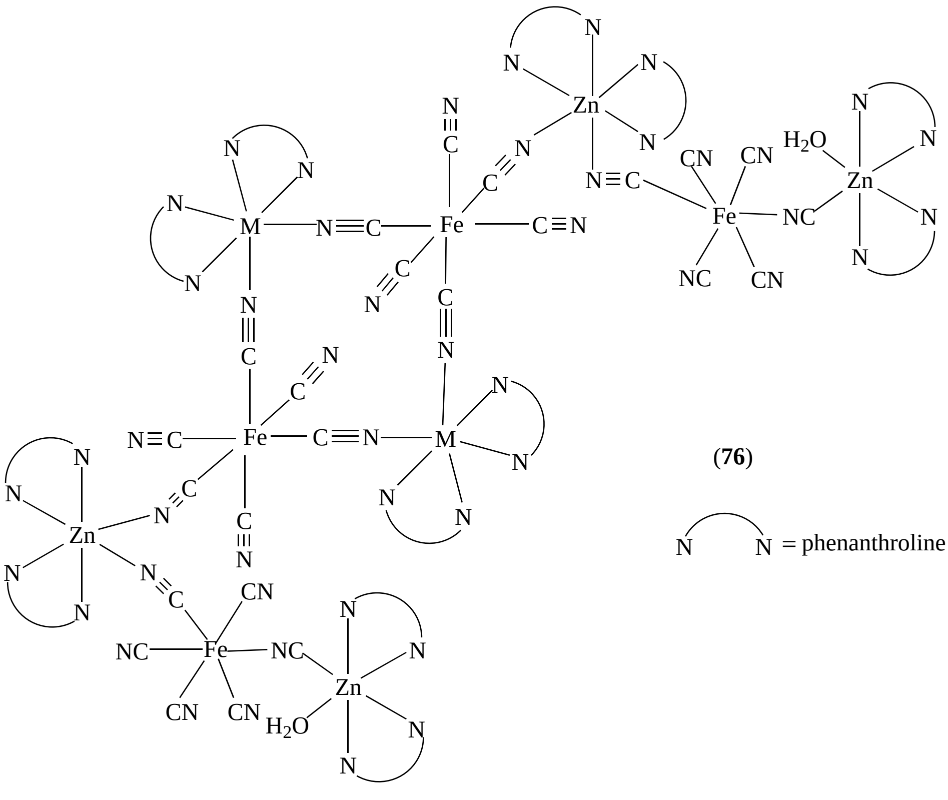


N N = 2,2-bipyridine

M = Ni (**74**), Zn (**75**)

One advantage of the use of hexacyanometallates in the aforementioned reactions is that the free cyanides (*see Cyanides*) can be used for the elaboration of squares into larger assemblies. The molecular pentamer $[\{Ni(bpy)_2(H_2O)\}\{Ni(bpy)_2\}_2\{Fe(CN)_6\}_2]$ (**74**) has been isolated from the reaction of $[Ni(bpy)_2(H_2O)_2](OTf)_2$ with $K_3[Fe(CN)_6]$ in water.[42] The formation of the pentanuclear species can be viewed as the addition of an additional $[Ni(bpy)_2(H_2O)]$ unit to the $[\{Ni(bpy)_2\}_2\{Fe(CN)_6\}_2]$ square. The molecule is neutral, which accounts for its preferential crystallization from the reaction solution. An analogous compound was isolated with Zn(II), namely $\{Zn(bpy)_2(H_2O)\}[\{Zn(bpy)_2\}_2\{Fe(CN)_6\}]_2$ (**75**).[43] The concept of adding building blocks to the central square unit can be extended to the formation of even larger molecules, as evidenced by the isolation of the highly unusual decanuclear cluster (*see Cluster*) $[\{Zn(phen)_2\}\{Fe(CN)_6\}]_2[\{Zn(phen)_2\}\{Zn(phen)_2(H_2O)\}\{Fe(CN)_6\}]_2$ (**76**) from $Zn(phen)_2(NO_3)_2$ and $K_3Fe(CN)_6$.[43]

Other molecular geometries besides squares have been isolated from a building-block approach. Slow diffusion of solutions of $[K[18]crown\text{-}6)]_3[Mn(CN)_6]$ and $[Mn(tmphen)_3(NO_3)_2]$ (tmphen = tetramethylphenanthroline) in acetonitrile leads to the formation of the cyanide cluster $\{Mn(tmphen)_2\}_3\{Mn(CN)_6\}_2\}$ (**77**) as shown in Figure 3. The molecular symmetry of (**77**) is nearly that of a trigonal bipyramid (tbp) (*see Trigonal Bipyramidal*) in which low-spin Mn(III) ions occupy the apical positions and high-spin (*see High-spin & Low-spin Compounds*) Mn(II) ions reside in the equatorial plane. Each apical Mn(III) ion is linked to Mn(II) centers via three linear cyanide bridges and is capped by three terminal cyanide ligands. The Mn(II) ions are coordinated to cis tmphen ligands as well as to the N ends of two cyanide bridges. The Mn(II) centers in each molecule are homochiral, but the molecules crystallizes as a racemic mixture in the centrosymmetric space group $P2_1/c$. Magnetic studies of the compound reveal that it behaves as a single-molecule-magnet.[45] Reactions of $[Co(bpy)_3(ClO_4)_2]$ and $K_3Fe(CN)_6$ produce a similar tbp molecule $[\{Co(bpy)_2\}_3\{Fe(CN)_6\}_2](ClO_4)$ (**78**).[42] It was noted that complex (**78**) is the result of a spontaneous redox



(**76**)

N N = phenanthroline

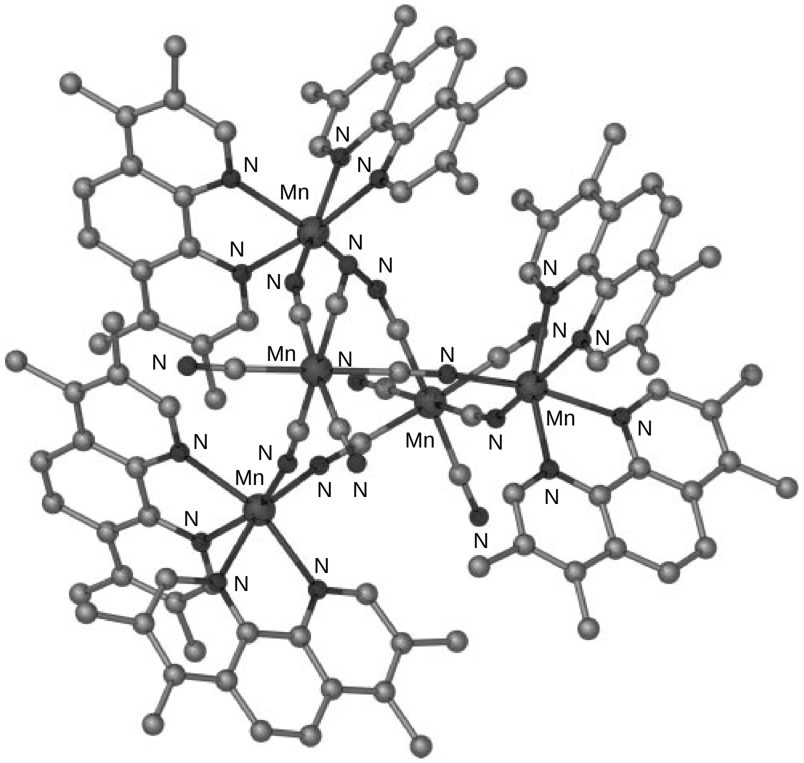


Figure 3 Plot of the molecular structure of $\{Mn(tmphen)_2\}_3\{Mn(CN)_6\}_2$ (**77**)

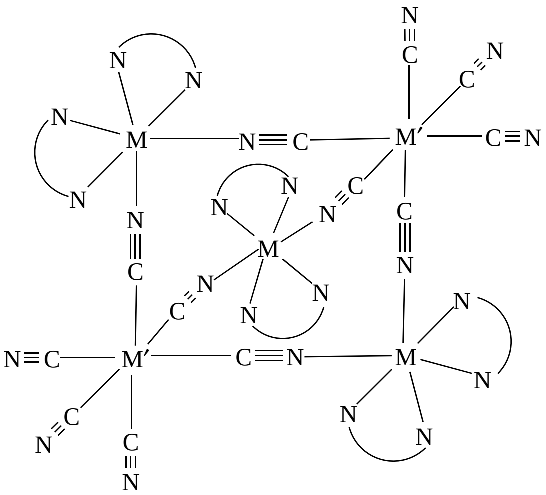
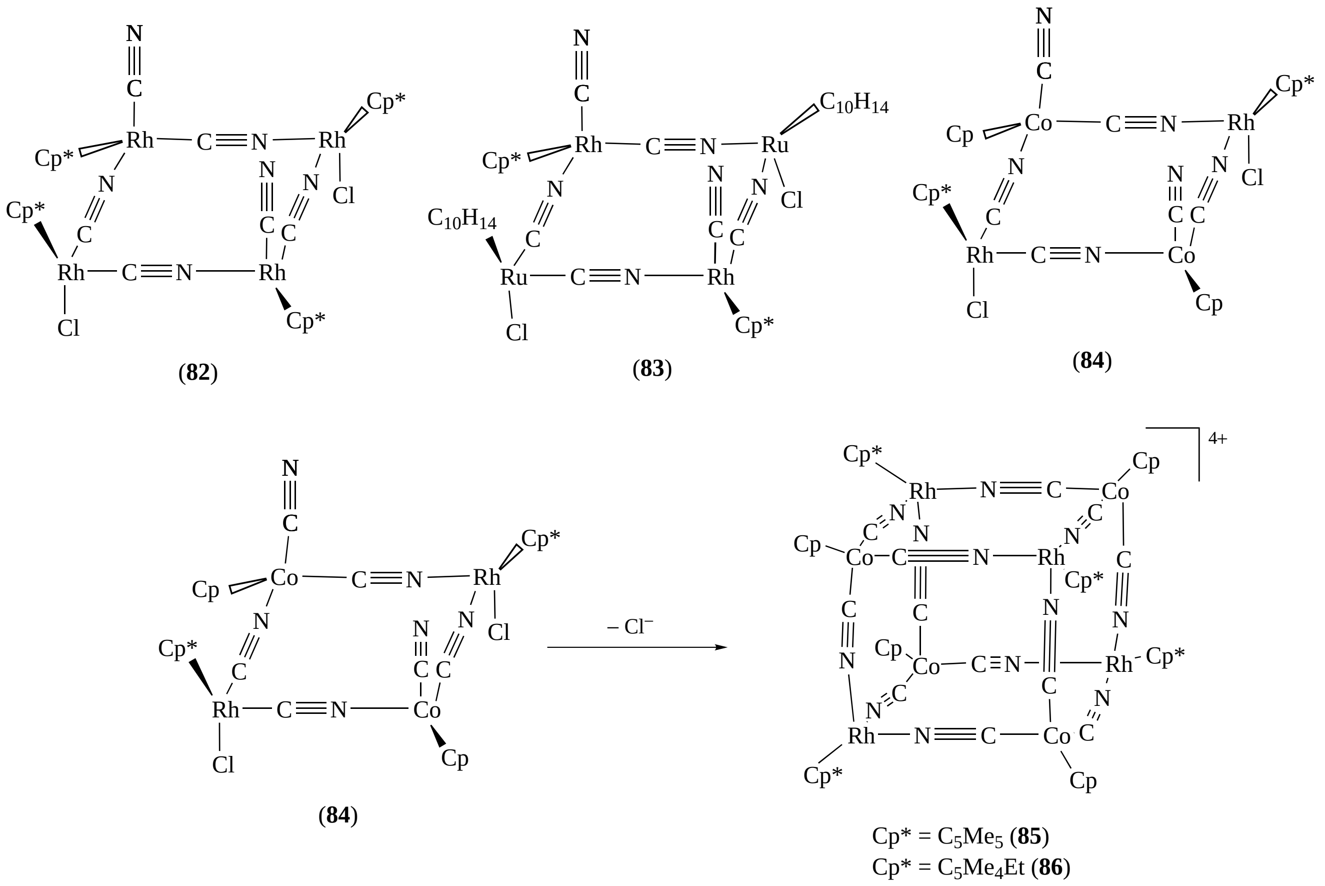
reaction. This conclusion was based on the fact that this compound is diamagnetic and contains two low-spin Fe(II) and Co(III) ions. Similar tbp structures having the general formula $[\{Ni(bpm)_2\}_3\{Fe(CN)_6\}_2]$ (bpm = bis-(1-pyrazolyl)methane) (**79**)[46] and tmphen (**80**)[47] have also been characterized. A similar structure for the $[\{Ni(impy)_2\}_3\{Cr(CN)_6\}_2]$ (**81**) has been proposed (Scheme 21).[48] The use of the bulky radical ligand precludes the formation of an extended network structure and also increases the ground state (*see Ground State*) spin value.

Considerable efforts have been made to synthesize discrete clusters that are analogues of a single cube unit of PB structures. To prevent the formation of a three-dimensional framework, ligands such as 4-isopropyltoluene (*p*-cymene), 1,4,7-triazacyclononane (tacn), triphos (triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane) and cyclopentadienyl (*see Cyclopentadienyl*) (Cp) ligands have been used to cap one face of an octahedron whose other three *fac* (Facial) positions are occupied by CN ligands. Assembly of these tricyanometallate building blocks with three mutually orthogonal, dangling CN ligands has led to a series of molecular cube compounds. For example, the reaction of $[Et_4N][Cp^*Rh(CN)_3]$ and $[\{Cp^*RhCl_2\}_2]$ reported by Rauchfuss and coworkers produces the molecular square (**82**) with Rh atoms at the vertices. The structure of the compound was confirmed by X-ray crystallography (*see X-ray Crystallography*). Analogous mixed-metal $[Rh_2Ru_2]$ (**83**) and $[Co_2Rh_2]$ (**84**) squares have



NN	M	M′	Code
bpy	Co	Fe	**78**
bpm	Ni	Fe	**79**
tmphen	Ni	Fe	**80**
impy	Ni	Cr	**81**

Scheme 21

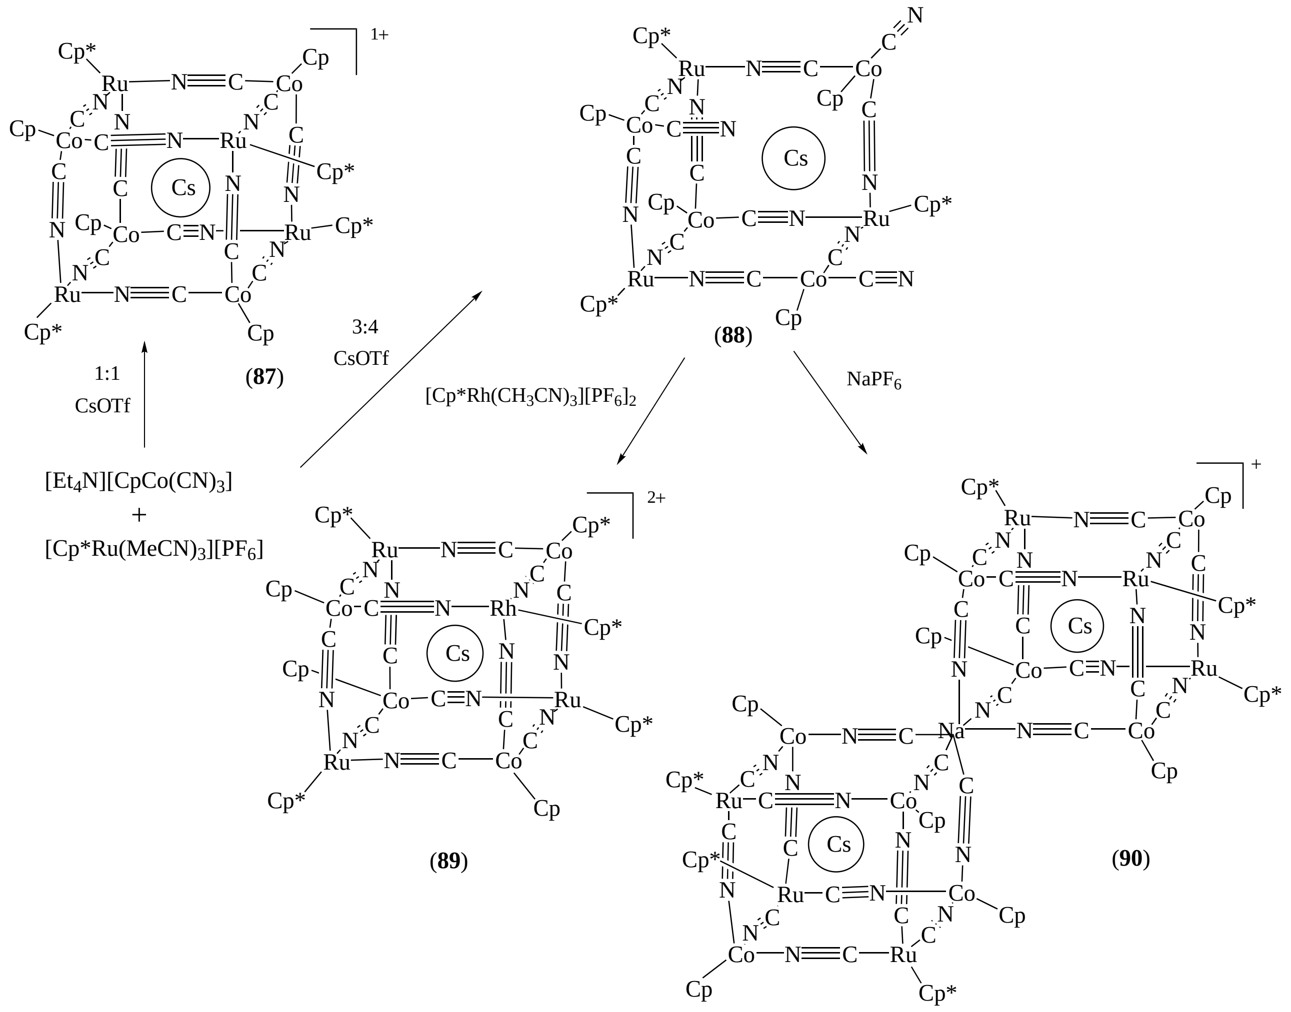


Scheme 22

also been reported. Upon removal of the Cl^- ligands from (**84**), the $[Rh_4Co_4]$ cube (**85**) is formed (Scheme 22). Compound (**85**) was characterized by ESI-MS studies. The crystal structure (*see Crystal Structures*) of (**86**) was obtained, which confirmed the cubic architecture and the presence of C_5Me_4Et as the capping ligand.[49]

In related reactions, Rauchfuss explored condensation reactions of $[Et_4N][CpCo(CN)_3]$ and $[Cp^*Ru(NCMe)_3][PF_6]$ in the presence of cesium ions. This reaction leads to the formation of $[Cs\subset\{CpCo(CN)_3\}_4\{Cp^*Ru\}_4]$ (**87**), a molecular cage with an encapsulated cesium ion.[50] Although a myriad of other cations such as Cs^+, K^+, Rb^+, $NH_4{}^+$, $MeNH_3{}^+$ can be encapsulated by this cage, when the reaction is carried out in the presence of $EtNH_3{}^+$ ions, the empty molecular box $[\{CpCo(CN)_3\}_4\{Cp^*Ru\}_4]$ is formed in high purity.[51] Reaction of $[Et_4N][CpCo(CN)_3]$, $[Cp^*Ru(NCMe)_3][PF_6]$ and CsOTf in a 4:3:1 ratio in acetonitrile led to the isolation of the incompletely formed cube (**88**) (Scheme 23). The ESI-MS of (**88**) exhibits a molecular ion peak at $m/z = 1649$ and an absence of signals for the cube (**87**). Apart from the structural features of (**88**), this molecule represents an opportunity to incorporate other metal ions into the assembly, by a reaction described as a 'box-completion' process. Treatment of (**88**) with $[Cp^*Rh(NCMe)_3](PF_6)_2$ gives the Cs^+ encapsulated box (**89**). The product was characterized by ESI-MS and NMR spectroscopy. Treatment of (**88**) with $NaPF_6$ produces the 'double molecular box' fused at one corner. The structure of $[Na\{Cs\subset \{CpCo(CN)_3\}_4\{Cp^*Ru\}_3\}_2]\,PF_6$ (**90**) consists of two $Cs\subset \{CpCo(CN)_3\}_4\{Cp^*Ru\}_3$ cages conjoined at a Na^+ ion. The Cs^+ ions are situated at the center of two *pseudo* boxes. The smaller Na^+ ion is coordinated to six terminal cyanides from two incomplete box structures in an octahedral arrangement.

Long and coworkers have contributed a considerable body of work to the area of paramagnetic cube molecules based on bridging cyanide ligands. Formation of the $[Cr_4Co_4]$ cube $[Cr_4Co_4(CN)_{12}(tacn)_8][OTf\,]_{12}$ (**91**) has been reported to occur from the reaction of equimolar amounts of $[Cr(H_2O)_3(tacn)][OTf\,]_3$ and $[Co(CN)_3(tacn)]$ in water. The molecular cube $[Co_8(CN)_{12}(tacn)_8][OTs]_{12}$ (**92**), with eight Co atoms at the vertices, has also been reported and characterized by X-ray crystallography. A high R-factor for this structure was attributed to anion disorder but is also likely to be a result of the high symmetry of the cubic clusters. As in the case of fullerenes (*see* ***Carbon: Fullerenes***), these clusters exhibit rotational disorder that greatly affects the quality of



Scheme 23

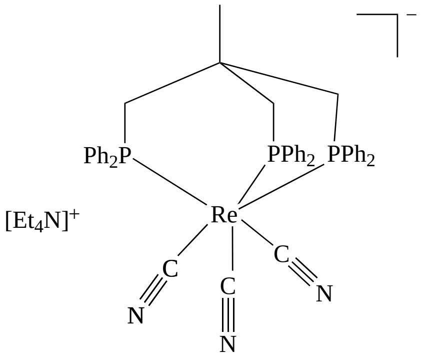
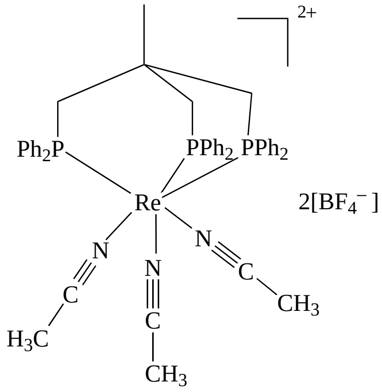
Scheme 24

the diffraction data.[52] Complex (**92**) was synthesized using the same protocol (Scheme 24) described for the preparation of (**91**), which is clearly a general method for synthesizing molecular cubes with metal ions at the vertices. In a similar vein to tacn, the triphos ligand coordinated to paramagnetic Re(II) (d^5) ions ($[Re(triphos)(CH_3CN)_3][BF_4]_2$ (**93**) and $Et_4N[Re(triphos)(CN)_3]$ (**94**)) has been successfully exploited by Dunbar and coworkers for the purpose of making cubes. Self-assembly reactions of (**94**) with MCl_2 in CH_3CN (M = Mn, Fe, Co, Ni, Cu, Zn)[53] provides a family of molecular cubes of general formula $[\{Re(triphos)(CN)_3\}\{MCl\}]_4$. The Oak Ridge Thermal Ellipsoid Plot (ORTEP) diagram (*see ORTEP Diagram*) for one such cube $[\{Re(triphos)(CN)_3\}\{MnCl\}]_4$ (**95**) is shown in Figure 4.[54]



(**94**)



(**93**)

Precursors for cubes based on carbonyl ligands can be prepared from $Mo(CO)_6$, for example, the molecule $(C_6H_3Me_3)Mo(CO)_3$ reacts with $Et_4N[Cp^*Rh(CN)_3]$ in the presence of alkali metal ions to give $(Et_4N)_3[M_a \subset \{Cp^*Rh(CN)_3\}_4\{Mo(CO)_3\}_4]$ (M_a = Cs (**96**), K (**97**)).[55] The cubic architectures of these complexes were established by crystallography. Self-assembly of $Mo(CO)_3(CH_3CN)_3$ molecules in the presence of $[Et_4N]CN$ and KPF_6 ions leads to the formation of the trigonal prismatic (*see Trigonal Prism*) cage compound $(Et_4N)_8[K\subset \{Mo_6(CN)_{19}(CO)_{18}\}]$ (**98**).[56] The crystallographic analysis revealed the existence of a $Mo_6(CN)_{19}$ cage with idealized D_{3h} symmetry. A potassium ion is located near the center of the cage.

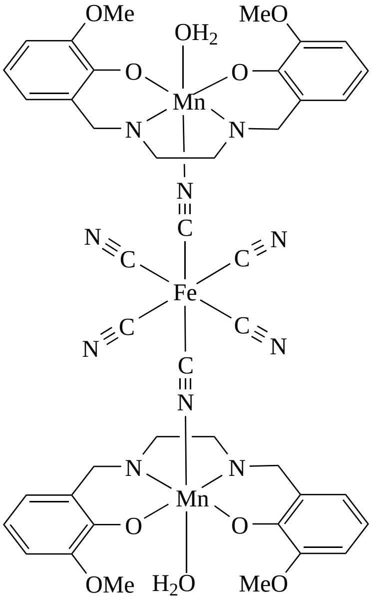
A large body of work has been devoted to the synthesis of discrete clusters as well as one, two, and three-dimensional extended structures by employing site-protected metal complexes with cyanometalates.[57] Strategies for assembling $[M(CN)_6]^{3-}$ with mononuclear metal complexes $[M'L_4(H_2O)_2]^{n+}$ and $[M'L_5(H_2O)]^{n+}$ bearing tetradentate (L_4) (*see Tetradentate Ligand*) and pentadentate (L_5) ligands (*see Pentadentate Ligand*) have been developed. The coordinated water molecules are labile and can be displaced by the N end of the cyanide ligands of a cyanometalate to produce discrete molecules. The multidentate ligands restrict the dimensionality and molecules with high-spin ground states are obtained. The tetra- and penta-amines and their corresponding mononuclear complexes have been synthesized. A series of trinuclear $\{M^{III}(CN)_4\}\{NCM'^{II}L\}_2\}^+$ (M = Cr, Co; M′ = Ni, Co, Cu), tetranuclear $\{M^{III}(CN)_3\}\{NCM'^{II}L\}_3\}^{3+}$ (M = Cr; M′ = Co), and heptanuclear $\{M^{III}\{NCM'^{II}L\}_6\}^{9+}$ (M = Cr, Co; M′ = Ni, Mn, Cu) complexes were isolated and their structures established by X-ray crystallography.[58] The neutral trinuclear bimetallic complex (**99**) is a typical example.[59]

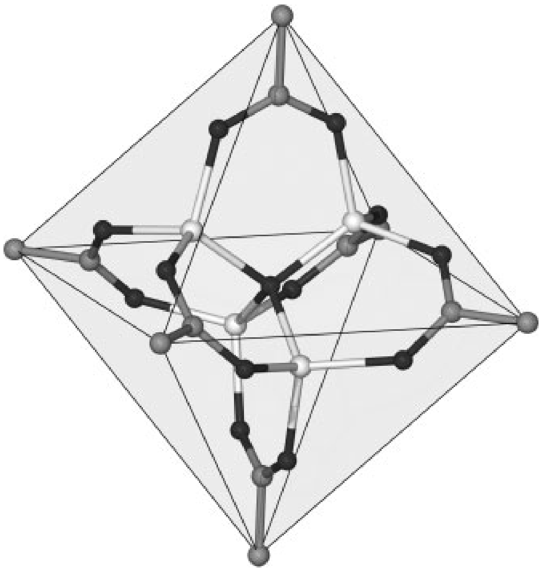


(**99**)

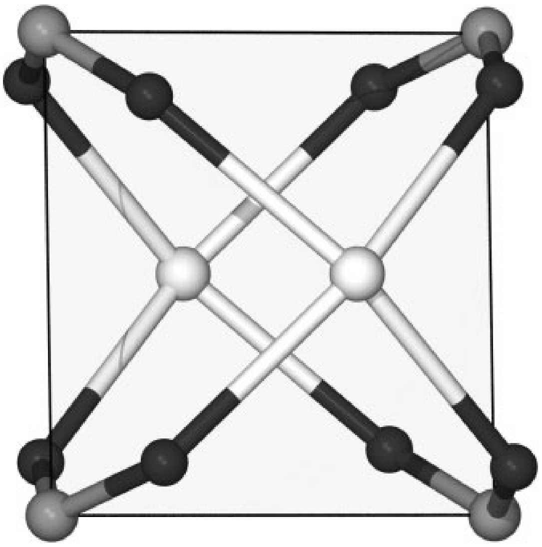
5 CARBOXYLATE LIGANDS

A perusal of the literature indicates that there is a general lack of control on the outcome of reactions of transition metal ions and nitrogen donor ligands. This uncertainty arises from the fact that metal–ligand interactions tend to be weaker than other covalent bonds (*see Covalent Bonds*) and that coordination angles about metal ions are flexible. This situation is in sharp contrast to the formation of organic molecules, for which traditional rules of covalent bonding apply. In organic chemistry, a small set of building blocks, in principle, can be used to build practically any larger organic molecule. The introduction of metal ions results in a much higher degree of complexity owing to a larger variation in bonding patterns and structures. Clearly, developing a set of building blocks for predictable self-assembly of inorganic compounds is a challenge. The use of well-defined and rigid molecular building blocks whose structural integrity is maintained throughout the construction process, however, has been shown to result in predetermined structures.

The term ‘building units’ (BU) has been used to define a group of atoms with a certain geometry, the condensation of which results in a three-dimensional solid. Such units can be molecules, inorganic polyhedra, or metal centers coordinated by organic ligands. The term ‘secondary building units’ (SBU) was introduced by Yaghi and coworkers to describe a conceptual building block[60] that is not necessarily an isolable, chemically distinct entity, but rather a fragment whose geometry plays an important role in determining the three-dimensional structure of the solid. The structural rigidity of certain metal–carboxylate clusters has been exploited for the formation of well-defined structures. For example, the



$Zn_4O(CCO_2)_6$
Octahedral SBU



$M_2(CO_2)_4$
Square SBU

Scheme 25

four ZnO_4 tetrahedra (having a common vertex) and the six carboxylate C atoms of $Zn_4O(CO_2)_6$ units (Scheme 25) define an octahedral building block. Similarly, the paddle-wheel unit $M_2(CO_2)_4$ constitutes an example of a square building block. The reaction conditions that yield the paddlewheel (square SBU) and the basic zinc acetate (octahedral SBU) have been identified.

Organic SBUs are pre-assembled, rigid and have well-defined geometries. Condensation of symmetric building blocks results in topologies with high symmetry that are referred to as default structures.[61] For example, addition of the organic ligand adamantine tetracarboxylate (a tetrahedral SBU) to the paddlewheel (square SBU) gives the *default* PtS structure. Similarly, addition of benzenetricarboxylate (a triangular SBU) to the square paddle-wheel SBU results in the *default* Pt_3O_4 structure.[62] The successful synthesis of complexes with low-symmetry topologies requires the use of more complex building blocks coded for the specific product. External influences such as templates have also been noted to be instrumental for achieving the desired product.

Diffusion of triethylamine into a solution of $Zn(NO_3)_2$ and H_2BDC (1,4-benzenedicarboxylic acid) in N,N'-dimethylformamide (DMF)/chlorobenzene results in the formation of a three-dimensional metal-organic-framework (MOF) structure with the composition $Zn_4O(BDC)_3$. A single-crystal X-ray diffraction study revealed a simple cubic topology (Figure 5) in which the vertices are occupied by $Zn_4O(CO_2)_6$ units and the edges are the phenyl moieties of the BDC molecules. The octahedral SBU consists of a single O atom bonded to four Zn atoms forming a regular Zn_4O tetrahedron. Each edge of the Zn tetrahedron is capped by a $-CO_2$ group to form a $Zn_4O(CO_2)_6$ cluster.[63]

In the area of SBU chemistry, there is considerable effort being applied to the design of structures with the same skeleton but with different functionalities and dimensions. In this respect, a total number of sixteen isoreticular structures involving octahedral zinc acetate SBU and dicarboxylate linkers of varying length and ring substituents have been synthesized.[64] Each structure exhibits the same network

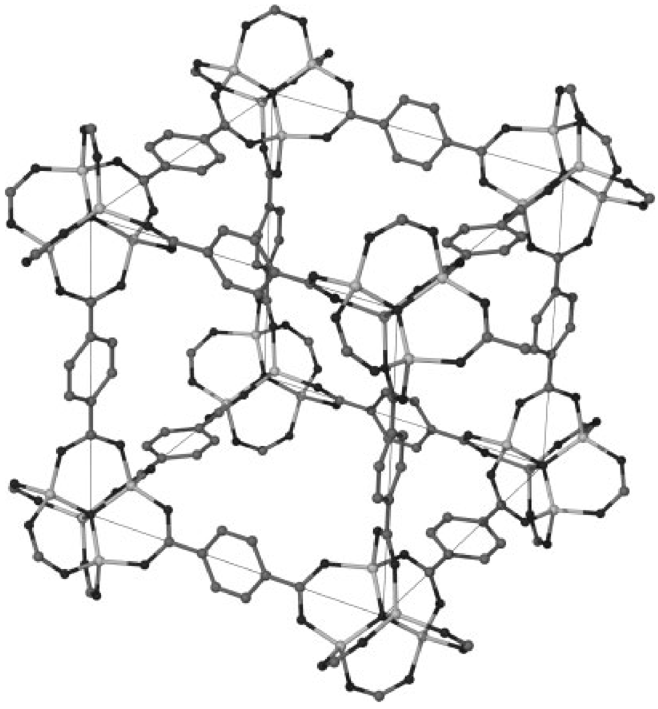


Figure 5 The cube topology of the 3-D extended structure of $Zn_4O(BDC)_3$

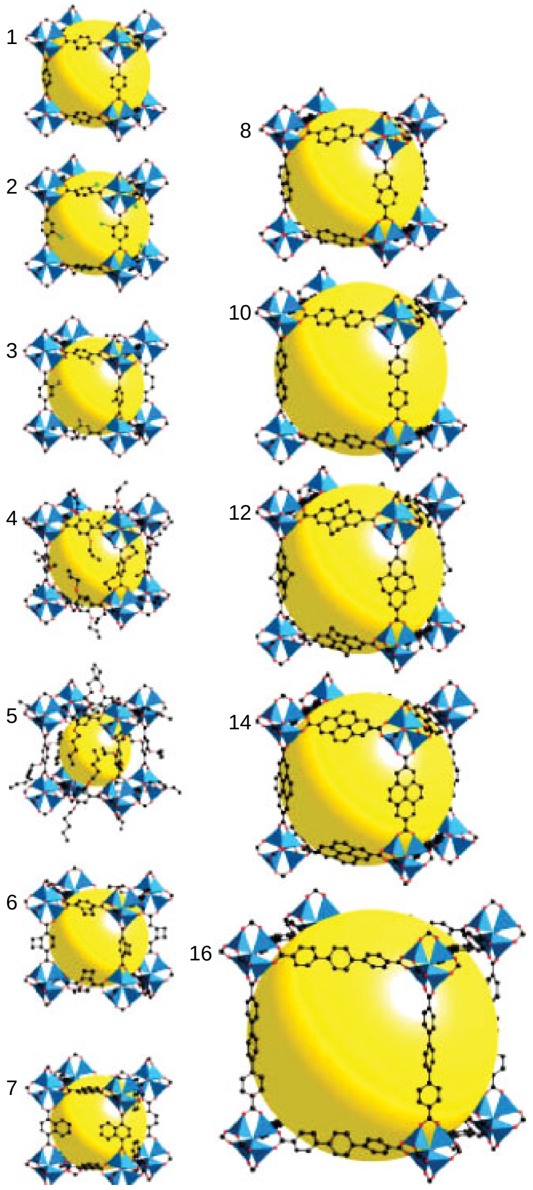

Figure 6 Isoreticular structures having the same network topology but with different linkers. (Reproduced from N.L. Rosi, M. Eddaoudi, J. Kim, M. O'Keeffe, O.M. Yaghi, *CrystEngComm.*, 2002, **4**, 401 by permission of Royal Society for Chemistry)

topology and has been synthesized using exactly the same synthetic parameters except for the desired linkers (Figure 6).

For a given inorganic SBU, the geometry of the organic SBU (linker) has a dramatic influence on the resulting MOF. The use of benzenedicarboxylates with square paddle-wheel SBU's illustrates this point. A truncated cuboctahedron (zero dimensional) structure MOP-1 (metal-organic polyhedron) results with 1,3-benzenedicarboxylate in which the paddle-wheel units are at 120°.[65] The 1,4-benzenedicarboxylate places the paddlewheel at 180° to each other and gives MOF-1 with the square grid structure (two-dimensional).[66] The linker 2-bromo-1,4-benzenedicarboxylate, which places the paddlewheel at 90° angles, yields MOF-2 exhibiting the expected NbO network (Figure 7).[67]

Exquisite control over the outcome of reticular synthesis has also been developed using site-blocked dimetal complexes that dictate certain angular requirements for bonding. The use of site-blocked paddle-wheel dimetal precursors lead to molecular architectures as opposed to the network structures discussed in the preceding section. The use of dicarboxylate bridging ligands to link multiply-bonded dimetal complexes into open-chain oligomers and polymers was first reported by Chisholm and coworkers over ten years ago.[68] Recently, Cotton and coworkers have reported a variety of supramolecular arrays that involve dimetal units.[69] A generic paddle-wheel complex contains eight equatorial and two axial sites (Scheme 26). The precursors are designed such that some of the equatorial positions of the paddlewheel are occupied by nonlabile groups such as formamidinate or diphosphine, while the remaining coordination sites are coordinated by easily substituted ligands such as acetonitrile,

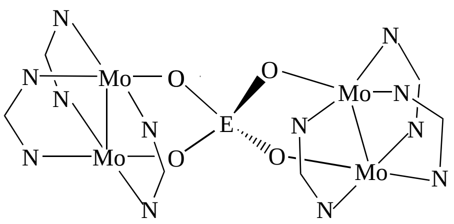
acetate, and so on. Two M_2 units can be assembled by three basic modes, namely by equatorial linkers, by axial linkers, and by both equatorial and axial linkers.

Precursors based on Mo_2^{4+} and Rh_2^{4+} cores have been used in combination with dicarboxylate linkers to construct supramolecular arrays. Dimer-of-dimers, trimer-of-dimers (molecular triangles), and tetramer-of-dimers (molecular squares) have been prepared using this approach. Judicious selection of precursors and linkers are essential for the successful synthesis of the desired molecular architectures. A total of twelve dimer-of-dimers (**100–111**) of general formula $[(DAniF)_3Mo_2]O_2C\text{-}X\text{-}CO_2Mo_2[(DAniF)_3]$ (DAniF = *N*,*N*′-di(*p*-anisyl)formamidinate) have been synthesized in which two Mo_2 units are connected by bridging dicarboxylates.[70] These compounds were prepared in one-pot reactions (Scheme 27). It is important to note that the six equatorial positions of the precursors are blocked in order to produce exclusively dimer-of-dimers products. The two M_2 units are nearly coplanar in all of these molecules except for the case of the carboxylates $O_2C–C{=}C{=}C–CO_2$. It has also been demonstrated that the two $[M_2]$ units are coupled perpendicular to each other when the tetrahedral linkers EO_4^{2-} are used (E = S (**112**), Mo (**113**), W (**114**)).[71]



E = S (**112**); Mo (**113**); W (**114**)

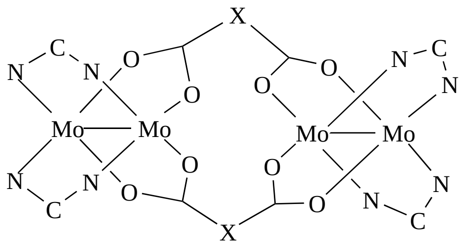
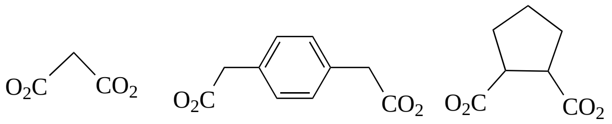
(DAniF = N,N′-di-p-anisylformamidinate)

Scheme 27

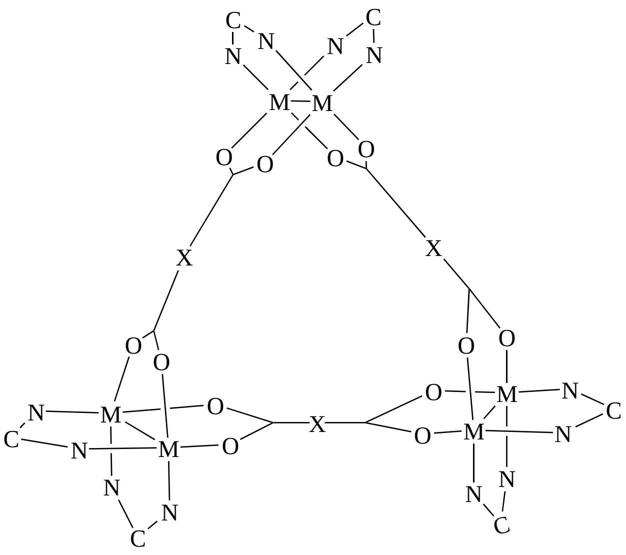
The use of cis-protected [M_2] units provides right angles between the planes defined by the metal atoms and the labile equatorial ligands. Molecular loops, triangles and squares have been designed by a specific choice of the placement of carboxylate functionalities in the linker ligands. Reaction of [*cis*-$Mo_2(DAniF)_2(CH_3CN)_4](BF_4)_2$ with the bent dicarboxylate linkers malonic acid, 1,4-phenylenediacetic and *trans* cyclopentane-1,2-dicarboxylic acid yield the corresponding molecular loops (**115**), (**116**), and (**117**) respectively.[72] A similar reaction of [*cis*-$Mo_2(DAniF)_2(CH_3CN)_4](BF_4)_2$ with *trans* 1,4-cyclohexanedicarboxylate produces the molecular triangle (**118**).[73] The midpoints of the Mo_2 bond vectors define a triangle with the average distance between vertices being 11.16 Å. The neutral triangle (**119**) based on Rh_2 units bridged by oxalate was synthesized by treating [*cis*-$Rh_2(DAniF)_2(CH_3CN)_4](BF_4)_2$ with the oxalate anion in a 1:1 ratio.[74] An excess of the ligand, however, leads to formation of the molecular square [*cis*-$Rh_2(DAniF)_2(O_2CCO_2)_4$] (**120**). This is the only known example of a reaction involving dimetal units wherein both triangle and square structures exist for the same linker. The ^{1}H NMR spectra of these two compounds are identical, but their electrochemical signatures are different, which helps to identify them in a mixture.

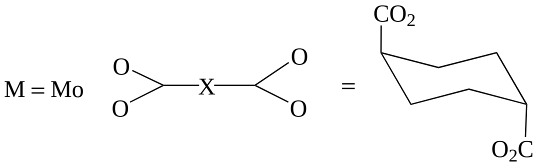




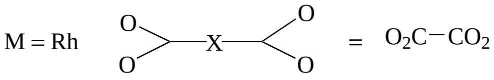
(**115**) (**116**) (**117**)

Reactions that involve cis-protected '$Mo_2(DAniF)_2$' units have led to a variety of square structures with dicarboxylate anions. The linkers that have been used are oxalate (**121**), fumarate (**122**), ferrocenedicarboxylate (**123**) and 4,4′-biphenyldicarboxylate (**124**).[75] The midpoints of the Mo_2 units constitute a square, and their structures have been confirmed by ^{1}H NMR spectroscopy and X-ray studies. Similar molecular squares containing Rh_2^{4+} units have been prepared with linkers such as oxalates (**120**), bicyclo[1.1.1]pentane-1,3-dicarboxylate (**125**), tetrafluoroterephthalate (**126**), 1,4-cubanedicarbboxylate (**127**), terephthalate (**128**), fumarate (**129**) and *trans* 1,4-cyclohexanedicarboxylate (**130**). The structures of these molecules have been established by spectroscopic and single-crystal diffraction studies. Detailed electrochemical investigations of these complexes have also been undertaken.[76]





(**118**)



(**119**)

The use of 1,3,5-tricarboxylic-substituted benzene ligands positions the three M_2 units in a triangular disposition. An X-ray structural analysis of $[(DAniF)_3Mo_2]_3(1,3,5\text{-}C_6H_3(CO_2)_3)$ (**131**) revealed a highly symmetrical structure in which each $(DAniF)_3Mo_2$ unit is bound to each of the three carboxylate groups of the trimesic acid anion.[77] The three carboxylate groups are canted out of the plane of the aryl group, which leads to a molecular propeller shape. The three-dimensional cage molecules have been isolated from reactions of [*cis*-$M_2(DAniF)_2(CH_3CN)_4](BF_4)_2$ [M = Mo, Rh] with the trimesate anion.[78] The ^{1}H NMR spectra of the products indicated that the structures are symmetrical. A single-crystal X-ray diffraction study confirmed the structures as being three-dimensional cage molecules involving six $M_2(DAniF)_2$ units and four trimesate anions. The centers of the four benzene rings of the carboxylate linkers define a tetrahedron, and the midpoints of the six M_2 units define an octahedron. The core structure with Mo_2 cage is shown in Figure 8.

In all the discrete structures described above, the axial sites are either open or bound to a weak donor ligand. A number of extended structures have been made by reacting [{*cis*-$Rh_2(DAniF)_2$}$(O_2CCH_2CO_2)]_2$ and [{*cis*-$Rh_2(DAniF)_2$}$(O_2CCO_2)]_4$ with the polypyridine or polynitrile ligands. The resulting structures include one, two-, and three-dimensional molecular tubes that are described in detail elsewhere.[79]

Analogous chemistry has been developed by employing the diphosphine ligands bis-diphenylphosphinomethane (dppm) as protecting ligands for Re_2 cores. The complexes $Re_2Cl_2(dppm)_2(O_2CCH_3)$ and *cis*-$Re_2Cl_2(dppm)_2(O_2CCH_3)_2$

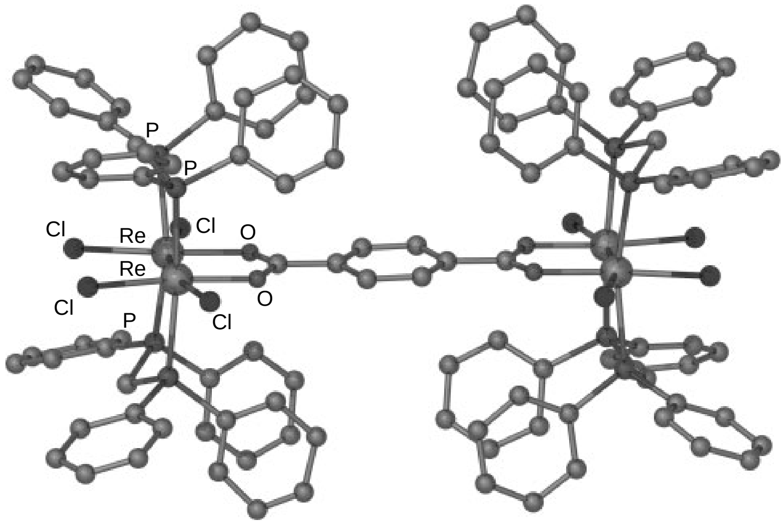

Figure 9 Single-crystal X-ray structure of (**132**)

were reacted with terephthalic acid to form the dimer-of-dimers $[cis\text{-}Re_2Cl_2(dppm)_2]_2[O_2CC_6H_4CO_2]$ (**132**) and the molecular triangle $[cis\text{-}Re_2Cl_2(dppm)_2(O_2CC_6H_4CO_2)]_3$ (**133**).[80] The molecular structures of (**132**) and (**133**) are shown in Figure 9 and 10 respectively. Interestingly, the ferrocenedicarboxylate does not produce the expected molecular triangle or square but rather $cis\text{-}Re_2Cl_2(dppm)_2(O_2C\text{-}Fc\text{-}CO_2)$ (**134**) (Figure 11).[81]

With the goal of connecting M_2 and M' units, the isonicotinate ligand, whose possible coordinating motives are depicted in Scheme 28, has been employed. Specifically,

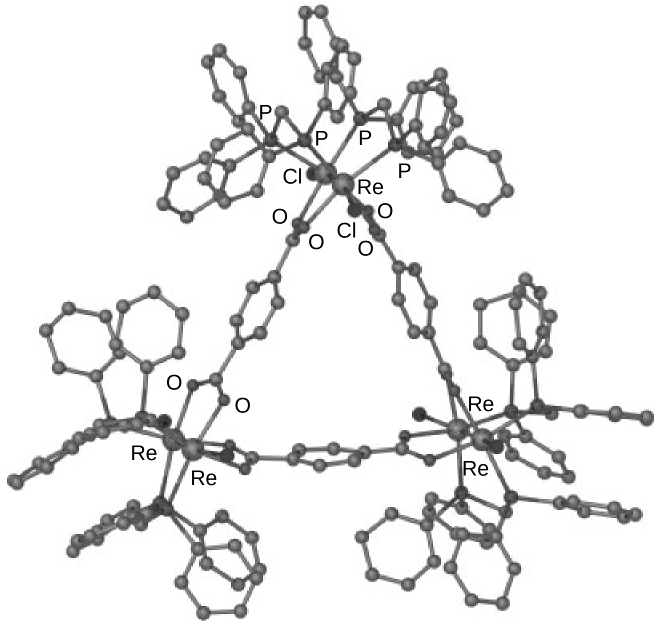

Figure 10 Single-crystal X-ray structure of (**133**)

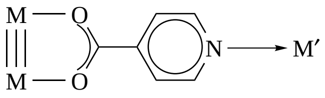

Scheme 28

the precursor molecule $cis\text{-}Re_2Cl_2(dppm)_2(O_2CC_5H_4N)_2$ (**135**) was synthesized (Figure 12). A variety of building blocks have been used in reactions of (**135**), including $Pt(dbbpy)(OTf)_2$ (dbbpy = di-tertbutyl bipyridine), $ZnCl_2$,

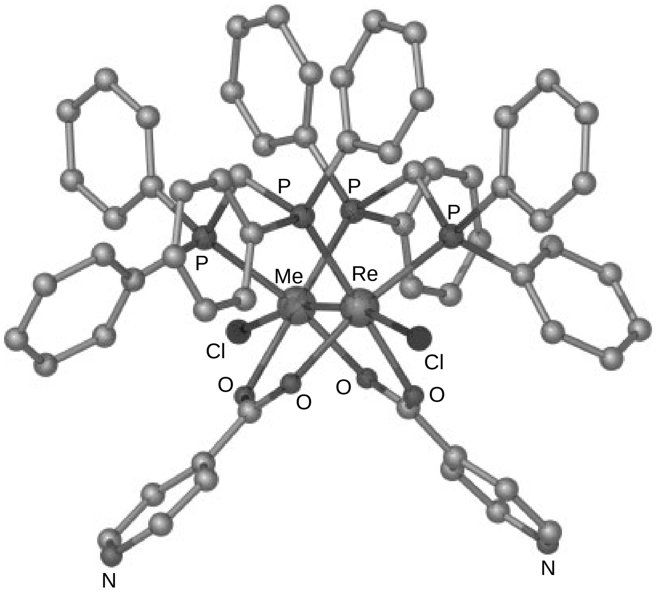

Figure 12 Single-crystal X-ray structure of (**135**)

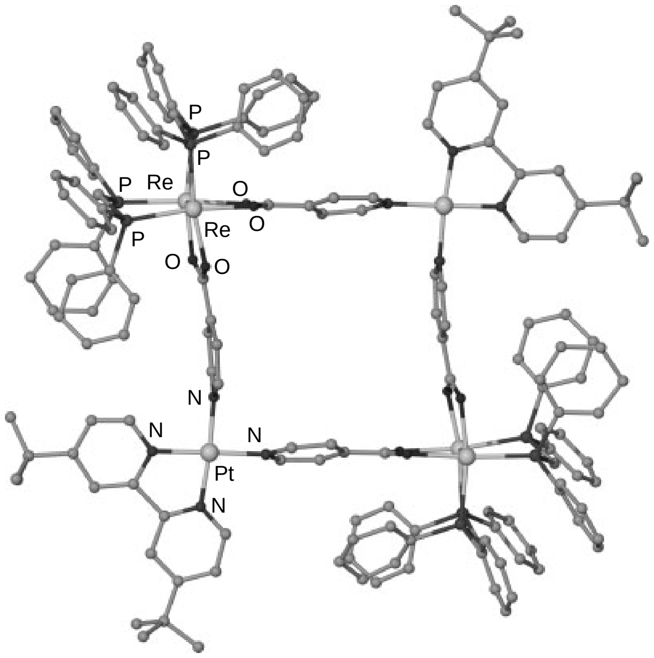

Figure 14 Single-crystal X-ray structure of (**137**)

Ag(OTf), *cis*-$Re_2Cl_4(O_2CCH_3)_2(H_2O)_2$ and $Rh_2(O_2CCH_3)_4$. All of these precursors have at least two positions available for facile substitution, but they differ in the geometry and disposition of available metal binding sites. The *hybrid* molecular squares [{*cis*-$Re_2(OTf)_2(dppm)_2(O_2CC_5H_4N)_2$}{Pt(dbbpy)}]$_2$[OTf]$_4$ (**136**) (Figure 13) and [{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N)_2$}{$ZnCl_2$}]$_2$ (**137**) (Figure 14), composed of alternating Re_2(II,II) and M(II) (M = Pt and Zn) corners, were isolated from the reactions of (**135**) with $Pt(dbbpy)(OTf)_2$ and $ZnCl_2$, respectively.[82] In contrast, the reactions of (**135**) with AgOTf, *cis*-$Re_2Cl_4(O_2CCH_3)_2(H_2O)_2$ and $Rh_2(O_2CCH_3)_4$ yield the open-chain polymeric structures [{*cis*-$Re_2(OReO_3)_2(dppm)_2(O_2CC_5H_4N)_2$}{Ag•$ReO_4$}]$_\infty$ (**138-a**), [{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N)_2$}{*cis*-$Re_2Cl_4(O_2CCH_3)_2$}]$_\infty$ (**138-b**) and [{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N)_2$}{$Rh_2(O_2CCH_3)_4$}]$_\infty$ (**138-c**), respectively (Figure 15).[83]

6 HYDROGEN BONDING (*See Hydrogen Bonding & Dihydrogen Bonding*)

Numerous large, complex assemblies have been isolated by taking advantage of the formation of hydrogen bonds.[84] Most of the early studies were restricted to organic molecules, but in the quest for new electronic and magnetic materials, considerable effort has been launched towards the construction of inorganic and organometallic architectures that combine metal–coordination and hydrogen bonds.[85] Pyridine-carboxylic acid and carboxyamides have been used together with a variety of metal ions to form hydrogen-bonded frameworks as shown in Scheme 29. Coupling (*see Coupling*) of two PtBr(4,4′-di-t-butyl-2,2′-bipyridine)$(CH_3)_2(CH_2C_6H_4COOH)$ molecules (**139**) through bridging bis-pyridyl ligands yields (**140**) and (**141**). The carboxylic acid groups appended to the alkyl–platinum

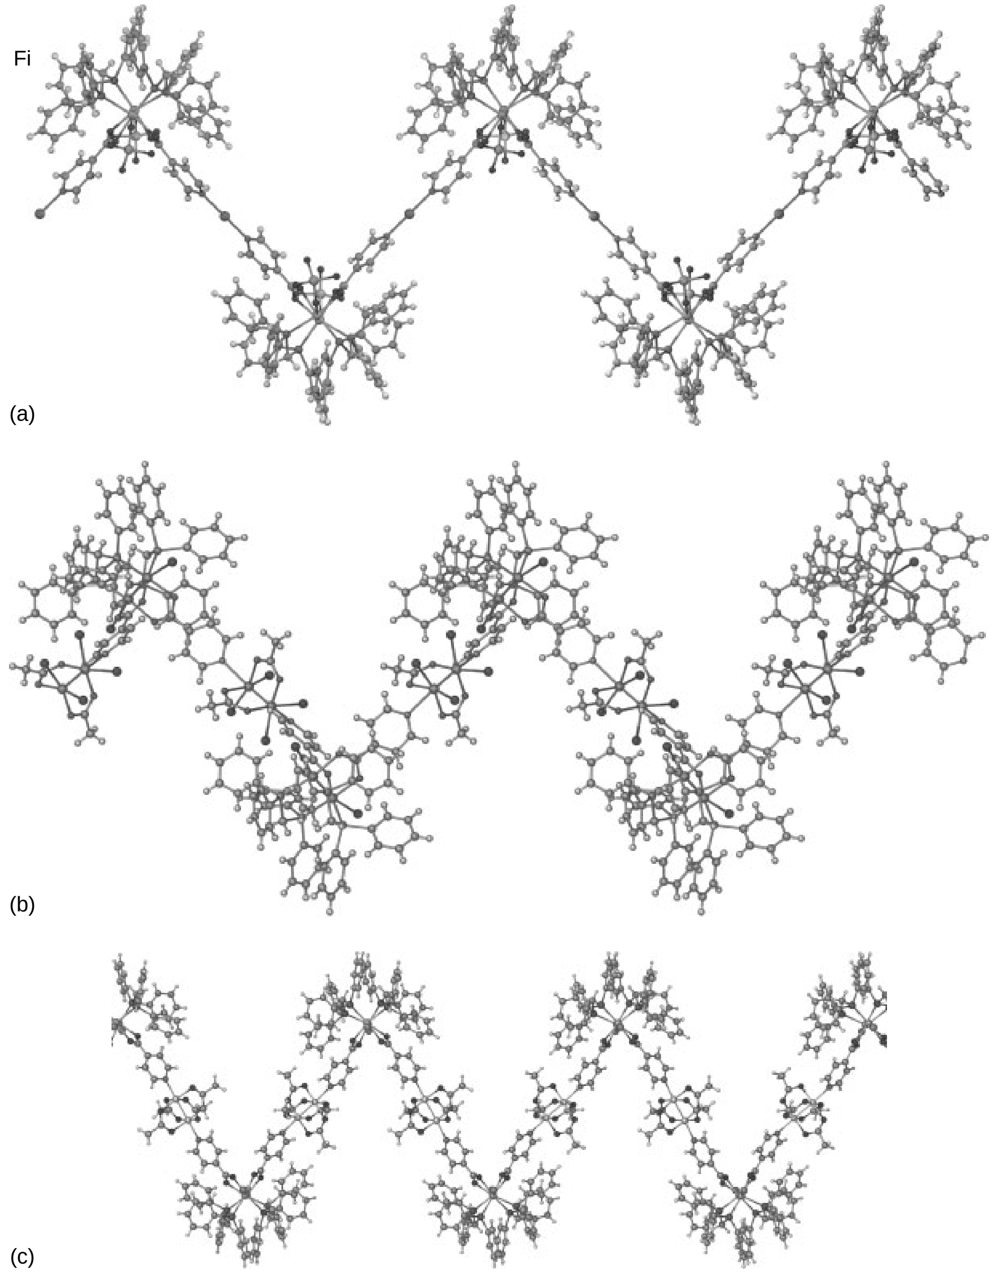

Figure 15 Plots of the open-chain polymeric structures of (a) $[\{Re_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{Ag\}]_\infty$ in (**138-a**), (b) (**138-b**), and (c) (**138-c**)

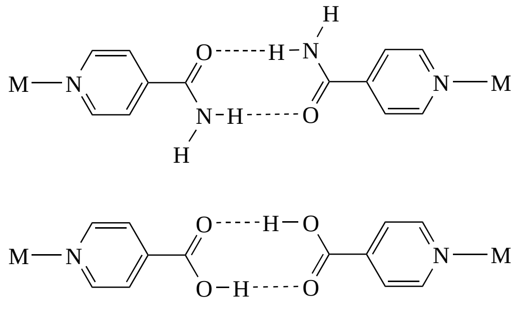
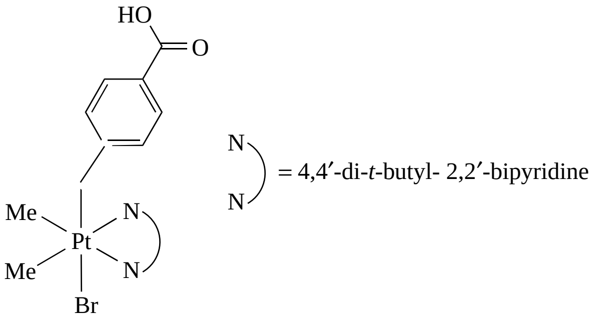
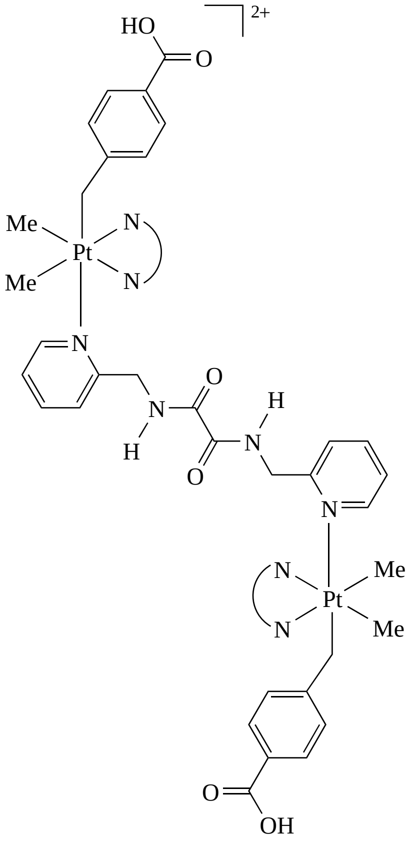
unit engage in intermolecular (*see Intermolecular*) hydrogen bonding to form a one-dimensional polymer. In addition, the amide groups of 4-py-CH_2NHCOCONHCH_2-py-4 in complex (**141**) induce long-range helicity.[86] The twists at the two CCH_2N and CCH_2Pt groups leads to the formation of a helical loop in such a way that the two carboxylic acid groups are positioned in an *anti* conformation that facilitates the formation of hydrogen-bonding interactions. The di-cation has approximate C_2 symmetry, but there is no crystallographically imposed symmetry; the result is an isotactic polymer chain with the pitch of the helix being 26.1 Å.



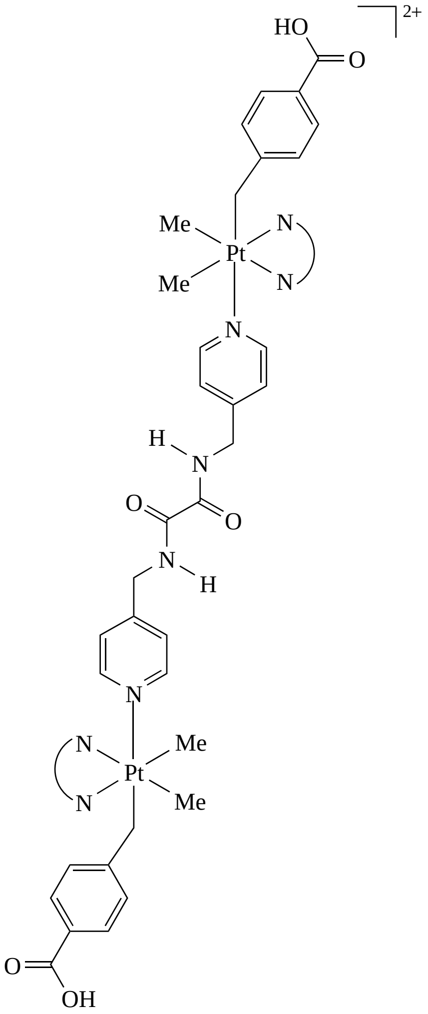
Scheme 29



(**139**)



(**140**)



(**141**)

In a similar fashion, the cation [*cis*-$(Et_3P)_2Pt(NC_5H_4CONH_2)]^{2+}$ (**142**) crystallizes via interactions involving the amide functionality resulting in infinite, parallel zig-zag chains. In contrast, $[(C_5Me_5)Rh(NC_5H_4CONH_2)_3]^{2+}$ (**143**) crystallizes via the same amide functionality to produce infinite, double-stranded, interwoven chains.[87] Dunbar *et al.* have used nicotinamide and isonicotinamide to form assemblies of multiply-bonded dimetal building units via a combination of coordinate bonds and intermolecular hydrogen bond interactions.[88] The compounds *cis*-$Re_2Cl_4(O_2CCH_3)_2$ (**144**) and $Rh_2(O_2CCH_3)_4$ (**145**)[89] have been used in these reactions owing to the fact that they have a strong tendency to engage in axial interactions with pyridine-based ligands. Polymeric networks of the linear, zigzag and sinusoidal varieties were isolated depending on the ligands and metal precursors involved (Figure 16).[88]

Puddephatt and coworkers have reported a series of complexes of general formula *trans*-$PdCl_2L_2$ in which L is a pyridine or quinoline ligand with one or two carboxylic acid functionalities.[90] The complexes $[PdCl_2(NC_5H_4\text{-}4\text{-}COOH)_2]$ (**146**), $[PdCl_2(NC_5H_4\text{-}3\text{-}COOH)_2]$ (**147**), and $[PdCl_2(2\text{-}Ph\text{-}NC_9H_5\text{-}4\text{-}COOH)_2]$ (**148**) form one-dimensional polymers through O–H···O hydrogen–bonding interaction as shown in Scheme 30. It has been demonstrated in this study that the presence of polar solvents such as DMSO or DMF leads to a disruption of the extended H–bonding network.

Two-dimensional structures result when pyridine-dicarboxylic acids are used. The complex *trans*-$PdCl_2L_2$ (L = 2,6-dimethyl pyridine-3,5-dicarboxylic acid) (**149**) self-assembles to yield a two-dimensional sheet structure that involves hydrogen bonding between the carboxylic acid groups mediated by methanol solvent molecules (Scheme 31).

The coordination of four *n*-butylnicotinamide ligands to a Pt(II) center provides access to organized amide H–bond

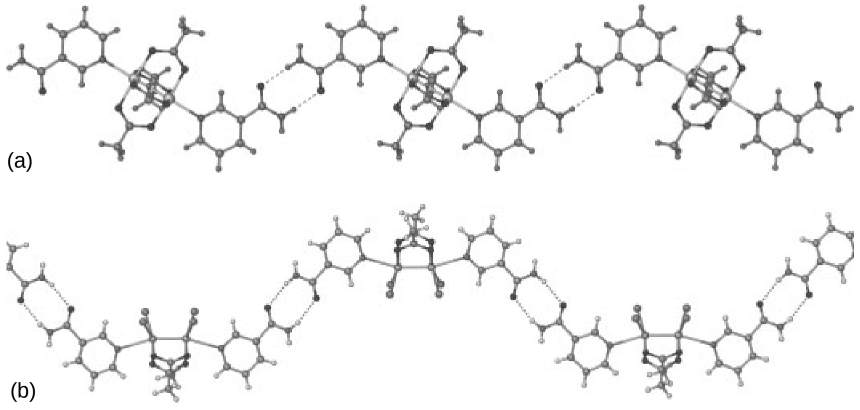


Figure 16 Molecular chain structures of the polymeric compounds formed from axial interactions of (**144**) and (**145**) with pyridine-based ligands

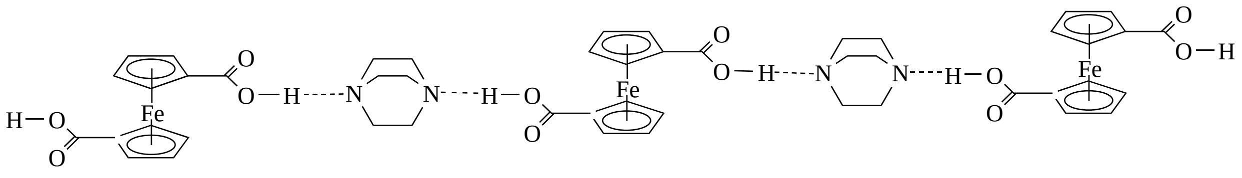
Scheme 32

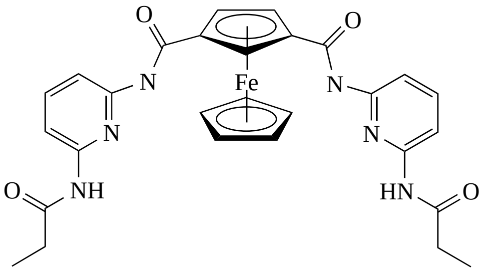
donors that are suitable for anion binding. ^1H NMR studies confirmed the 1:1 binding of (**150**) with ReO_4^-, $CF_3SO_3^-$ and HSO_4^-.[91] An X-ray structure of [(**150**)·ReO_4]ReO_4 revealed hydrogen-bonding interactions between amide hydrogens and CH hydrogens of the ligand and oxygen atoms of the perrhenate anion.

Metallocenedicarboxylic (*see Metallocene Complexes*) acids form dimeric structures in the solid-state. Two typical examples include [Fe(II)(η^5-$C_5H_4COOH)_2$] (**151**) and [Cr((η^6-$C_6H_5COOH)_2$] (**152**) (Scheme 32).[92] Complex (**151**) is known in two polymorphic modifications (the monoclinic and triclinic form) that contain the same dimeric unit but with different arrangement in the solid-state.[93] Self-assembly of (**151**) with DABCO (1,4-diazabicyclo[2.2.2]octane) in a 1:1 ratio occurs with grinding in the solid-state to form [Fe(II)(η^5-C_5H_4COOH)(η^5-C_5H_4COO)($HC_6H_{12}N_2$)] (**153**). The X-ray structure of (**153**) confirms the presence of linear hydrogen-bonded chains mediated through the N-atoms of DABCO.[94] Upon heating, complex (**153**) loses DABCO and reverts to (**151**) in quantitative yields. Grinding (**151**) and DABCO in ratios other than a 1:1 stoichiometry leads to mixtures of (**153**) with excess, unreacted reagent.

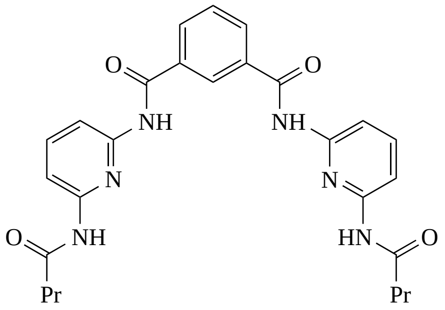


(**153**)

The organometallic receptor (**154**) was designed for complexation to ureas and barbitals through hydrogen-bonding interactions. The formation of 1:1 complexes via the formation of complementary hydrogen bonds was established by NMR spectroscopy and X-ray crystallography.[95] The role of the spacer group in the binding ability of the receptors was emphasized in this study. In the acyclic receptor (**155**), where the spacer is the 1,3-isophthalic acid group, the binding constant with barbital is one-order of magnitude greater than that between (**154**) and barbital. Both geometric and electronic factors have been attributed to this effect.



(**154**)



(**155**)

Supramolecular synthons composed of H–bonding interactions between metal–X acceptor and N–H donors (Scheme 33) have been exploited to form hydrogen-bonded network solids.[96,97] Three classes of tetrachlorometallate salts of stoichiometry [4,4′-H_2bpy][MCl_4] have been prepared. For the square-planar anions $[MCl_4]^{2-}$ (M = Pt, Pd), linear hydrogen-bonded ribbons are formed (Scheme 34).[98] In contrast, a cyclic dimer motif (Scheme 35) was reported for [4,4′-H_2bpy][$CoCl_4$].[99] Low-temperature diffraction data of [4,4′-H_2bpy][MCl_4] [M = Zn, Hg, Co] revealed one short NH···Cl hydrogen bond and an additional CH···Cl interaction with a second chloride ligand and an ortho-CH group as shown in Scheme 36. The solid-state structure of the hydrogen-bonded dimeric ring in [4,4′-H_2bpy][$ZnCl_4$] is shown in

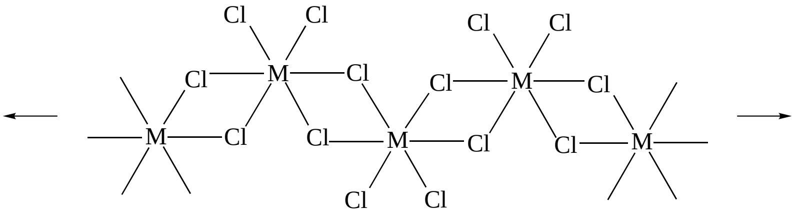
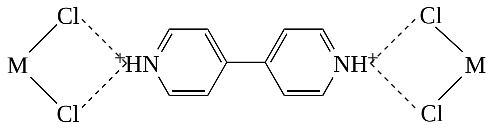
Scheme 34

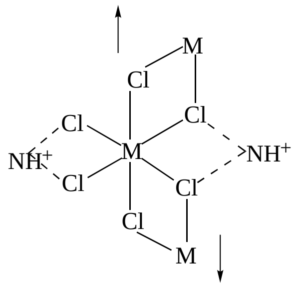


Scheme 38

Scheme 37. When M = Mn, Pb or Cd, the $[MCl_4]^{2-}$ moiety is polymerized and forms the zig-zag edge-sharing octahedral chains shown in Scheme 38. The $[\{MCl_4\}_n]^{2n-}$ chains are cross-linked by hydrogen bonds at both ends of the di-cation as shown in Scheme 39 and at both sides of the $[\{MCl_4\}_n]^{2n-}$ unit as shown in Scheme 40.[100]



Scheme 39



Scheme 40

In the simple salt $[4,4'\text{-}H_2bpy]Cl_2$, ribbons of the type shown in Scheme 41 are observed. Analogously, the structure of $[4,4'\text{-}H_2bpy][Cu_2Cl_6]$ consists of a planar anion with the two square-planar metals that are in place of the two chlorides (Scheme 42). The same bonding patterns are noted in $[4,4'\text{-}H_2bpy][MCl_6]\cdot$(M = Os, Pt) and $[4,4'\text{-}H_2bpy][FeCl_5]$, albeit in a form in which the chloride is also bonded to a metal ion.[101] The ribbons are cross-linked by the metal ions such that the trans-chloride ligands on the metal centers belong to different ribbons (Scheme 43).

The 2,2′-biimidazolate mono-anion ($Hbim^{-1}$) forms metal–chelate complexes and also provides access to intermolecular complementary H–bonding with two sets of NH donors and N acceptors as shown in Scheme 44.[102] By altering the metal-coordination sphere, a variety of neutral metal–$Hbim^{-1}$ complexes with hydrogen-bonded infinite superstructures have been synthesized. The $[Cu(II)(Hbim)(SalenNMe_2)]$ complex forms a H–bonded dimer of the type as described in Scheme 45. The cation $[Cu(II)(Hbim)(tacn)]^+$, however, forms a H–bonding interaction with the $[ClO_4]^-$ anion rather than forming self-complementary NH···N interactions between the $Hbim^{-1}$ ligands.[103] The authors concluded that the neutral complexes are better precursors than the charged species for the formation of regular self-assembled superstructures.

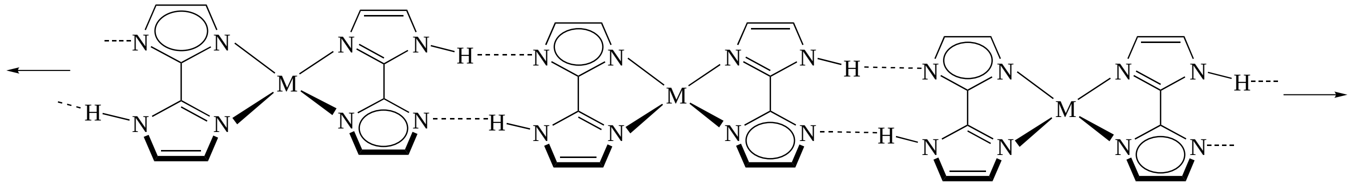
M = Cu(SalenNMe$_2$)

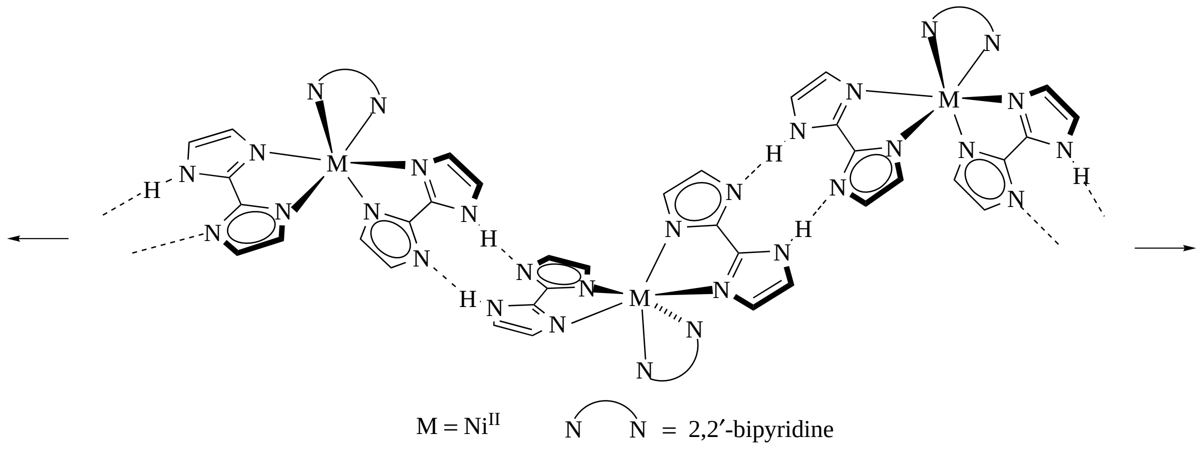
Scheme 45

The complex *trans*-Ni(II)(Hbim)$_2$(t-Bupy)$_2$ contains two Hbim ligands that engage in intermolecular self-complementary H–bonding interactions, which leads to the formation of linear chains (Scheme 46). The two Hbim ligands engaged in H–bonding interactions occupy the equatorial positions of a distorted octahedron with the two axial positions being occupied by two monodentate t-Bupy ligands (*see Monodentate Ligand*). The linear chain motif can be altered to a one-dimensional zig-zag ribbon structure by changing the disposition of the H–bonding sites in the building blocks. A zig-zag ribbon is formed from Ni(II)(Hbim)$_2$(bpy), which consists of one-dimensional ordered arrays formed by alternating H–bonding between different optical isomers Δ and Λ (Scheme 47). The neutral, racemic complex [Ru(II)(Hbim)$_3$] with D_3 symmetry crystallizes in a two-dimensional honeycomb sheet of the type shown in Scheme 48. All three Hbim ligands are involved in the intermolecular H–bonding interactions and alternative between optical isomers Δ and Λ. In contrast, the two chiral building units of Δ-[Co(III)(Hbim)$_3$] and Λ-[Co(III)(Hbim)$_3$] form one-dimensional helical chains with a left-handed and right-handed chirality respectively.

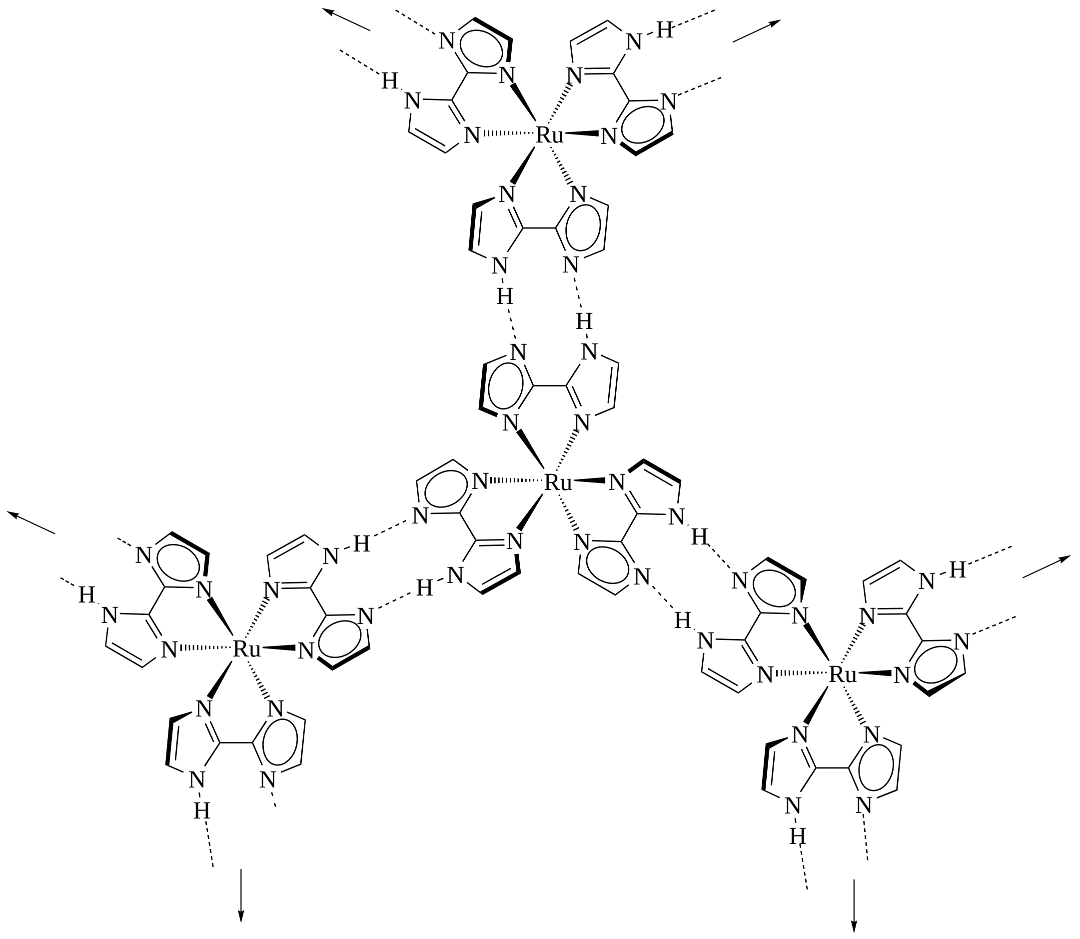


M = *trans*-Ni (t-Bupy)$_2$

Scheme 46



Scheme 47



Scheme 48

Each one-dimensional helical chain involves intermolecular H−bonds between the same optical isomers with two of the three Hbim ligands being involved (Scheme 49). A third Hbim moiety is blocked by H−bonds to interstitial 2-propanol molecules and therefore does not participate in the helical-chain architecture.

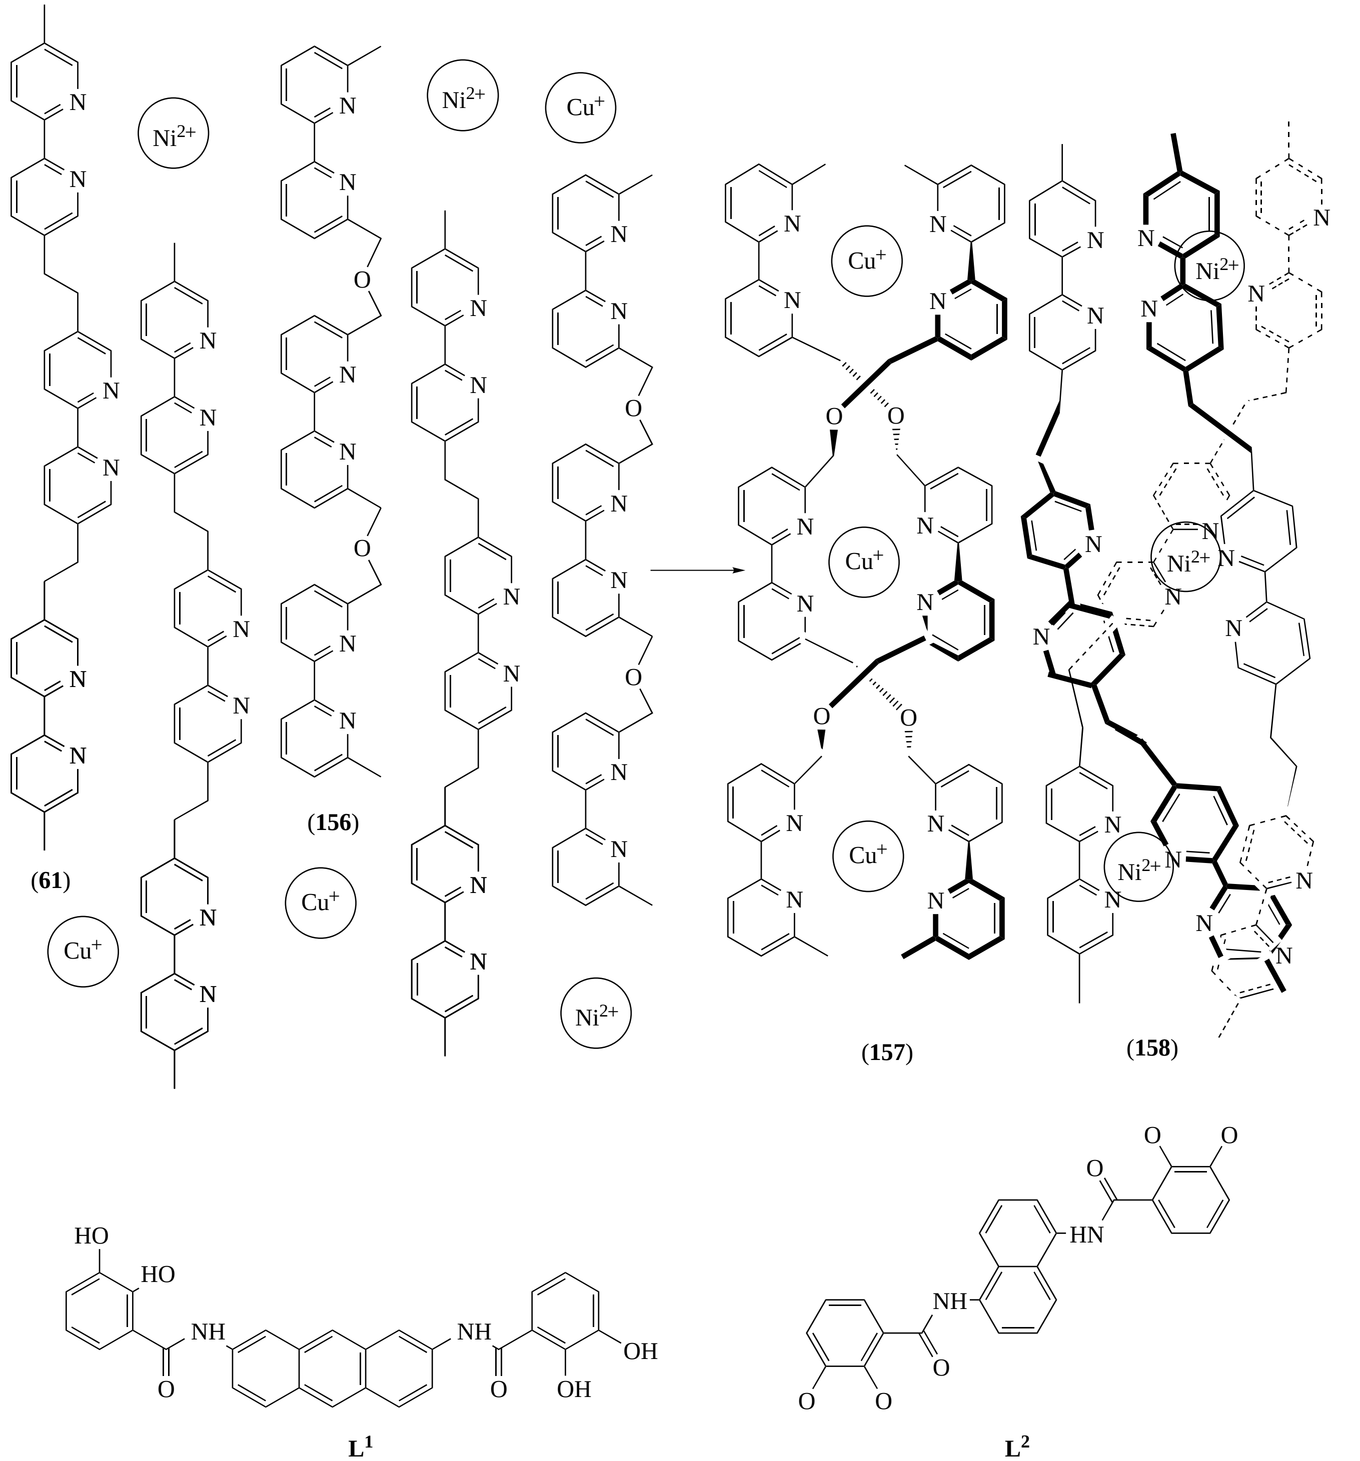
7 SUPRAMOLECULAR ASSEMBLY DYNAMICS

A self-assembly reaction that involves the connection of individual building blocks via noncovalent interactions permits the rational integration of desired functional groups into the resulting molecules. Transition metal coordination bonds have been exploited in the synthesis of numerous metal–based supramolecular architectures in recent years. Complexation of metal ions to multidentate ligands generates equilibrium mixtures of various structures based on numerous possible combinations of metals and ligands.[104] In the situation of thermodynamic control (*see Thermodynamics: Laws*), the product distribution depends on a combination of enthalpic (*see Enthalpy*) and entropic (*see Entropy*) considerations. The factors that influence the geometry of these structures are complex and include the number, relative strength, and directionality of the metal–ligand interactions. The product distribution also depends on the concentration, that is, dilute solutions favor ring closure whereas concentrated solutions yield higher-order oligomers culminating in polymer formation at the limit of high-monomer concentrations. The self-assembly reaction also depends on a variety of parameters such as temperature, pressure, and solvent identity.[105]

Inorganic supramolecular chemistry is dynamic by nature because of the kinetic lability (*see Kinetic Lability*) of the coordinate bonds. The reversibility of the association process of metal and ligands permits a continuous alteration of the products. Intrinsic factors such as the stability of a particular species or extrinsic factors such as the presence or absence of a template allow for the isolation of a particular product. In this vein, the dynamic self-assembly of helicates has been studied by Albrecht–Gary, Lehn, and coworkers in detail. Several kinetic intermediates were identified in the spectroscopic studies of the double-stranded helicates M_3L_2. These misaligned kinetic species engage in structural self-correction that results in the eventual formation of the thermodynamic product.[106] In a mixture of building units, self-selection occurs when the structural instructions are 'strong'. For example when a mixture of the two tris-bipyridine ligands (**61**) and (**156**) are reacted with Cu(I) and Ni(II), only the double helicates (**157**) and triple helicate (**158**) products are formed. These systems are the result of self-assembly of helicates with self-recognition (Scheme 50).[107]

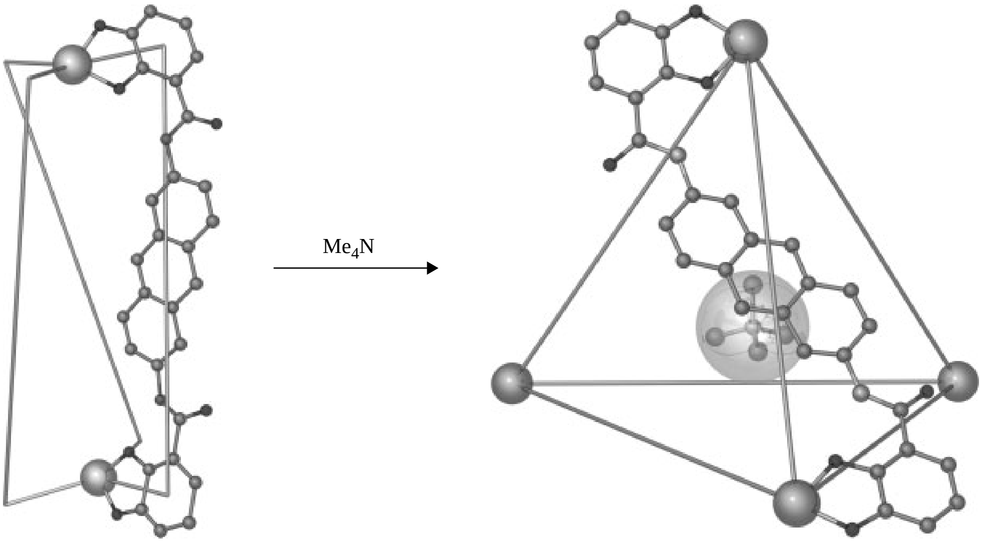
Armed with an increasing knowledge of supramolecular interactions,[108] chemists are applying the tools of molecular recognition for the optimization of reaction conditions to favor a particular product at the expense of others in the equilibrium mixtures. One useful approach in this regard is to use a chemical species that selectively recognizes and stabilizes one of the products in a mixture via supramolecular interactions. These species are commonly referred to as templates, and their role in a thermodynamic process may be likened to that of catalyst in a kinetically controlled synthesis.[104] For example, Raymond and coworkers have reported the slow conversion of a dinuclear triple-stranded helicate ($M_2L'_3$) to a tetranuclear tetrahedron ($M_4L'_6$) with the addition of the Me_4N^+ guest (Scheme 51). The conversion takes place at 70 °C over 24 h duration and no intermediate species were detected.[109] Selective encapsulation of various cationic guests $Me_2Pr_2N^+$ and Pr_4N^+ has been observed for the tetrahedral $[M_4L''_6]^{12-}$ anionic hosts. A ^1H NMR study revealed that the alkali metal ion K^+ does not interact with the interior of the cluster,[110] but that the corresponding alkali ion–crown ether complex is encapsulated into the host molecule.[111] In a similar vein, Lehn and coworkers have reported the conversion of a triferrous linear triple helicate to a pentaferrous circular helicate (**62**) with the addition of chloride as a guest.[37]



(61) (156) (157) (158) L^1 L^2

Scheme 50

In related work, Dunbar *et al.* recently described the anion templated (*see Templating*) self-assembly reactions of solvated metal ions with bptz. The role of the anions in the preferred stabilization of metallocyclophanes of varying nuclearity has been examined in detail both in solution and in the solid-state. Reactions of the mononuclear precursors $[M(II)(CH_3CN)_4][X]_2$ ($X = BF_4$ or ClO_4; $M = Ni$ and Zn) with bptz in a 1:1 molar ratio afford molecular squares (**57–60**) of the type $[M_4(bptz)_4 \subset X]^{7+}$.[36] Analogous reaction of $[Ni(CH_3CN)_6][SbF_6]_2$ with bptz yields the



Scheme 51

molecular pentagon $[\{Ni_5(bptz)_5(CH_3CN)_{10}\}\subset SbF_6](SbF_6)_9$ (**64**) rather than the squares. ESI-MS studies confirmed that the molecular squares are the major products when $[BF_4]^-$, and $[ClO]_4^-$ are present and exclusively a molecular pentagon, when $[SbF_6]^-$ is present, respectively.[39] The dimeric $[Ni_2(bptz)(CH_3CN)_8][ClO_4]_4$ complex and the polymer $\{[Mn(bptz)(CH_3CN)_2][BF_4]_2\}_\infty$ were isolated as minor products, indicating their presence in equilibrium mixtures. The templating abilities of anions in the organization of squares and pentagons have been linked to the weak anion-π interaction of the anion and tetrazine unit of the bptz ligands.[112]

8 INORGANIC ASSEMBLIES WITH FUNCTIONALITY

The field of inorganic supramolecular chemistry has witnessed tremendous growth in recent years. An increasing understanding of noncovalent interactions has prompted many inorganic chemists to explore new structures with supramolecular interactions. Recent advances in X-ray technology with the advent of the CCD detector have enabled us to obtain reliable structural information on tiny, weakly diffracting crystals whose structural determination would have been impossible a few years ago. The future of the field, however, lies in our ability to prepare functionally important systems. Indeed, progress is being made towards this goal; for example Fujita and coworkers have demonstrated that the cavities of their structures not only act as reaction vessels, but also serve as molds for product synthesis.[113] The availability of a nanoscale reaction vessel is an attractive approach for the synthesis of new materials. One example of this methodology is the synthesis of a reactive phosphonium–acetone adduct inside the M_4L_6 cavity in aqueous media.[114] The free adducts decompose rapidly in aqueous solution and can be stabilized only with the protection of the hydrophobic cavity of the molecular tetrahedron.

The use of inorganic supramolecular compounds in catalysis has also been successful in recent years. Hupp *et al.* incorporated a Mn(III)-porphyrin (*see Porphyrin*) epoxidation catalyst inside a molecular square,[115] a system that shows enhanced catalyst stability and substrate selectivity as compared to the free catalyst. In another example, chiral metallocyclophanes were constructed from $Pt(PEt_3)_2$ units and enantiopure atropoisomeric 1,1′-binapthyl-6,6′-bis-(acetylenes) and used in enantioselective diethyl zinc addition to aldehydes to afford chiral secondary alcohols.[116] The first organometallic triangle based on Pt(II) and alkyne-di-substituted-binaphthyl system was reported and found to effect asymmetric catalysis reactions of aldehydes to alcohols with excellent conversion rates and enantiomeric excess.[117]

Apart from the use of molecular reaction vessels, there is much promise for the use of solids prepared by Yaghi and others which are highly porous and serve as excellent host structures. The MOFs of composition $Zn_4O(BDC)_3$ with a cubic three-dimensional extended porous structure absorbs hydrogen gas up to 4.5 wt %, that is, 17 hydrogen molecules/formula unit at 78 K and 1.0 wt % at room temperature and pressure of 20 bar, respectively.[118]

Chirality can also be introduced into these framework solids as evidence by the work of Lin and coworkers, who

used specifically designed ligands to create hosts that offer chiral discrimination.

Supramolecular chemistry is poised to make a big impact on numerous fields of science including molecular biology as well as chemistry. Complex structures that would be impossible to prepare in a stepwise fashion with covalent bonds are easily formed by the self-assembly process. The advances to date notwithstanding, there is much to learn about the molecular basis of self-organization. Given that one of the 'holy grails' of chemistry is to unravel the processes of evolution and adaptation displayed by biological systems, it is clear that supramolecular chemists have their work cut out for them.

1 INTRODUCTION

The periodic table is one of the great classifications of the natural world and ranks on a par with several other major classifications, including the classification of plant species by Linnaeus in the 1750s, the classification of stars by Hertzsprung and Russell in 1913, and the classification of subnuclear particles by Gell-Mann and Ne'eman in the 1950s. The periodic table has for its primary purpose the classification of the chemical elements, the basis for this being the analogies they exhibit in their physical and chemical properties. As the story of the periodic table is closely entwined with that of the elements, we shall explore these two concepts concomitantly here. From this broad perspective, some of the most colorful events that have occurred in chemical history over the past 2600 years are encompassed. In developing our theme, we shall endeavor to stimulate a greater interest in and bring a new awareness of the very rich legacy bequeathed to us by our pioneering predecessors. It is our hope that such an approach may in some way compensate for the often rather cursory treatment afforded our theme in elementary chemistry textbooks and foundational courses.

Because there can be no periodic table without an understanding of the nature of the elements, we shall start by delving into the history of the chemical elements. First, we mention the somewhat ironic fact that around nine genuine elements were known in ancient times, these being carbon, sulfur, copper, iron, lead, tin, mercury, silver, gold, and possibly antimony, though none of them was recognized as an element. Like everything else that was material, these true elements were thought to be composed of metaphysical entities such as essences or principles. The notion that all material objects consisted of essences or principles was a remarkably enduring one that was to persist for well over 2000 years. In fact, this notion remained dominant until the end of the alchemical era was reached toward the end of the eighteenth century. In the Western World, the conception of metaphysical elements is usually traced back to and considered to originate from certain of the natural philosophers of ancient Greece. However, it is important to point out that all of the other major civilizations of the past paid homage to the idea that physical reality manifests itself in terms of metaphysical entities that were regarded as elements. There was even substantial overlap in these entities in different civilizations. Thus, virtually all of the early civilizations conceived of air and fire as elements.

Before probing further into the history of the elements, a brief comment on the etymological derivation of the word *element* seems appropriate. The first usage of the term element was made by the Greek philosopher Plato (427–347 BCE) in the fifth century BCE.[1] The actual word he employed was *στοιχειον* (*stoicheion*), which has the basic meaning shape because it was believed at the time that objects assumed differing shapes or forms when they were fashioned from supposedly amorphous primary matter. The Latin equivalent of this Greek term is *elementum*, and this was first used by the Roman poet Lucretius (ca. 97–55 BCE) in his famous poem *De Rerum Natura* (*On the Nature of Things*) extolling the virtues of an atomic conception of the world.[2] While on the subject of words, we mention in passing the origin of the word quintessence. It was thought by the ancient Greeks that four elements comprised all of the matter on Earth whereas the celestial sphere was constituted from only one transcendent element referred to as the *ether* or the *quinta essentia*, the fifth essence, from which our modern word quintessence is derived. Interestingly, the ether turned out to be by far the longest lived of the Greek elements, for it was not until the dawn of the twentieth century that belief in the ether was finally abandoned.

2 EARLY NOTIONS OF THE ELEMENTS

The earliest philosophers of ancient Greece came to the conclusion that everything in the physical world consisted of one single reality, even though it was manifested in many different forms. This single reality, or single element in modern parlance, was variously interpreted. Thales (650–546 BCE) thought that it was water, Anaximenes (560–500 BCE) that it was air, while Heraclitus (536–470 BCE) maintained that it was fire. As no general agreement could be reached, their several ideas were eventually incorporated into a multielement theory of reality. This theory was put forward by Empedocles (490–430 BCE) who asserted that the world was derived from four basic roots, these being earth, air, fire, and water. He was thus the originator of the much celebrated concept of the four terrestrial elements that was to dominate scholastic

thinking for the next two millennia. Plato (427–347 BCE) adopted the four elements and introduced a fifth element, the ether or quinta essentia mentioned earlier, that he believed was the constituent of all matter in the celestial sphere. Plato also associated each of these five elements with one of the five Platonic polyhedra: fire with the tetrahedron, air with the octahedron, water with the icosahedron, earth with the hexahedron (cube), and the ether with the dodecahedron.

Because of the association of the elements with the Platonic polyhedra, it was argued[3] that the elements were constructed from two distinct types of triangle: an isosceles right-angled triangle (two sides equal) and a scalene right-angled triangle (no sides equal). Moreover, it was supposed that the elements air, fire, and water were mutually interconvertible, a supposition that gave rise to the alchemical notion of the transmutation of the elements. Thus, an icosahedron of water (with 20 faces) could be partitioned into two octahedra of air (with a total of $2 \times 8 = 16$ faces) and one tetrahedron of fire (with four faces). The element earth was thought to be too stable to partake in such splitting and the element ether was deemed to be too exalted to do so. The greatly varying characteristics of the materials extant on Earth could be accounted for in terms of (1) the differing sizes of the triangles from which they were constructed, (2) the distinct ratios of the elements of which they were composed, and (3) the varying proportions they contained of the four qualities of dryness, wetness, hotness, and coldness. The behavior of the elements could also be correlated with their specific shapes. Because fire, for instance, consisted of tetrahedral particles with comparatively sharp points, it was thought that fire could cut into and therefore dissolve many material substances. That such notions persisted well into the seventeenth century is seen from Figure 1 which reproduces a depiction of the elements by Kepler[4] dating from 1619.

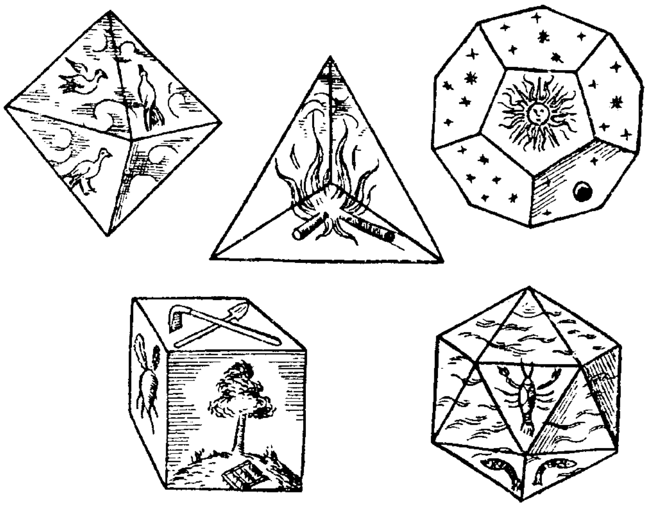

Figure 1 A depiction of the five elements shown here as the five Platonic solids. From Johann Kepler's book *Harmonices Mundi* of 1619

It was during the Middle Ages that the number of the metaphysical elements began to increase. In the eighth century, the somewhat obscure Arab alchemist Jabir ibn Hayyan (ca. 721–815) added two new elements. He argued that all metals are comprised of the elements mercury and sulfur, the element mercury being coagulated by the element sulfur to form individual metals. The specific metal that was formed depended on the relative amounts of the mercury and sulfur it contained. Reference was made here not to the substances mercury and sulfur themselves but to their essences, which were thought to be so rarified that they could not be obtained experimentally. In the sixteenth century, Theophrastus von Hohenheim (1493–1541), also known as Paracelsus, introduced the concept of the *tria prima*, the three principles, which developed the thinking of Jabir ibn Hayyan. Paracelsus asserted that the three fundamental principles were sulfur (the combustible principle), mercury (the liquidity principle), and salt (the incombustibility principle). This trio of elements was allegedly present in all materials whether they be of animal, vegetable, or mineral origin. Mercury was considered to be the spirit of the material, with sulfur its soul, and salt its physical body. By the end of the Middle Ages, the number of metaphysical entities regarded as elements had thus increased to eight.

3 DISCOVERY OF THE CHEMICAL ELEMENTS

The gradual move away from the notion that elements were metaphysical in nature toward a broad acceptance that they are real substances occurred during the seventeenth century. From around the 1630s the conventional wisdom of the day began to be questioned. One of the first to do so was the German alchemist Joachim Jungius (1587–1657), who doubted that the elements were metaphysical entities but saw them rather as corpuscular in structure and comprised of pure and simple substances.[5] In his celebrated book The *Sceptical Chymist*, published in 1661, Robert Boyle (1627–1691) put forward[6] a new definition of an element. It was his intention to discredit the prevailing thinking of the time and to point out that elements always consisted of actual substances. In what is now regarded as the first modern definition of an element, Boyle stated that elements were 'primitive and simple, or perfectly unmingled bodies; which not being made of any other bodies, or of one another, are the ingredients of which all of those called perfectly mixed bodies are immediately compounded, and into which they are ultimately resolved'. This definition found little resonance among Boyle's contemporaries and so was largely ignored during Boyle's lifetime.

In fact, a century elapsed before Boyle's definition began to be taken seriously and put into practice. One of the great luminaries of science, the French chemist Antoine-Laurent Lavoisier (1743–1794), sometimes called the father of modern chemistry, decided to put Boyle's arguments to the test. To determine which substances were elements,

Figure 2 A listing of the chemical elements according to Antoine-Laurent Lavoisier. From his book *Traité Élémentaire de Chimie* of 1789

Lavoisier resolved materials into their ultimate constituents, that is, he decomposed them chemically until 'the last point that analysis is capable of reaching'. By this means, he was able to draw up a table of simple substances that he claimed were elements. This table was published[7] in his groundbreaking book *Traité Élémentaire de Chimie*, which appeared in 1789. The reproduction of his table here in Figure 2 shows that it contained many substances that are now considered to be elements. The table also includes light and caloric, the latter being regarded by Lavoisier as a material fluid that functioned to separate the particles of elementary substances and thereby maintain them in the gaseous state. However, the rejection by Lavoisier of the alchemical notion of phlogiston, which he considered had made chemistry 'obscure and unintelligible', rendered possible a much more realistic understanding of the reactions that the elements entered into and thus afforded new insights into the nature of the elements themselves.

The next major step toward construction of the periodic table was taken in 1803 by the English chemist John Dalton (1766–1844). He demonstrated[8] that, if the hydrogen atom be assumed to have unit weight, then it was possible to assign relative weights to all of the other atoms. This he did by taking the combining weights of various pairs of elements and making the further assumption that the elements combined in a ratio of 1:1. Thus, it was known to Dalton that 12.6 parts of hydrogen combined with 87.4 parts of oxygen by weight. Taking the formula of water to be HO, he deduced that the oxygen atom must be 87.4/12.6 times heavier than the hydrogen atom. In other words, he had determined that the atomic weight of oxygen was seven (rounded to the nearest integer). Although the underlying reasoning was sound, there were two problems with Dalton's approach. First, the combining weights were not accurately known at the time and this led to errors. Second, and more seriously, Dalton's assumption that the elements combined in a 1:1 ratio, and that the formulas for water and ammonia were respectively HO and NH, generated a chaotic situation that was not cleared up for another 60 years. Dalton had, however, pioneered the way in showing that a natural number, that is, the atomic weight, could be associated with each element.

4 RELATIONSHIPS AMONG THE ELEMENTS

The idea that patterns of behavior were to be discerned among the elements was first established by the German chemist Johann Döbereiner (1780–1849). Early in the nineteenth century he began a series of extensive studies on groups of three elements that exhibited analogous behavior. The first group he investigated consisted of the trio *calcium-strontium-barium*. He demonstrated that these elements not only behaved in a chemically similar fashion but also were connected by a mathematical relationship. Döbereiner had shown that the equivalent weight of strontium oxide was almost exactly the mean of the equivalent weights of calcium oxide and barium oxide. In many other respects, the element strontium possessed properties that placed it precisely between the elements calcium and barium.[9] Several additional studies on element trios, including *lithium-sodium-potassium*, *chlorine-bromine-iodine*, and *sulfur-selenium-tellurium*, revealed that similar relationships applied in a number of other cases.[10] Trios of analogous chemical elements began to be referred to as triads and the mathematical relationship they satisfied was called the law of triads.

Important new insights into the various ways in which the elements could be interrelated were gained during the middle decades of the nineteenth century. The German chemist Leopold Gmelin (1788–1853) pointed out[11] in 1843 that whereas in some triads the atomic weights hardly differed at all, for example, in *chromium-manganese-iron*, in other triads the difference was considerable, for example, in *chlorine-bromine-iodine*. It was even shown[12] in 1850 by the German chemist Max von Pettenkofer (1818–1901) that some triads, for example, *fluorine-chlorine-bromine*, did not satisfy the law of triads. Further work also enabled von Pettenkofer to introduce the concept of the tetrad of elements, after he had studied the tetrads *magnesium-calcium-strontium-barium* and *oxygen-sulfur-selenium-tellurium*. Among many other relationships between the elements that were discovered around this time, mention has to be made of the existence of pentads of elements. In 1858, the French chemist Jean Dumas (1800–1884) first discovered[13] the pentad *nitrogen-phosphorus-arsenic-antimony-bismuth*. The earliest attempt to classify all of the elements into natural families was made[14] in 1857 by the English chemist William Odling (1829–1921). The 13 families he devised have a familiar ring to them. In group I, the elements fluorine, chlorine, bromine, and iodine were included; in group II, oxygen, sulfur, selenium, and tellurium; and in group III, nitrogen, phosphorus, arsenic, antimony, and bismuth. By developing such a scheme, Odling came close to discovering the periodic table, a feat he achieved seven years later in 1864.

In 1857, the time was not ripe for the advent of the periodic table because until the early 1860s the great uncertainty surrounding the true values of the atomic weights resulted in considerable confusion. Indeed, it was not unknown for chemists to use their own individual sets of atomic weights! The problem was finally resolved shortly after the first major international gathering of chemists held in Karlsruhe, Germany in September, 1860. At the end of this meeting, the Italian chemist Stanislao Cannizzaro (1826–1910) had a pamphlet distributed that revealed how reliable atomic weights could be calculated. Basically, Cannizzaro had reformulated the earlier work of his compatriot Amadeo Avogadro (1776–1856) who in 1811 had put forward a hypothesis now known as Avogadro's law. The updated version of this law stated[15] that 'the different quantities of the same element contained in different molecules are all whole multiples of one and the same quantity, which, always being entire, has the right to be called an atom'. This new formulation had a dramatic impact on many of the chemists who attended the conference. The German chemist Lothar Meyer (1830–1895) commented after reading it that 'the scales fell from my eyes, doubts vanished, and a feeling of calm certainly came in their place'.

5 THE ADVENT OF THE PERIODIC TABLE

As soon as accurate atomic weights for the elements became available, all of the necessary groundwork had been laid for the appearance of the periodic table. In fact, it was only some 18 months after the Karlsruhe Congress that the first periodic table was published.[16] The French mineralogist Alexandre

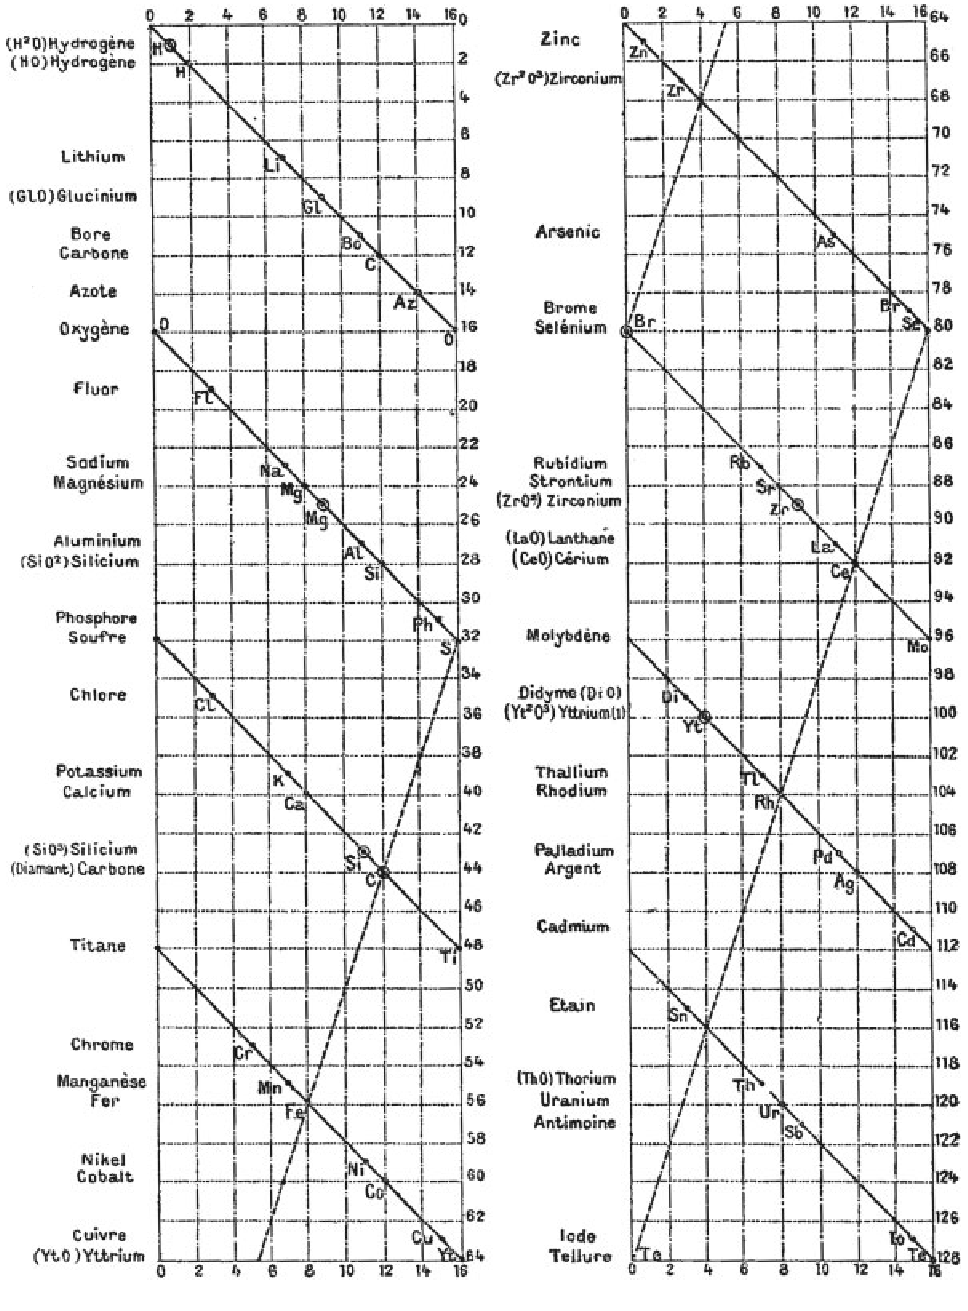

Figure 3 The first prototype of the periodic table put forward by the French mineralogist Alexandre Beguyer de Chancourtois in 1862

Beguyer de Chancourtois (1819–1886), who was seeking for a way to classify geological rock specimens, discovered a prototype version of the periodic table in April, 1862. His prototype assumed the form of a continuous line of the elements ordered according to the recently revised atomic weights. The element line was wound around a right cylinder from the top at an angle of 45°, an arrangement that permitted analogous elements to be aligned along vertical lines drawn on the surface of the cylinder. The first winding of the element line through 360° included all of the elements up to oxygen, the second 360° winding the elements from fluorine to sulfur, and so on until all 59 of the then known elements had been accommodated. This new device was designated as the Telluric Screw, from the Latin word *tellus* that signified both the Earth from which all of the elements derive and the fact that the element tellurium was located at the center of the device. A two-dimensional representation of de Chancourtois' prototype of the periodic table is reproduced in Figure 3.

Following the pioneering work of de Chancourtois, no fewer than five other authors independently put forward periodic tables during the succeeding seven years. Shortly after de Chancourtois' breakthrough, the British chemist John

Newlands (1837–1898) published his first table in 1864 and noted[17] that '. . . the eighth element starting from a given one is a kind of repetition of the first, like the eighth note of an octave of music'. By a remarkable coincidence, the third periodic table author came from the same district of London as Newlands and published his table in the same year, 1864. William Odling (1829–1921) not only managed to include 57 of the 60 elements then known, but also drew a clear distinction between main group and subgroup elements.[18] The fourth discoverer of the periodic table was the Danish American Gustavus Hinrichs (1836–1923) who developed[19] a system for the natural classification of the elements in 1867. In 1868, the fifth author, the German Lothar Meyer (1830–1895) produced a full periodic table that assumed the form of 15 columns of elements, though this was not published immediately. By the time it was eventually published[20] early in 1870, the sixth and final discoverer of the periodic table, the Russian Dmitrii Mendeleev (1834–1907), had already published a 63-element version of the periodic table. The first printed version of the periodic table developed by Mendeleev was intended for distribution to his colleagues. We reproduce it here as Figure 4. A listing of the six independent discoverers of the periodic table is presented in the compilation below.

Odling	1864	System of the elements
Hinrichs	1867	Natural classification of elements
Meyer	1868	System of the elements
Mendeleev	1869	System of the elements

A listing of the various designations adopted for the periodic table by its six independent discoverers during the years 1862–1869.

Because Mendeleev is nowadays often regarded as the sole discoverer of the periodic table, it seems fitting to take a closer look at his contributions. A book offering a comprehensive review of his life and times appeared recently.[21] Mendeleev made a point of explicitly formulating the law underlying the periodic table and this he termed the periodic law.[22] Although he presented his law in the form of eight statements, only the first is necessary to grasp the law as the other seven are essentially embellishments of the first. The first statement reads: When the elements are arranged according to their atomic weights, they show an evident periodicity in their properties. This law, however, was not a strict one and even Mendeleev was not averse to making exceptions when these seemed to be called for. Thus, he reversed the order of the elements tellurium and iodine in his table, even though in terms of their atomic weights iodine should precede tellurium.

Mendeleev trusted the periodic law enough to leave gaps in his table for elements that were unknown at the time. He predicted the existence of the elements germanium, gallium, and scandium and gave a forecast of their properties that proved to be spectacularly accurate.[23] All three of these elements were discovered within 15 years of the prediction of their existence and this caused excitement in the chemical community and raised Mendeleev's profile. But it should not be forgotten that Mendeleev made around 20 such predictions in all and, apart from the three great successes, his other predictions proved to be either fortuitous guesses or completely wrong. Especially misconceived were his predictions of the elements newtonium (atomic weight 0.17) and coronium (atomic weight 0.4) as well as six new elements that allegedly existed between hydrogen and lithium.

6 COPING WITH THE ANOMALIES

Toward the end of the nineteenth century it became increasingly clear that the periodic law was subject to a number of violations and even Mendeleev himself came to regard it as no more than rough and ready manifestation of some much stricter, mathematical law that remained to be identified. The periodic law was put to the test and found to be wanting when the noble gases began to be discovered in the 1890s by William Ramsey (1852–1916) and his collaborators. The periodic law had not been able to predict the existence of the noble gases, could give no explanation of their unusual properties (they appeared to be completely unreactive chemically), and there seemed to be no space to accommodate them in the periodic

table.[24] To cope with the apparently intractable problem posed by the noble gases, Ramsey suggested to Mendeleev in 1900 that an extra group be added to the periodic table. After much soul searching, Mendeleev incorporated a new group 0 into his periodic table to make room for the noble gases. It was quickly realized that this new group, which was initially placed at the extreme left of the table and then immediately to the right of the halogens, fitted naturally into the periodic table. Mendeleev spoke of a 'magnificent survival' of the periodic law in what had proved to be a 'critical test' for it.[25]

The next of the problems to be confronted was one that threatened the very existence of the periodic table and ultimately had the effect of modifying the periodic law as stated by Mendeleev. In 1919, Francis Aston (1877–1945) had demonstrated that in general the elements are comprised of isotopes, that is they consist of atoms with the same number of protons but differing numbers of neutrons.[26] This new insight soon unleashed vigorous debate on whether the periodic table was capable of accommodating all of the elemental isotopes that were beginning to be discovered in large numbers by Aston and several other workers. There was a widespread sentiment that the periodic table would have to be replaced by some much more complex and cumbersome structure that could incorporate all of the isotopes. Just as talk of an abandonment of the conventional periodic table was reaching a peak, the day was saved by experimental work[27] that showed that the presence of isotopes in an element had no effect on its chemical behavior. The only exception to this universal rule was the element hydrogen, the isotopes of which were found to differ quite markedly in their chemical and physical properties. Thus, apart from the case of hydrogen, the substitution of one isotope by another in a given element was of no chemical significance, a finding that meant there was no need to alter either the group or the period structure of the periodic table.

Recognition of the fact that elements always displayed the same chemical behavior – regardless of their isotopic composition – led to a reformulation of the periodic law. The idea that each element was characterized by a unique number had already been demonstrated experimentally by Henry Moseley (1887–1915). By studying the X-ray diffraction patterns produced by a variety of elements, he discovered[28] that the frequencies of the K lines differed from element to element in a predictable and consistent fashion. He went on to show that 'the frequency of any line in the X-ray spectrum is approximately proportional to $A(N-b)^2$, where A and b are constants' and N is an integer that he termed the atomic number of the element. Moseley was able to identify the number N with the number of protons in the atomic nucleus. Plots of the square root of the frequency for the K and L lines in the X-ray spectra of the elements versus their atomic number, reproduced in Figure 5, show almost straight lines. From this work, it became clear why the order in which certain element pairs appeared in the periodic table needed to be reversed. The pairs in question are argon (39.95) and potassium (39.10); cobalt (58.93) and nickel (58.69); and tellurium (127.60) and iodine (126.91), the atomic weights being given in parentheses. The reversal was necessary because the atomic weights of the element pairs, that is, the mean weights averaged overall of the isotopes present, were out of step with the atomic numbers. The periodic law formulated by Mendeleev thus needed to be updated to read: When the elements are arranged according to their atomic numbers, they show an evident periodicity in their properties.

7 THE LONG END OF THE TABLE

The headway made by the physicist Moseley meant that it became possible to determine which substances were elements and also which elements were missing from the periodic table. Moseley himself had pointed out that three elements were missing, that is, the elements numbered 43 (technetium), 61 (promethium), and 72 (hafnium). These anticipated elements were eventually found, though only hafnium occurred naturally, the remaining two being artificially synthesized. The so-called rare earth elements began to be studied in the latter half of the eighteenth century and the last such element (lutetium) was discovered in 1907. The rare earths comprised an eclectic group thought to number up to 32 elements that clearly did not fit neatly into the periodic table and even created doubts about the table itself. Mendeleev remarked[29] that 'a whole large period is wanting between Ce = 140 and Ta = 183 . . . and therefore this portion of the periodic system is, in a way, broken and requires fresh researches'. It has even been observed that, had a majority of the rare earth elements been known in the 1860s, it is unlikely that the periodic table would have been discovered during that decade. The term 'rare earths' is no longer in current use both because it is ill-defined and the materials so characterized are not now regarded as rare.

The difficulties encountered in attempting to classify the rare earth elements were not satisfactorily resolved for several decades. In fact, a major breakthrough in our understanding of atomic physics was required before the issue could be said to be concluded. From the 1880s, versions of the periodic table that broadened out as the table progressed began to be proposed, this being done to allow extra space for the rare earth elements. Early examples of such tables were devised by Hans Thomsen (1826–1909) in 1895[30] and Alfred Werner (1866–1919) in 1905.[31] An important advance in shaping these expanded, two-dimensional periodic tables was made in 1922 when the renowned Danish physicist Niels Bohr (1885–1962) put forward[32] the table reproduced in Figure 6. Although this table had its origins in Bohr's preceding work on the electronic structure of atoms, the structures for many of the heavier atoms were still undetermined at the time. In the case of the rare earth elements, Bohr was thus forced to rely on spectroscopic data. These confirmed that the rare earth elements should indeed occupy a separate location in the periodic table and so he placed the elements

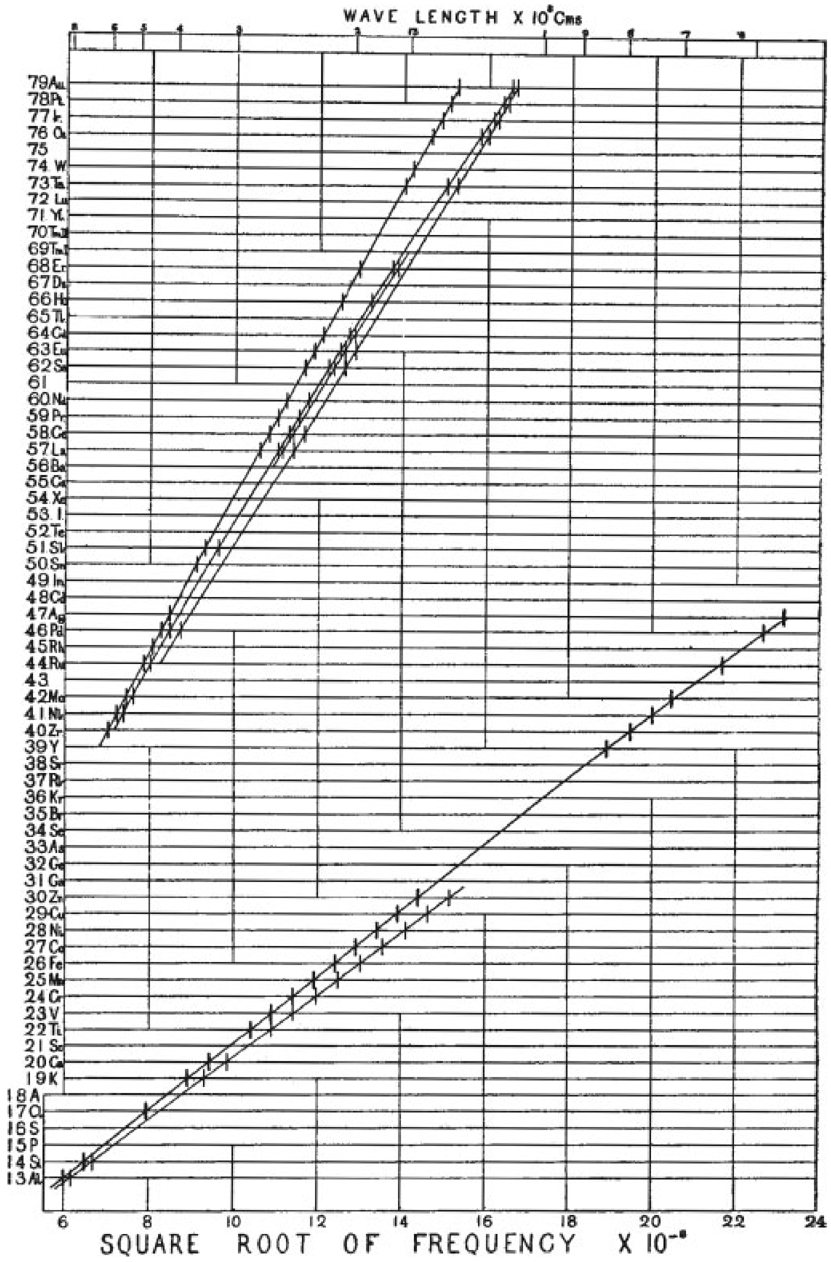

Figure 5 Plots of the square root of the characteristic X-ray frequencies of the elements against their atomic number. Published by Henry Moseley in 1914[28]

cerium through ytterbium in a box within a box. The reason for their singular behavior became clear a few years later when it was realized that in these elements the inner 4f orbitals were being successively filled with electrons. The outer, valence electrons are largely unaffected by this and so all of these elements exhibit remarkably similar chemical behavior.

The elements Bohr had placed in a double box became known as the lanthanides (or lanthanons) because they followed directly after element 57 (lanthanum). Bohr's ideas sparked considerable debate and nowadays element 71 (lutetium) is included among the lanthanides, this being the element at which the 4f orbitals became completely filled. Moreover, there remains some uncertainty whether the element lanthanum itself should be regarded as a lanthanide. From Bohr's periodic table in Figure 6 it can be seen that he left an additional double box for another series of elements that he believed would be analogous to the lanthanides. As he was not sure where this second series might begin, he placed it immediately after element 92 (uranium). However, in 1944, Glenn Seaborg (1912–1999) reconsidered this positioning and decided[33] that the series should start after element 89

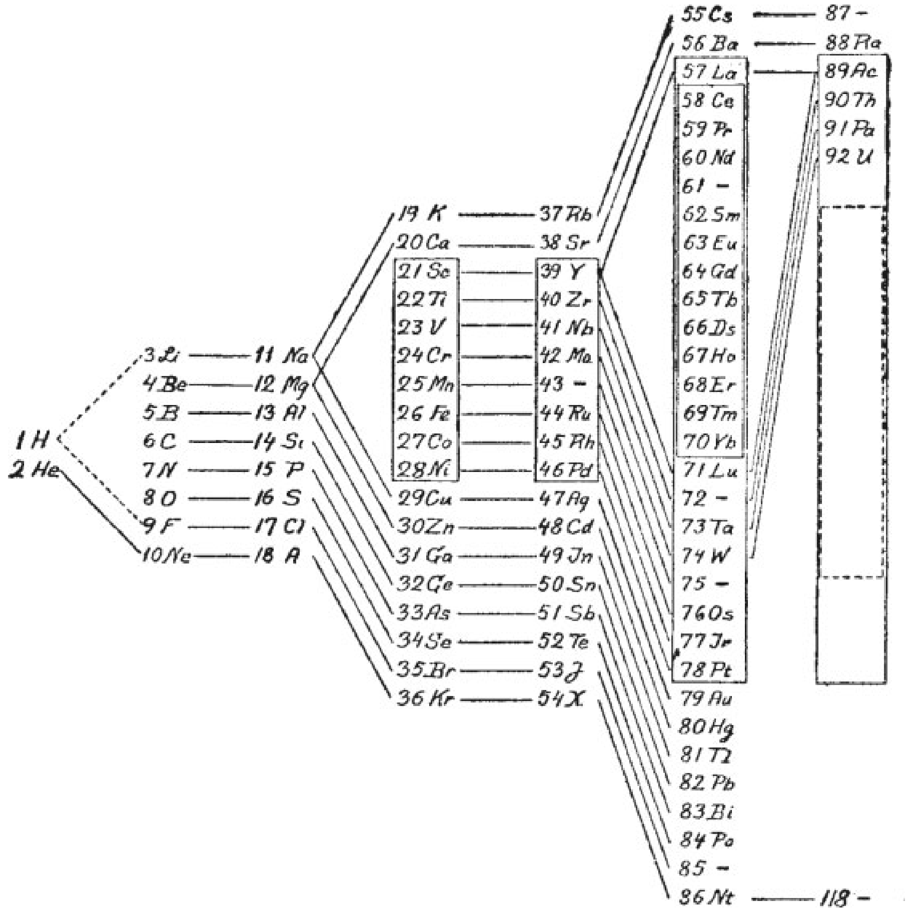

Figure 6 The periodic table of the elements put forward by Niels Bohr in his book *The Theory of Spectra and Atomic Constitution* in 1922[32]

(actinium). The series thus became known as the actinides and there are again 14 of them because in these elements the 5f orbitals are being filled. This series started with the known elements 90 (thorium), 91 (protactinium) and 92 (uranium) and thereafter the elements had to be synthesized beginning with element 93 (neptunium) in 1940[34] and ending with element 102 (lawrencium) in 1961.[35] Several reviews on the synthesis of transuranic elements are now available.[33,36,37] After element 122, it is now generally thought that yet another special series known as the superactinides begins with the filling of the 6f orbitals, but this is a story that remains to be told.

Glossary

A–H: a weak acid, A being an electronegative element or group
B: a weak base
DHB: dihydrogen bond (A–H···H–E)
E–H: an element–hydrogen bond

1 INTRODUCTION

The hydrogen bond involves the interaction of a weak acid OH, NH, or similar bond A–H with a weak O or N or similar base, B, to give a linear adduct A–H···B (**1**). Arguably, the most important intermolecular interaction in chemistry, it is responsible for the strength of materials such as wood and spider silk and for many of the physical properties of water such as its surface tension and elevated melting and boiling points relative to its non-hydrogen-bonding analogue, H_2S. Numerous monographs have been devoted to the phenomenon since Pimentel and McClellan's[1] classic 1960 book, *The Hydrogen Bond*, including some very useful recent books.[2,3] From a historical perspective, it was Pauling's[4] celebrated 1939 book *The Nature of the Chemical Bond* that brought the hydrogen bond to the attention of a wide audience, and the early (1950s) recognition of its key role in both the protein alpha helix and the nucleic acid double helix underlined its central importance in biology.

The hydrogen bond has taken center stage with the rise of supramolecular chemistry and molecular recognition.[5,6] It constitutes one of the forces employed in this field, together with aromatic stacking, ion pairing, and coordinate bonding. Hydrogen bonding is particularly important because it is directional and undergoes rapid make and break equilibria that allow a thermodynamically stable structure to be attained rapidly. Important processes like protein folding, enzyme action, and nucleic acid strand recognition rely on these aspects of hydrogen bonding.

In a recent and specifically inorganic development (1990s), dihydrogen bonding has been recognized as a class of hydrogen bonding in which the weak acid A–H component of the hydrogen bond interacts with a hydridic element hydrogen bond H–E, to give an adduct A–H···H–E (**2**) having similar energetics to the classical A–H···B case. Its name, the dihydrogen bond, or DHB, comes from the presence of two hydrogens in close proximity.[7–9] The involvement of an inorganic E–H bond makes it particularly relevant to inorganic chemistry. The ease of calculation in such a simple system has also attracted strong theoretical interest. In spite of its recent discovery, there are already hundreds of papers on the topic. Brammer,[10] who characterized the A–H···M (**3**) hydrogen bond has reviewed the whole area of hydrogen bonding in transition metal chemistry (Scheme 1).

2 NATURE, STRUCTURE, AND SPECTROSCOPY

The hydrogen bond results from the interaction of a weak base, B, (hydrogen bond acceptor) with a weak acid, AH, (hydrogen bond donor) to give the structure A–H···B where the dotted line represents the hydrogen bond.[1–4] This is usually weaker and longer than a normal bond, the bond strength typically amounting to 4–10 kcal mol^{-1} and the bond length to about 0.2–0.7 A less than a van der Waals contact. It is the presence of the hydrogen bridge that gives it the name hydrogen bond. In the terminology of the field, the weak acid component AH is termed a hydrogen bond donor because it donates a proton, and B is likewise termed a hydrogen bond acceptor (i.e. proton acceptor). This can be confusing because in every other area of acid–base chemistry, a base is considered as a donor of a lone pair of electrons and an acid an acceptor. The hydrogen bond can be considered as a structure that results from incomplete proton transfer because AH is too weak an acid and B too weak a base to consummate the transfer. Hydrogen-bonded species are likely transient intermediates in proton transfers in general.

The interaction is predominantly electrostatic (**4**), the A–H dipole interacting with the negatively charged lone pair of electrons on B. For the interaction to be significant, both A and B have to be electronegative groups, as in the water dimer HO–H···OH_2. The approximate linearity of the A–H···B system can be explained on the basis of the electrostatic repulsion of the A and B groups (or as the preferential approach of B along the A–H σ^* direction). This type of hydrogen bond typically shows a double minimum potential energy well as in the case of [PhO–H···OPh]$^-$, where by symmetry the proton can be transferred to the phenolate ion base to give [PhO···H–OPh]$^-$.

 (**1**)	*Hydrogen bond*	linear	A and B are electronegative
 (**2**)	*Dihydrogen bond*	bent	A is electronegative; E electropositive
 (**3**)	*Hydrogen bond*	linear	A is electronegative; M is a transition metal

Scheme 1 Types of hydrogen bonds

(**4**)

(**5**)

(**6**)

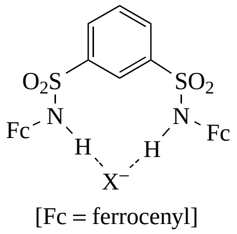
A class of strong hydrogen-bonded species has a single symmetrical potential energy well, leading to a symmetrical structure; these have a high covalent contribution to the bonding. The outstanding example of a strong hydrogen bond is the bifluoride ion, $[F–H–F]^-$ (**5**). The bond lengths are now only slightly longer than in HF itself and the hydrogen bond strength (27 kcal mol^{-1}) becomes very large. In such a case, the covalency of the H–F bonds becomes significant, and the bonding can be considered to involve donation from the F^- lone pair into the HF σ^* orbital (**6**). This is exactly analogous to the bonding situation found in hypervalent main group species such as SF_6, where the F^- lone pair donates into the σ^* orbital of the SF bond trans to itself; another way to view the bifluoride ion is therefore as an example of a hypervalent 2-coordinate 4-electron hydrogen. When hypervalency was believed to require d orbital participation, such an identification would have been unacceptable but modern theories[11] of hypervalency have abandoned this old idea of d-participation. Disorder in the crystal containing $[X–H\cdots X]^-$ can lead an unsymmetrical hydrogen bond to appear symmetrical, so care needs to be taken in the interpretation of structural data. Neutron diffraction provides the most reliable data. Interesting metal bifluoride complexes are now known.[12]

Because of the soft potential of hydrogen bonds relative to normal bonds, deformations can occur in crystals where the presence of other forces can lead to problems in trying to estimate relative hydrogen bond strengths from the observed bond lengths.[13] A good example of hydrogen bond lengths in an inorganic species not following bond strengths is given by Brammer.[10] Use of X-ray structural data leads to a systematic error in the H distances, and A–H distances are therefore normalized to their expected neutron diffraction distance before estimating the H···B bond length. Ideally, neutron-diffraction structures are used to characterize important new examples of hydrogen bonding.

Spectroscopic methods are useful for characterization. The A–H stretching frequency in the IR spectrum typically falls on hydrogen bond formation and the AH proton resonance also shifts to high field. Where A or B has a nuclear spin (e.g. ^{19}F), the coupling constant between A or B and H can be used as long as exchange is not too rapid. For example, in the gas phase, HF has an H,F coupling constant near 600 Hz, but in amine···H–F adducts, this value falls to about 450 Hz.[14]

3 APPLICATIONS

Along with aromatic stacking and hydrophobic forces, hydrogen bonds are applied widely in supramolecular chemistry.[15] For example, N–H···X hydrogen bonds are commonly used in anion receptor molecules (X = anion) such as catapinates[16] and isophthalamides,[17] and in crystal engineering.[18] Etter's rules[19] have been used to try to rationalize hydrogen bonding patterns in crystals. Anion receptors such as (**7**), based on redox-active metal complexes, have been used for anion sensing.[20] Much of this work relates more to organic than inorganic chemistry, however, so in what follows we concentrate on the inorganic applications.



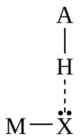
[Fc = ferrocenyl]
(**7**)

4 HYDROGEN BONDING INVOLVING METAL COMPLEXES

In inorganic chemistry, interest has centered recently on unconventional hydrogen bonds of different sorts. For example, it has proved possible to replace both the AH and B components of the A–H···B system by inorganic groups. Substitution of the hydrogen bond acceptor (weak base) has been the most common. Several classes of substitution have proved successful where the weak base is: (1) a metal-based nonbonding pair of electrons or (2) a lone pair of a ligand bound to the metal or (3) an M–H bond (see Section 5). In case 2, the classical hydrogen bond lone pair is still present, in case 1 it is replaced by a metal-based nonbonded electron pair, but in case 3 no lone pair is involved at all and the base is a bonding electron pair.

A–H···M hydrogen bonds (type 1, **3**) were studied by Brammer,[10] who used neutron diffraction to unambiguously characterize the structure. An example is (**8**). Basic metal centers that can protonate with strong acids are particularly likely to show hydrogen bond structures with weak acids. The AHM system is linear and A is an electronegative element, as in the classical hydrogen bond.

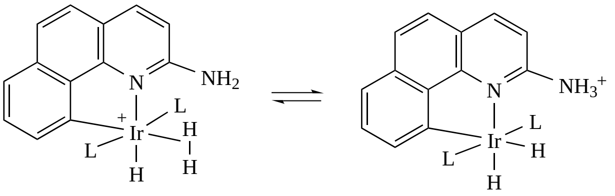
(**8**)



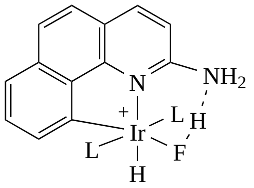
(**9**)

A–H···X–M hydrogen bonds[7,8] (type 2, **9**) have been seen on numerous occasions. Brammer[10] has again done much to characterize these interactions structurally. The M–X···H angle is usually bent because of the presence of sp^3 (F) or p (Cl–I) lone pairs; the preferred angle is smaller for Cl–I than for F. A cis MX_2 unit is a particularly good hydrogen bond acceptor because an approach of the AH between the two X groups allows interaction with both X groups within the favorable range of angles.

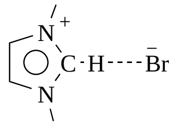
Intramolecular proton transfer is also possible via a hydrogen-bonded form in the case shown in equation (1), where the size of the L groups determines which isomer is stabler.[21] This arises from ion pairing with the counterion, as shown by combined theoretical/experimental studies. If L is small (e.g. PMe_2Ph), the anion can bind close to the metal at the preferred binding site and the H_2 complex is formed. If this site is blocked by employing a large L (e.g. PPh_3 or $P(cyclohexyl)_3$), then the anion binds at the remote $-NH_3^+$ site, in which case proton transfer occurs to make this site a better anion acceptor. The same system can stabilize HF binding (**10**), where the F–H···N hydrogen bond is essential to stabilization of the complex; the high J_{HF} of 440 Hz, observed by NMR spectroscopy at low temperature, identifies the species as having an H–F bond.



(1)



(**10**)



(**11**)

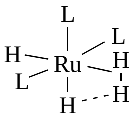
The usual OH or NH acid component of the hydrogen bond can be replaced by an acidic CH, as in the acid 2-position of an imidazolium salt (**11**) where the anion forms an ion pair, aided by the accompanying hydrogen bond. Ion pairing of this sort has been shown to strongly influence the outcome of metallation reactions of imidazolium salts to give normal (C2) versus abnormal (C4,5) metallated carbenes, depending on the strength of hydrogen bonding.[22]

The area of hydrogen bonding in inorganic chemistry has seen a great increase in activity in the last decade and may even find application in homogeneous catalysis in the years to come. In metal-free ‘organocatalysts’, hydrogen bonding clearly plays a dominant role.[23]

5 DIHYDROGEN BONDING

The possibility that a protonic and a hydridic hydrogen could show an attractive interaction was first raised[24] (1990) in relation to Milstein’s complex, *cis*-$[L_4Ir(OH)H]BF_4$, where the OH was pointing towards the adjacent Ir–H. The HH distance, d_{HH}, was a long 2.4 Å, however, equal to the sum of the covalent radii for two H atoms, so the interaction was clearly weak. Later theoretical work[25] showed that this species does not contain a true hydrogen bond, but the general principle suggested in the 1990 work was nonetheless valid even if the particular example was flawed. In the same year, a very close d_{HH} (1.86 Å) was seen by neutron diffraction in a $[L_3Ru(H_2)H_2]$ species (**12**), where the acidic H_2 ligand interacts with the cis Ru–H group.[26] The origin of this effect was correctly identified as the attraction of oppositely charged H atoms. This complex was therefore the first authentic example of the effect.

The concept of the proton−hydride interaction or dihydrogen bonding (DHB) was generalized by Morris[27]



[L = PEt_2Ph]

(**12**)

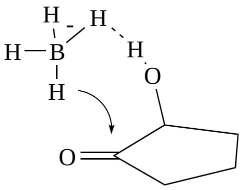
and by Crabtree[28,29] from 1994, who described a series of compounds in which a variety of OH and NH bonds interact with metal hydrides, in both intra- and intermolecular fashion. The d_{HH} values typically associated with such structures proved to range from 1.7–2.1 Å. A particularly convincing case was the neutron-diffraction structure of the adduct $[ReH_5(PPh_3)_2\cdot$indole], where the indole NH was found to be very close (1.753 Å) to one of the ReH hydrides.[30] Being an intermolecular adduct, one could no longer consider that the two H atoms were merely being forced into apparent association by conformational forces. Subsequent work has shown that in many cases, a dihydrogen-bonded adduct can form in solution, but on crystallization, the pure hydride crystallizes without the Lewis acid component. $ReH_5(PPh_3)_2$ and indole were specifically chosen for this work because they crystallize poorly; indeed, indole is a liquid.

One possible ambiguity with the interpretation of the DHB as a proton–hydride attraction was still unresolved, however. Transition metals of the type mentioned above have nonbonding d_π electron pairs, analogous to lone pairs, pointing toward the A–H group. There was still legitimate doubt about whether these compounds were just special examples of A–H···M systems (type 2) since the main interaction might be with a 'lone pair' on the metal, not with the M–H bond. Such interactions, mentioned in Section 4, do indeed genuinely exist. To remove this ambiguity,[31] BH_3NH_3 was studied by a variety of techniques with the conclusion that exactly the same type of bond exists in this species where there are no lone pairs as in $[ReH_5(PPh_3)_2\cdot$indole]. The interaction was therefore termed the dihydrogen bond to emphasize this point.

Just as proton transfer within A–H···B gives A^- and BH^+, proton transfer within A–H···H–M gives A^- and (H_2)–M^+, a dihydrogen complex. Cases are even known (equation 2) where proton transfer occurs to the hydride initially, followed by rearrangement to the more stable dihydride form.[32] The kinetic product being an (H_2)–M species is consistent with protonation requiring a hydrogen bond adduct as an intermediate and with this adduct being of the A–H···H–M type.

$$\mathrm{Cp^*FeH(dppe)} + \mathrm{H^+} \xrightarrow{-80\,^\circ\mathrm{C}} \mathrm{Cp^*Fe(H\text{–}H)(dppe)^+} \xrightarrow{\text{warm}} \mathrm{Cp^*Fe(H)_2(dppe)^+} \quad (2)$$

Applications of dihydrogen bonding have been reported. Jackson[9] has shown how the attack of borohydride on a hydroxyketone shows a high selectivity for hydride addition from the same face of the ketone as the OH group is located. He showed that the BH_4 anion interacts with the OH via a DHB (**13**) by blocking the effect with a F anion and by demonstrating that no borate ester is formed under the conditions used. Dihydrogen-bond-promoted catalysis has recently been seen in the catalytic hydration of nitriles with an indenylruthenium hydride complex, $[(\eta^5\text{-}C_9H_7)Ru(dppm)H]$ (dppm = bis(diphenylphosphino)methane). In this reaction, water is proposed to bind to Ru–H as Ru–H···H–O–H, causing the water oxygen to be correctly placed for a nucleophilic attack at the nitrile carbon.[33]



(**13**)

Weak C–H···H–M dihydrogen bonds have been proposed in a number of PPh_3-substituted hydride complexes, to account for the abnormally close (1.6–2.1 A) contacts very commonly found in these species.[34]

6 DISTINCTION BETWEEN HYDROGEN BONDING AND SIGMA COMPLEXATION

In an inorganic context, there are two possible types of E–H–M bridge (E = element). The two cases need to be carefully distinguished.[35] In a hydrogen bond,[9] EH contains an electronegative element, typically NH or OH, but an activated CH bond is possible. The geometry is linear (**14**) and the EH proton shows a low-field proton NMR shift on adduct formation, just as in classical hydrogen bonds.

Sigma complexes,[36–38] including agostic and dihydrogen complexes, also have an E–H–M bridge, but E is a less electronegative element, typically, H, C, B, or M. The bridge is bent, as EH binds side-on to M (**15**), and the H shows a high-field proton NMR shift on adduct formation.

(**14**)

(**15**)

Hydrogen bonds contain linear 4e,3-center E–H–M bridge bonds with hypervalent hydrogen, while sigma complexes contain bent 2e,3-center E–H–M bridge bonds with electron-deficient hydrogen. In the former, the metal acts as a weak base, while in the latter it acts as a weak acid. In principle, intermediate situations are possible where both interactions compete but information is still sparse in this area.

Glossary

Dihydrogen complex: complex of H_2 which retains the H–H bond
Nonclassical hydride: hydride with H···H interactions, for example an H_2 complex
Polyhydride: complex of the type L_nMH_x ($x > 3$)

1 INTRODUCTION

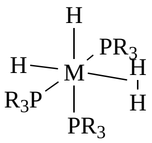
The Kubas[1] dihydrogen complex (1984), $[W(H_2)(CO)_3(P\{C_6H_{11}\}_3)_2]$ (**1**) was the first recognized example of simple dihydrogen binding to a metal without cleavage of the H–H bond or other subsequent process taking place. It was important because the $M(H_2)$ bond provides the simplest and clearest cut case of a σ-complex,[1,2] one in which a sigma bonding electron pair acts as the donor to a metal in a coordination complex. The field of coordination chemistry originated with lone pair donor ligands (e.g. Cl^-, NH_3). The recognition from the 1950s that ligand π-bonding electrons (e.g. $C_5H_5{}^-$) could also donate to a metal in a complex led to the development of organometallic chemistry. Although σ-complexes were first seen in the 1970s, they were not given special attention until the 1980s, a development that was strongly accelerated by the discovery of complex (**1**). There are now (2004) well over a thousand papers on H_2 complexes.

These complexes are sometimes called 'nonclassical' hydrides because prior classical hydrides always had terminal M–H bonds or M–H–M bridges. Dihydrogen complexes are often indicated using the notation $M(\eta^2\text{-}H_2)$ or $M(H_2)$. The early examples all had H···H distances, d_{HH}, below 1 Å, and most had d_{HH} in the range 0.8–0.9 Å. Only later[3] did it become clear that rare examples of dihydrogen complexes have H···H distances much longer than this, typically in the range $d_{HH} = 1.1$–1.5 Å.[4] These 'stretched' or 'elongated' dihydrogen complexes are clearly on the way to forming dihydrides where the 'nonbonding' H···H distances are typically above 1.6 Å.

A very useful monograph[4] on H_2 complexes, a key resource in the field, also covers alkane and silane sigma complexes $M(\eta^2\text{-H-XR}_3)$ (X = C, Si), both fully covered in a recent review.[2]

Since H atoms are not accurately located by X-ray diffraction, and neutron diffraction studies cannot be carried out on a routine basis, spectroscopic methods have proved most useful in this area. The best way to characterize dihydrogen complexes relies on NMR spectroscopy: a large $^1J(H,D)$ of the corresponding HD complex reveals the presence of the H–D sigma bond.

Some polyhydrides, for example, $Fe(H_2)H_2L_3$ (L = a series of phosphines), are in fact nonclassical dihydrogen complexes. In such cases, rapid fluxionality can occur. The true structure (**2**, M = Fe) is not readily apparent from the resulting spectrum because all the hydrides appear equivalent. In such a case the $^1J(H,D)$ measurement is not usually useful. To cover this class of complex we[5,6] proposed the T_1 method, arguing that the close approach of two hydrogens would lead to observable changes in the NMR relaxation time. Morris[7] developed the most useful analysis of the data that even allows the d_{HH} extracted, given certain assumptions.[8] In certain cases, the ν(H–H) stretching mode can be detected in the IR spectrum.[4] While the Kubas complex was the first recognized H_2 complex, we were able to provide evidence that several polyhydrides that had been in the literature for many years were in fact also (H_2) complexes. $RuH_4(PPh_3)_3$, first reported in 1976,[9] was identified by Singleton[10] in 1976 as having a 'dihydrogen-like nature' but no physicochemical evidence was obtained until our 1986 report[11] of the T_1 data. As early as 1971, Aresta[12] had called attention to an unusual IR band in $FeH_4(PEtPh_2)_3$ not suspecting it was an H–H stretching frequency. Our T_1 data and proposal of an (H_2) complex followed in 1986. The 1990 neutron diffraction work by Caulton and Koetzle[13] settled the issue – the complex is in fact $[Fe(H_2)(H)_2(PPh_3)_3]$ (**2**, M = Fe).



(**2**)

2 STRUCTURE AND BONDING

Following Saillard and Hoffman,[14] the bonding is generally considered to involve a Chatt-Dewar scheme with $H_2(\sigma)$ as the donor and $H_2(\sigma^*)$ as the acceptor. Some back donation is required for an isolable H_2 complex to be formed, because pure Lewis acids like $[Eu(fod)_3]$ do not give isolable adducts.

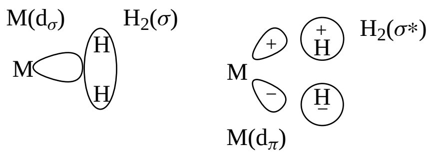
Good structural evidence comes from neutron diffraction data but this is only obtainable for a very restricted number of complexes.[13] The librational motion of the H_2 can cause problems even in neutron diffraction by making the d_{HH} seem smaller than it is. Modeling the motion more realistically gives better data.

Zilm's[15] solid-state powder NMR method, which measures the H–H dipolar coupling, is less affected by motional problems and may give a better estimate of d_{HH}. Ligand deuteriation is, however, usually needed for optimum results. The kind of accuracy that can be achieved is illustrated by the d_{HH} for Kubas complex, 0.890 ± 0.006 Å. In the absence of neutron data, X-ray diffraction has been used but its reliability is questionable for H_2 complexes. If $^1J(H,D)$ is observable in the corresponding HD complex, Morris' equation[16] can be used. This reliably relates the $^1J(H,D)$ value directly to d_{HH} (and to the bond order).

$$d_{HH}(\text{Å}) = 1.42 - 0.0167\{J_{HD}(\text{Hz})\} \quad (1)$$

Considering first the unstretched H_2 complex, by far the commonest class, the elongation of the H_2 on binding is rather small (from 0.74 Å in free H_2 to 0.8–0.9 Å in the complexes) consistent with the idea that the main interaction $H_2(\sigma)$ to $M(d_\sigma)$ donation, with a relatively minor contribution from $M(d_\pi)$ to $H_2(\sigma^*)$ back donation (Scheme 1). The consequence is that the H_2, depleted of negative charge in the complex, acts as an acid. Some H_2 complexes even have negative pK_a's and so are strong acids.[4]

The stretched class with $d_{HH} = 1.1$–1.5 Å are clearly associated with a much enhanced degree of $M(d_\pi)$ to $H_2(\sigma^*)$ back donation. As a consequence, the H_2 remains more nearly neutral in charge terms in the complex and is less acidic. The first such case[3] was $[ReH_5(H\cdots H)(P\{p\text{-}CH_3C_6H_4\}_3)_2]$ and a few tens of examples are now well-established.



Scheme 1

Interestingly, some systems, such as (**1**) itself, show a tautomeric equilibrium between an H_2 complex and a classical dihydride form; others show a stretched H_2. In the first case we have a double minimum on the potential energy surface (PES) (H_2 and dihydride) and in the other a single minimum. The difference appears to lie[3,17] in the motion of the heavy ligands that produces a barrier to the dihydrogen/dihydride tautomerism and where there are no such heavy atom rearrangements, the barrier disappears and a stretched H_2 becomes possible.

The relative simplicity of density functional theory (DFT) calculations involving H has made this area extremely well served by computational studies. Excellent reviews are available.[18–20] Oxidative addition of H_2 can proceed with low or zero barrier for the most exothermic reactions. In contrast to $Pt + H_2$ that gave a low barrier oxidative addition of this sort, the $Pd + H_2$ system was shown to have a stable $Pd(H_2)$ in matrix in 1986.[21]

The energy difference between (H_2) and $(H)_2$ forms has been related to the singlet triplet (S/T) gap in the metal fragment. A small S/T gap favors the (H_2) form because H_2 complexation requires the S form while oxidative addition involves the T form.

Recent Mossbauer data suggests H_2 can be a better back bonder than originally thought.[22]

The ligand trans to the H_2 plays a key role. High trans effect ligands like CO or H are most effective in promoting the H_2 form. In $[IrHCl_2(H_2)(PR_3)_2]$, the d_{HH} increases from ca. 0.8 to 1.4 Å on moving from the isomer with Cl trans to (H_2) to that with H trans to (H_2).[23]

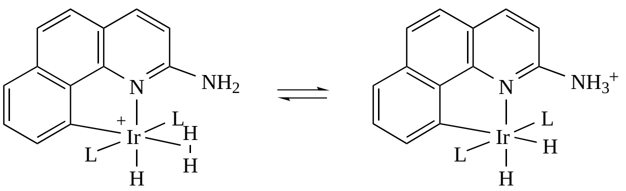
According to the valence bond order concept as applied to the case of stretched H_2 complexes by Limbach,[24] there is a significant H–H bond order p_{HH} even at $d_{HH} = 1.6$ Å, implying that stretched dihydrogen complexes are not usefully considered as 'compressed dihydrides'.

Stretched H_2 complexes are often poorly modeled in DFT work because the PES is very flat. Lluch and Lledos[25] combined DFT with nuclear motion calculations to suggest that the time-averaged d_{HH} should be temperature dependent, explaining the unusual temperature dependence of the J_{HD} in $[Cp^*Ru(H_2)dppm]^+$, and the isotope dependence of J_{HT} and J_{DT} values.[26]

Eisenstein[27] showed computationally that there is a cis interaction in $[Fe(H_2)(H)_2(PEtPh_2)_3]$ (**2**, M = Fe) by which a protonic H of the H_2 ligand is attracted to a hydridic H of a cis-terminal hydride. This can now be seen as an example of a 'dihydrogen bond'.

Finally, Eisenstein[28] was also able to show that the H_2 splitting reaction in equation (2) was governed by the ability of the counterion to ion pair. For small PR_3, this ion pairing takes place at the coordinated H_2. For large PR_3, the ion pairing occurs at the more remote pendant NH_2, in which case

the proton transfer occurs to minimize charge separation in the low dielectric solvent used (CD_2Cl_2).



(2)

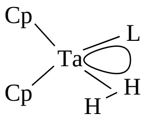
3 SPECTROSCOPY

As a result of the close approach of the two H atoms, the T_1 relaxation of an H_2 complex can be very much shorter than that of the other resonances. The H_2 resonance can be broad – often even broader than the T_1 value would lead one to expect.[29] In such cases it now seems likely that tight ion pairing with the F-rich counterion may be responsible for the excess broadening via unresolved coupling to ^{19}F.

The short T_1 allows the H_2 signal to be selectively nulled by a suitable inversion recovery sequence. Such a study allowed Kubas *et al.*[1,4] to observe the full hydride NMR spectrum of the minor tautomer, $[W(H)_2(CO)_3(P\{C_6H_{11}\}_3)_2]$ at $-82\,°C$ ($T_1 = 1.7$ s), which was normally obscured by that of the major species, $[W(H_2)(CO)_3(P\{C_6H_{11}\}_3)_2]$ ($T_1 = 4$ ms). Where alternative H sites are present, fast exchange usually occurs on the NMR timescale, and it can be hard to correctly identify the situation. If the complex is partially deuterated, the light isotope shows a marked preference for the site with the softer vibrational potential. Deuterium therefore prefers classical sites in complexes of type $[L_nM(H_2)_xH_y]$ because of zero point energy differences and this can lead to isotope perturbation effects[12] even in the high-temperature limit where site exchange is fast; these effects are magnified when tritium partial labeling is employed. Each isotopomer now resonates at a different chemical shift and analysis of the temperature dependence of the signals allows the chemical shifts associated with each site to be deduced.[30]

Normally, an H_2 ligand rotates too fast about the $M-(H_2)$ bond for separate rotamers to be observable. In d^2 complexes, however, where only one d orbital is available, back donation is only possible in one plane but not at right angles to that plane. This means that the H_2 loses all the back donation stabilization when it has rotated 90° from its preferred conformation. This in turn provides a significant rotation barrier leading to the phenomenon of blocked rotation, detected by Chaudret and Sabo-Etienne[31] in compounds of the type $[Cp_2TaH_2L]^+$ (**3**), where barriers of up to 11 kcal mol^{-1} were found.

Apart from NMR studies, IR data has been the next most useful technique in the area. The selection rules normally forbid ν(HH) from having significant intensity, but in some cases, such as (**1**), the vibration can gain intensity from mixing



(**3**)

with allowed bands such as ν(CO). Raman studies have generally been disappointing since the irradiation commonly leads to decomposition, but success has been achieved in some cases.[32]

An η^2-HD complex has an IR spectrum that is not simply a superposition of that for the η^2-D_2 as would be the case for the classical $M(H)_2$ analogues. Instead ν(H–D) of the HD complex appears approximately halfway between the corresponding ν(H–H) and ν(D–D). The $\nu(H_2)$ stretching band, typically appearing near 2700 cm, does not correlate with binding strength because of extensive mixing of the many modes.

4 DYNAMICS AND ENERGETICS

The dynamics of $M(H_2)$ systems have been probed in detail by Eckert[33,34] using inelastic neutron scattering (INS), which is sensitive to the small rotational barriers, typically 1–2 kcal mol^{-1}, involved in unstretched d^6 H_2 complexes. The method also gives an indication of any differential back donation as the H_2 rotates, because the M–H_2 sigma bonding does not contribute to the barrier. From theoretical work,[35] some H_2 complexes can have somewhat higher rotation barriers (e.g. 4.8 kcal mol^{-1}) for $Cr(H_2)_2(CO)_4$ but these are in a range that no current experimental method can probe effectively. Even symmetrical H_2 complexes can have small barriers[4] (e.g. 0.7 kcal mol^{-1} for *trans*-$Mo(H_2)CO(dppe)_2$) that are probably related to the small rearrangements of the heavy ligands that accompany H_2 rotation. A more sophisticated model[34] that takes account of additional H_2 motion is required to fully account for the INS data.

In the case of unstretched H_2 complexes, the H_2 binding energy, obtained by time-resolved IR spectroscopy or photoacoustic spectroscopy, lies in the range $\Delta H =$ 10–20 kcal mol^{-1}, and is comparable to that of relatively weak ligands like N_2 or H_2O.[4] For stretched complexes like $[Os(H_2)(NH_3)_4L]^{n+}$, calculations[36] predict much larger values in the range 23–50 kcal mol^{-1}, depending on L, that are comparable – at least at the upper end of the range – with binding energies seen in the case of full oxidative addition to give a classical dihydride. As a result, stretched H_2 ligands are not readily displaced from the metal.

Polyhydrides that contain both (H_2) ligands and terminal hydrides are often highly fluxional on the NMR timescale. This is normally thought to occur via oxidative addition of the (H_2) and rearrangement of the resulting intermediate.

Occasional suggestions of an associative mechanism via an (H_3) transition state have been made.[37] Likewise, $Cp^*Zr(H)_2$ exchanges with D_2 presumably via a transient $Cp^*Zr(H)_2(D_2)$ and an associative pathway. An oxidative addition is not available in this d^0 system.[38] These data suggest that an isolation or at least detection of an (H_3) complex, so far unknown, is feasible.

Quantum mechanical exchange coupling (QMC) is a rare but interesting property of some polyhydrides in which different terminal hydrogen ligands need to be present in different chemical environments but must not exchange fast on the NMR timescale. For example, in $[CpIr(L)(H)_3]^+$ the three H's lie in a plane with two flanking H_a sites and one H_b in the middle position and with a d_{HH} of ca. 1.68 Å.

The variable-temperature NMR spectrum shows a highly temperature-dependent coupling between the two sites.[39] The size of the coupling can attain thousands of Herz and so not a plausible value for a conventional J coupling. This has been identified by Weitekamp[40] and by Zilm[41] as a tunneling phenomenon associated with the close approach of H_a and H_b during their thermal motion. While a fully formed (H_2) intermediate is not proposed, a close approach of the two hydrogens is undoubtedly assisted by the involvement of a stretched (H_2) interaction during the close approach. Calculations support these proposals.[42]

5 SYNTHESIS

All of the synthetic methods that give hydrides can in principle also give H_2 complexes, but the great majority have so far been synthesized either (1) by H_2 addition to a 16e species or intermediate, or (2) protonation of a classical hydride. Examples are given below. In the tungsten case, the starting material has an agostic CH bond which is displaced by H_2. In the Ir case, the product avoids being Ir(VII), an unknown oxidation state for this element by becoming a bis-dihydrogen complex of Ir(III); the conversion of a classical dihydride to a dihydrogen complex can be considered as an internal redox step in which two hydrogen atoms are oxidized by 1e ($H(-1) => H(0)$) and the metal is reduced by two units.

$$[W(CO)_3(PCy_3)_2] + H_2 = [W(H_2)(CO)_3(PCy_3)_2] \quad (3)$$

$$[IrH_5(PPh_3)_2] + HBF_4 = [IrH_2(H_2)_2(PPh_3)_2]BF_4 \quad (4)$$

In the case of a protonation, the acid must normally have a noncoordinating counterion, like BF_4 in the above example, to avoid subsequent displacement of the H_2 by the anion. Initial protonation can take place at the hydride to give an H_2 complex, even when the proton subsequently migrates to the metal to give a classical hydride. The reason seems to be that acid (A–H) tends to form a dihydrogen bond (*see* ***Alkane Carbon–Hydrogen Bond Activation***) with the metal bound hydride (M–H) to give a structure of the type M–H···H–A, which leads to transfer of the proton to the hydride, at least initially. Likewise, coordinated H_2 is often the site of highest kinetic acidity.[43,44]

6 REACTIONS

The most striking feature of H_2 binding, at least for unstretched cases, is the astonishingly high degree of acidification that results, specially for cationic systems.[44] Free H_2 has a pK_a of ca. 35, while H_2 complexes can have pK_a's in the range 15 to -5. The acidification of hydrogen, from $pK_a = 35$ for free H_2 to a pK_a as low as -5 for the most acidic H_2 complexes, is very much greater than that for lone pair donor ligands such as OH_2. This is presumably related to the weakness of the $M-(H_2)$ bond compared to the strength of the M–H formed on deprotonation. In this case it is the weak binding of H_2 that gives rise to such a high degree of activation.

$$M\text{–}(H_2) + B = [M\text{–}H]^- + [BH]^+ \quad (5)$$
$$(B = \text{base})$$

The acidification of H_2 may also be involved in hydrogenase action, where H_2 is believed to bind to an Fe(II) center.[4] Isotope exchange between H_2 and D_2O is catalyzed by the enzyme (*see* ***Nickel Enzymes & Cofactors***; ***Nickel: Models of Protein Active Sites***; ***Iron–Sulfur Proteins***.). Similar isotope exchange can also occur in H_2 complexes.[45]

Oxidative addition to give a classical dihydride is also a common reaction. $[W(H_2)(CO)_3(PCy_3)_2]$ is in equilibrium with about 20% of the dihydride in solution. This can lead to subsequent hydrogenolysis of M–C bonds as in the case of a cyclometallated phenylpyridine complex of Ir(III).[46]

Loss of H_2 generates an unsaturated intermediate that can be trapped by subsequent reaction, so H_2 complexes can be used as starting materials for the synthesis of the other species.

Binding energies of H_2 have been determined for several systems,[4] for example, the enthalpy of binding for Kubas complex itself is $9.4 \pm 0.9\,\text{kcal mol}^{-1}$. In this case, the H_2-OH form has an agostic CH so the enthalpy cited refers to the difference in the values for CH and H_2. Allowing for this factor, the binding energy to the 16-electron $W(CO)_3L_2$ system is estimated as $20 \pm 7\,\text{kcal mol}^{-1}$. Stretched ($H_2$) complexes seem to have much higher binding energies ($25-50\,\text{kcal mol}^{-1}$).

pK_a's for coordinated H_2 are normally measured by NMR measurements in THF.[47] When an (H_2) and corresponding $(H)_2$ complex are in equilibrium but have the same conjugate base, the relative acidities of the two species are governed by the equilibrium constant between them, the minor isomer

being more acidic.

$$\mathrm{p}K_\mathrm{a}\{\mathrm{M(H_2)}\} = \mathrm{p}K_\mathrm{a}\{\mathrm{M(H)_2}\} - \log K \qquad (6)$$

For a complex with terminal H ligands and an (H_2) ligand, the pK_a's of the sites are the same because they both give the same final product. The (H_2) site is usually a better kinetic acid, however, as was shown for the Ir benzoquinolinate complex of equation (2).

This implies that protonation of the corresponding terminal hydride of the neutral complex is also kinetically preferred. Such protonation probably occurs via an intermediate in which the acid is associated with the terminal hydride in a dihydrogen bond. (*see* ***Hydrogen Bonding & Dihydrogen Bonding***)

7 OTHER SIGMA COMPLEXES[3,4]

CH bonds can bind to metals as sigma complexes. Most commonly these are agostic species, where a ligand is already held to the metal by a strong M–L bond but a CH bond somewhere in the ligand's substituents binds to the metal. These have been reviewed by Brookhart and Green.[48] Much rarer are examples of alkane complexes where only the CH bond holds the ligand to the metal (*see* ***Alkane Carbon–Hydrogen Bond Activation***). Silane sigma complexes[49] are strongly held and do not need chelation. Sigma complexes of X–Y bonds lacking at least one H are very rare.[50]

1 INTRODUCTION

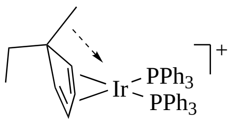
As a natural development of the intense activity in CH activation (*see* ***Alkane Carbon–Hydrogen Bond Activation***) since the 1970s, interest has arisen more recently in the closely allied area of CC activation. This process is much more difficult than CH activation and has so far been studied for its mechanistic interest rather than for any practical benefit. CX activation, on the other hand, is a major area of study because it is an initial step in many important and commercially valuable homogeneous catalytic reactions, such as Mizoroki–Heck, Suzuki–Miyaura, and Hartwig–Buchwald reactions. Here, an important practical goal is to avoid having to use the expensive iodides and bromides as ArX reagents in catalytic reactions and to work instead with chlorides and tosylates.

Activation involves binding of the intact C–C or C–X bond to the metal followed by C–C or C–X bond cleavage. The first goal is to understand how CC and CX bonds bind to metals without bond breaking. The next step is the bond breaking process itself, a step that is expected to proceed from the initial adduct. Reviews on metal binding of both halocarbons[1] and of sigma bonds[2] are available, and a book-length studies on sigma complexes[3] and on the activation[4] of a wide variety of bonds by transition metal complexes have very recently appeared.

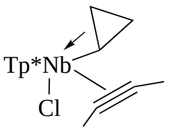
2 CC BOND COMPLEXES

The first complex in which a CC bond was proposed to bind to a transition metal without CC cleavage was $[(C_5H_4MeEt)Ir(PPh_3)_2]^+$ (**1**). More recently, this species was shown not to have an agostic C–C bond – instead there is just a close metal-ligand contact. Two criteria were proposed to make this distinction: (1) there must be an empty orbital capable of overlap with the C–C bond in question, often leading to a distortion of the geometry at the metal, (2) there must be also some evidence, either from calculation or spectroscopic data, of weakening of the agostic C–C bond.[5] In the case of (**1**), the empty orbital is in the square plane remote from the CC bond and DFT calculations, which reproduced the geometry, showed no elongation of the vicinal CC bond.

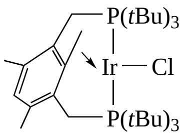
True examples of agostic CC bonds are still extremely rare and usually occur only when the system is strongly constrained so that no CH bond is available as an alternative ligand.[6–9] Some examples are shown in diagrams (**2**–**3**).



(**1**)



(**2**)



(**3**)

3 CC BOND ACTIVATION

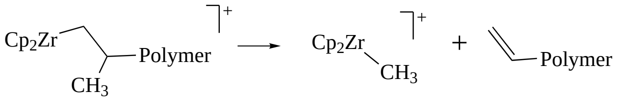
While C–H activations are often relatively fast, C–C activations are commonly slow. This is usually ascribed to the omnidirectional character of the H(1s) orbital allowing it to form strong bonds in the transition state, as well as to the lesser steric hindrance in the C–H case.

For the late metals where M–C bonds are less strong, CC bond activation seems always to need some special driving force, such as relief of strain, chelate assistance, or attainment of an aromatic product. For early metals, M–C bonds can be much stronger and simple CC bonds can be more easily cleaved. A classic early example from Watson[10] (equation 1) requires chelate assistance but C–C cleavage can be competitive with the alternate CH bond cleavage (beta-elimination) that normally dominates:

$$Cp^*_2LuCH_2CHMe_2 \longrightarrow Cp^*_2LuMe + CH_2{=}CHMe \qquad (1)$$

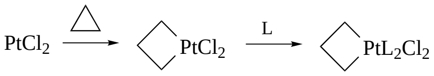
Many examples of such eliminations have now been seen for the f-block and for d^0 metals.[11] This type of β-alkyl elimination is recognized as an important chain transfer step in Ziegler–Natta and metallocene polymerization catalysis.[12] When it occurs the polymer chain terminates in a C=C bond (equation 2) and in certain cases the alkene chain end can undergo reinsertion and get back into the polymer growth

cycle.



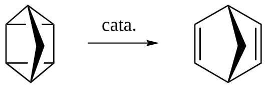
(2)

In the late metals, the classic example comes from Tipper's[13] 1955 reaction of cyclopropane with Pt(II) chloride to give a metallacyclobutane. This relies on ring strain to overcome the normally large barrier. The original formulation of the product as a simple CC bond complex of an intact cyclopropane, although plausible given the unsaturated character of the ring, proved to be incorrect; the true platinacyclobutane structure was determined by Chatt[14] with NMR and IR spectroscopic studies on the *bis*(pyridine) adduct. The platinacyclobutane product reacts with several nitrogen donor ligands (L = pyridine, 2-, 3-, and 4-methylpyridine...) to give a platinata(IV)cyclobutane derivative (equation 3). In addition to the relief of ring strain, the high reactivity of cyclopropane is associated with the fact that the C–C bond HOMO and LUMO have more p orbital character than in unstrained alkanes, which allows better interaction with the metal d orbitals.



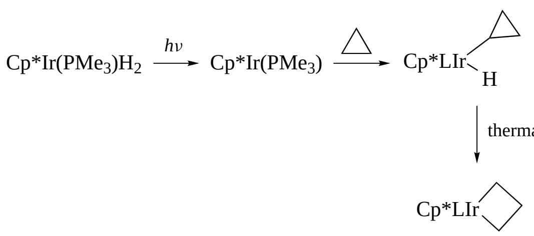
(3)

This was followed by a long series of studies in which the rearrangement of other strained organic ring systems was catalyzed by transition metal salts or complexes. A typical example is the conversion of quadricyclene to norbornadiene, catalyzed by Rh(I) or Pd(II) (equation 4),[15] for which Halpern[16] provided the accepted mechanism. An extensive review[17] of this early work is available.



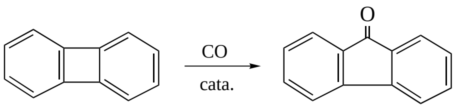
(4)

Surprisingly, mechanistic studies by Bergman *et al.* on the reaction of cyclopropane with the photogenerated $Cp^{*}Rh(PMe_3)$ fragment revealed that cyclopropane undergoes C–H activation prior to the rearrangement to a ring-opened product (equation 5).[18]



(5)

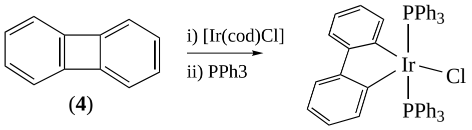
CC bonds between sp^2 carbons are more easily activated. While the Ph–Ph C–C bond is quite strong, diphenylene (**4**), with a 4-membered ring and lack of steric hindrance, allowing out-of-plane attack by the metal, readily gives CC bond cleavage[19,20] (equation 6). Even in this favorable case, temperatures of over 100 °C are often required. For example, $Cr(CO)_6$ was shown to give fluorenone at 225 °C.[21]



(**4**)

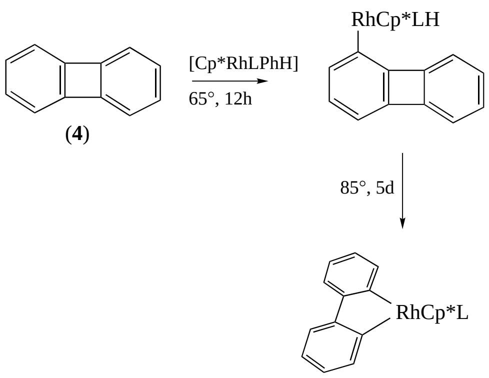
(6)

Opening of the diphenylene ring also led to a number of unusual five-coordinate complexes with a distorted structure intermediate between T- and Y-shape. The high trans effect of the phenylene rings may be part of the reason for the low-coordination number for Ir(III) (equation 7).[22]



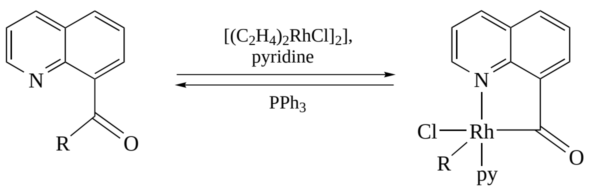
(7)

Initial insertion into an arene CH bond can be followed by CC cleavage[23] as shown in equation (8).



(8)

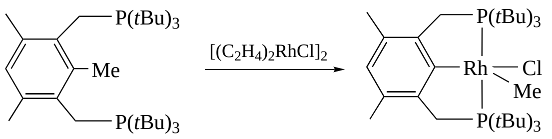
Suggs and Jun[24,25] used cyclometallation that involved *reversible* CC cleavage to achieve the reaction shown in equation (9) (R = benzyl).



(9)

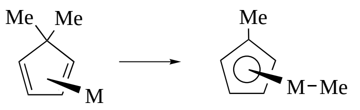
The ease of activation of CC bonds is inversely related to the bond strength: sp–sp > sp^2–sp^2 > sp^3–sp^3. This suggests that the enhanced accessibility of the sp–sp and sp^2–sp^2

bonds may facilitate reaction. Indeed, the CC bonds in the Suggs examples were often sp^2–sp, easier to activate than sp^3–sp^3.[25] Jun[26,27] has used this general principle to effect some conversions that have promise for application in organic synthesis. Milstein[28–30] found chelate-assisted examples with Rh(I) and Ir(I).

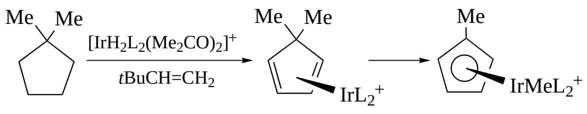


(10)

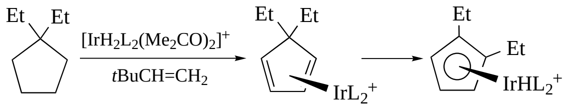
Aromatization of a cyclopentadiene to a cyclopentadienyl can occur with CC bond breaking.[31] Green reported an interesting reversible migration of an ethyl group from a cyclopentadienyl ring to a Mo metal, resulting in aromatization of the ring. The energy gain from the formation of the aromatic Cp must add 25 kcal mol^{-1} of stability to the product. Eilbracht[32] studied this class of reaction (equation 11) in detail. An alkane[33] CC cleavage reaction proved possible via initial dehydrogenation to a coordinated diene and then alkyl migration (equation 12) as in the reaction studied by Eilbracht and by Green. The migration is reversible as could be shown for the case of equation (13).



(11)

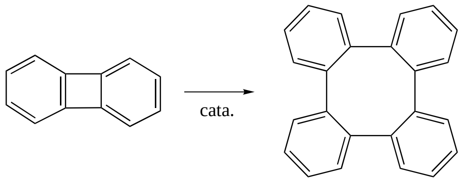


(12)



(13)

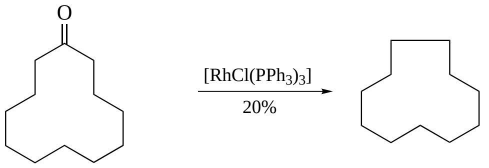
A number of catalytic reactions involve CC bond cleavage, often driven by strain. For example,[34] biphenylene can be converted to tetraphenylene with $Ni(cod)(PMe_3)_2$ at 100 °C or $Pt(PR_3)_3$ at 120 °C (equation 14). In the Pt case, a series of intermediates could be isolated that suggest a pathway involving double oxidative addition of the biphenylene CC bond, as in the stoichiometric reactions previously discussed, followed by double reductive elimination to give the product.



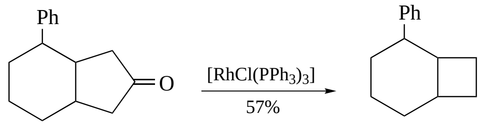
(14)

Equation (15) and (16) shows unusual cases[35] where a catalytic CC cleavage occurs with little or no acceleration via relief of strain, but the reactions are very slow and go in low yield.

Chaudret[36] induced aromatization of the B-ring of a number of 5,7-dienyl steroids by a CC cleavage reaction that removed the angular methyl group. This was possible using the electrophilic ruthenium fragment $[Cp^*Ru]^+$ as stoichiometric reagent.



(15)



(16)

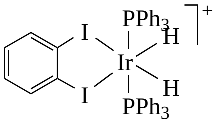
Suzuki[37] has shown how the triruthenium cluster $Cp^*_3Ru_3H_5$ readily gives CH and CC reactions with a wide variety of substrates.

It is also possible to activate a C–C bond by using bare transition metal ions, generated by ionization in the gas phase.[38] Using an ion-beam instrument, Armentrout and Beauchamp[39] were able to show that the reaction of Co^+ with n-butane to give $CoC_2H_4^+$ goes exothermally via a C–C insertion to the metal followed by β-hydrogen elimination and reductive elimination of ethane. In this case, the corresponding Co–C bond strengths are much higher than in the case of a metal complex and of course the Co^+ reagent is extremely unhindered.[40]

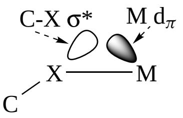
4 HALOCARBON COMPLEXES

In the earliest authentic halocarbon complex (1982), o-diiodobenzene was found to chelate to cationic Ir(III) as shown in diagram (**5**).[41] An earlier proposed example proved to be misidentified when the crystal structure was carried out. To be stable, any such complex must resist oxidative addition, hence the use of an oxidation state, Ir(III), that is only oxidized with difficulty. The normally rather weakly basic halocarbon lone pairs are often reluctant to bind, but chelation and involvement of the least electronegative halide, iodine, favor binding as does the cationic character of the complex. A series of such complexes was soon found, including complexes of Ir(I)[42] and a series of weakly bound dichloromethane complexes for certain systems.[43] These solvento complexes can be very labile and so find use as precursors for binding of other weakly basic ligands. Even fluorocarbon complexes proved viable.[44] A review of the area is available.[1] It now seems

likely that many oxidative addition reactions of halocarbons go via initial formation of halocarbon complexes. In such a complex, the C–X σ^* orbital is presented to the metal ready for electron transfer (**6**), a process that leads to the radical pathway for halocarbon oxidative addition, or for transfer of a pair of electrons, which would lead to the concerted oxidative addition pathway (see Section 5).



(**5**)

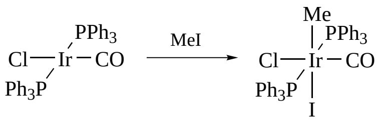


(**6**)

5 CX ACTIVATION

Oxidative addition of a C–X bond to a metal is of central importance to organometallic chemistry and specially to its application in organic synthesis. Apart from the classic Grignard synthesis of RMgX and related species, a multitude of palladium catalyzed reactions (Mizoroki–Heck, Suzuki–Miyaura, Hartwig–Buchwald ...) go by this initial step.

Among stoichiometric cases, Vaska's complex, IrClCO $(PPh_3)_2$, is the classic transition metal example.[45] It reacts with a number of alkyl halides such as MeI to give a trans adduct (equation 17).



(17)

One key goal of catalyst development is to move from the more expensive alkyl and aryl iodides and bromides to the cheaper chlorides and the environmentally more desirable tosylates. The latter tend to react less well but the use of basic, bulky ligands like $P(t\mathrm{Bu})_3$ and a number of ferrocenyl-substituted phosphines has improved the situation.

Three mechanisms[46] are usually considered for oxidative addition of alkyl and aryl halides: S_N2, radical and concerted. In the S_N2 pathway, the metal acts as a nucleophile, displacing the halide from RX, followed by coordination of the halide to the metal. The oxidation state of the metal rises by two units.

$$\mathrm{RX} + \mathrm{ML}_\eta \longrightarrow \mathrm{RML}_\eta{}^+ + \mathrm{X}^- \longrightarrow \mathrm{(R)(X)ML}_\eta \qquad (18)$$

The order of reactivity (1° > 2° > 3° alkyl) and the inversion of configuration at α-carbon both follow the precedent of the organic S_N2 case. The $\Delta S^\ddagger$ is typically strongly negative (~ -40 eu). The second step of equation (18) requires a vacant site on the metal. Where this is not present, the process may halt after the first step, as in equation (19).

$$\mathrm{CpIr(CO)_2} + \mathrm{MeI} \longrightarrow [\mathrm{CpIrMe(CO)_2}]^+\mathrm{I}^- \qquad (19)$$

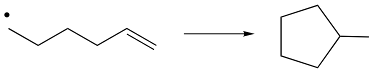
In concerted oxidative addition, the C–X bond breaking occurs with concerted formation of M–C and M–X bonds. Such is often the case for aryl halides where the S_N2 process is not applicable. In contrast with the trans product of equation (17), the initial concerted oxidative addition product is often cis. The concerted mechanism is also associated with negative $\Delta S^\ddagger$ (ca. -20 eu) because the transition state is highly organized.

Prior ligand dissociation sometimes occurs, as in the case of $\mathrm{Pd\{P(O\text{-}CH_3C_6H_4)_3\}_2}$ and aryl bromide, where the active intermediate is the highly unsaturated species, $\mathrm{Pd(PAr_3)}$.[47]

Radical processes involve single electron transfer with a change of oxidation state by one unit in the first step. The classic case[48] is that of $\mathrm{Ni(PR_3)_4}$, where the reactive species is $\mathrm{Ni(PR_3)_3}$ (equation 20). Radical chain pathways have also been proposed in certain cases, where the addition of a radical trap drastically slows the rate.

$$\mathrm{NiL_4} \rightleftharpoons \mathrm{NiL_3} \xrightarrow{\mathrm{PhBr}} [\mathrm{NiL_3}]^+[\mathrm{PhBr}]^- \longrightarrow [\mathrm{NiBrL_2}] + \mathrm{Ph}\bullet \longrightarrow [\mathrm{NiPhBrL_2}] \qquad (20)$$

Radical clock[49] rearrangements can be used to provide evidence for radical intermediates; these include the ring opening of cyclopropylmethyl radical and the ring closing of the hexenyl radical (equation 21).



(21)

The pathways differ in outcome with substrates of defined configuration: racemization for the radical path, inversion for the S_N2, and retention for the concerted route.

C–F bond activation is attracting increasing interest in connection with green chemistry. Perfluoroarenes are more reactive than the corresponding perfluoroalkanes, possibly because of the easier access to the C–F bond in C_6F_6 versus C_6F_{12}. Photochemical routes are common as in equation (22).[50]

$$\mathrm{Cp^*RhH_2PMe_3} + \mathrm{C_6F_6} = \mathrm{Cp^*Rh(F)(C_6F_5)} + \mathrm{H_2} \qquad (22)$$

The thermal process requires pyridine solvent and gives quite a different product of equation (23).[51]

$$\mathrm{Cp^*RhH_2PMe_3} + \mathrm{C_6F_6} + \mathrm{C_5H_5N} = \mathrm{Cp^*Rh(H)(C_6F_5)} + [\mathrm{C_5H_5NH}]\mathrm{F} \qquad (23)$$

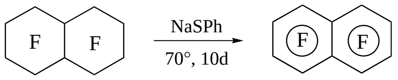
Catalytic reactions involving steps of this type have been developed by Milstein[52] (equation 24–25).

$$C_6F_6 + R_3SiH \xrightarrow{\text{cata.}} C_6F_5H + R_3SiF \qquad (24)$$

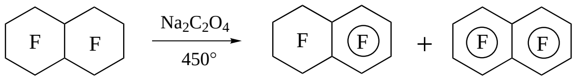
$$C_6F_6 + R_3N + H_2 \xrightarrow{\text{cata.}} C_6F_5H + [R_3NH]F \qquad (25)$$

Perutz and Eisenstein[53] have used a computational (DFT) approach to estimate the M–C bond energies of a series of partially fluoronated aryl ligands. They show that the main structural predictor of the M–C bond strength is the number of F atoms in the ortho positions, n_F. Higher M–C bond strengths are associated with larger n_F. This study shows the growing importance of computational work, particularly in cases like this where experimental determinations of the data are unreliable or unavailable.

Perfluoroalkanes are much less reactive but the classic 1959 work by Tatlow[54] in *Nature* attracted attention by showing that partial reduction to give definite products could occur (equation 26). In this work, perfluorodecalin (PFD) was reduced to perfluoronaphthalene (PFN) by NaSAr. Since then, several PFD conversions have been reported with transition metal reagents, either via photochemical or thermal routes.[55–57] For example, hot sodium oxalate (465 °C) aromatizes perfluorodecalin to give perfluorotetralin and perfluoronaphthalene (equation 27).[58] Decomposition of solid sodium oxalate at temperatures above 450 °C involves initial formation of elemental carbon that catalyzes the subsequent decomposition of oxalate, leading to the presence of an induction period in the overall decomposition reaction. Prior incipient decomposition of sodium oxalate to carbon and sodium carbonate is necessary for this reagent to effect aromatization.



(26)



(27)

6 CONCLUSION

CC activation is an emerging problem, where general solutions are still lacking. The reaction is rare and whenever CH activation can occur, it often dominates. Coupling reactions involving aryl halides are among the small group of transition metal catalyzed reactions that are most intensely used in organic synthesis. Carbon-halogen activation is well understood for Cl, Br, and I, and considerable progress has been made in moving from ArI and ArBr to the less reactive but cheaper ArCl as substrates in these reactions. CF activation, however, remains very hard and is still much less understood. The whole area of carbon-halogen activation has also been affected by the rise of the green chemistry[59] in which one goal is the destruction of persistent halogenated materials and another is replacement of halogenated materials by alternate substrates for coupling and related processes.

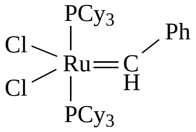
1 INTRODUCTION

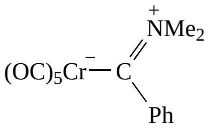
This article is adapted with permission from Chapter 11 of the author's book,[1] *The Organometallic Chemistry of the Transition Metals*. Carbenes of type CR_2 form complexes with a variety of transition metal fragments, for example, $Cl_2(Cy_3P)_2Ru{=}CHPh$ (**1**). Carbene complexes were first recognized in the 1960s but they have been a source of a succession of new and remarkable results ever since and interest in them is currently at a high point as a result of the success of the alkene metathesis reaction, for which complex (**1**) is perhaps the best-known catalyst.[2] This proceeds via carbene intermediates and has found a wide variety of uses both in organic synthesis and in polymer synthesis, as well as being of inorganic mechanistic interest.



(1)

2 FISCHER VERSUS SCHROCK CARBENES

The two extreme types of coordinated carbene, the Fischer[3] and the Schrock[4] type, can be thought of as complexes of singlet and triplet carbenes, respectively. Carbene complexes, $L_nM{=}CR_2$, have Fischer character where the substituents are π-donors and the empty p orbital of the singlet carbene is needed for back donation from the metal or from π-donor substituents R, such as –OMe or $–NMe_2$. Fischer carbenes are favored for low metal oxidation states, and for late transition metals having π-acceptor ligands. Such a carbene is electrophilic and broadly resembles other lone pair donor ligands such as CO or PPh_3. The M–C bond is essentially single, as illustrated by diagram (**2**).



(2)

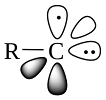
In contrast, Schrock character is shown by carbenes that form true double bonds to the metal (**3**), as is the case for higher oxidation state, early transition metals, having non π-acceptor ligands. Non π-donor R groups on the carbon such as H or alkyl are preferred since these do not stabilize the singlet form. In this case, the carbene behaves as a nucleophile, having a ∂^- carbon; indeed, a metala-ylid form can be considered as a description of the structure. Cases intermediate between the two extremes are especially common for $M{=}CHal_2$ because the halide has intermediate π-donor strength between H and –OMe.[5]

$$CpCl_2Ta{=}CHPh$$

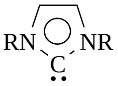
(3)

The term alkylidene refers to carbenes, CR_2 with alkyl substituents; for example, $MeCH{=}ML_n$ is an ethylidene complex but 'alkylidene' is sometimes used as a synonym for 'Schrock carbene' in the older literature because the first alkylidenes were of the Schrock type. There are electrophilic Fischer alkylidenes as well as Schrock ones, however, so the terms should be kept separate. For example, $[Cp_2W({=}CH_2)Me]^+$ and $Cp_2Ta({=}CH_2)Me$ are isoelectronic, but the former is electrophilic (Fischer) and the latter nucleophilic (Schrock) at the carbene carbon;[6] the net positive charge on the tungsten complex must stabilize the $M(d_\pi)$ levels and is therefore probably the main reason for the difference. Carbyne complexes contain an $M{\equiv}CR$ triple bond and are also known both for low and high oxidation states. We can look at the low-spin carbyne fragment as having an sp lone pair and a single electron in one of the two p orbitals (**4**). In the Fischer bonding scheme, we can consider that in forming its three bonds to the metal, the carbyne: (1) acts as a σ-donor via the C(sp) lone pair, (2) forms a normal π-covalency by the combination of its singly occupied C(p)-orbital with a singly occupied M(d)-orbital, and (3) accepts back-bonding from a filled M(d)-orbital into its empty C(p)-orbital. In the Schrock carbyne deriving from a high-spin ligand, we can consider the resulting $M{\equiv}CR$ bond as a true triple covalent bond. Oxidation states are usually counted by considering CR_2 as a neutral ligand for a Fischer and a dianionic ligand

for a Schrock case; in intermediate cases both models can be found, leading to oxidation state ambiguity.[1] N-Heterocyclic carbenes (NHCs), like (**5**), are a class of Fischer carbenes attracting increasing attention as spectator ligands in catalysis, where they can have superior properties versus phosphines, the most common current spectator ligands.[7]



(4)



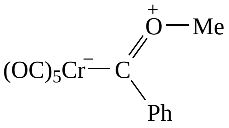
(5)

3 CARBENES: SYNTHESIS, SPECTRA, AND REACTIVITY

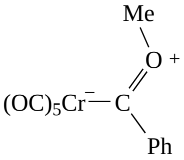
Fischer recognized the first carbene complexes in 1964.[3,8] They were formed by the attack of an alkyllithium on a metal carbonyl followed by methylation (equations 1 and 2). Resonance form (**2**), considered as the dominant one in the heteroatom stabilized Fischer carbenes, shows the multiple character of this carbon–heteroatom bond. This effect is responsible for the restricted rotation often observed for this bond in nuclear magnetic resonance (NMR) studies. For example cis and trans isomers (**6**) and (**7**) of methoxymethyl carbenes rapidly interconvert at room temperature, but can be frozen out in the proton NMR at $-40\,°C$.[9] By contrast, the M–C bond is close to single and often rotates freely.

$$(OC)_5Cr\text{–}CO + MeLi \longrightarrow (OC)_5Cr{=}C(OLi)Me \qquad (1)$$

$$(OC)_5Cr{=}C(OLi)Me + MeI \longrightarrow (OC)_5Cr{=}C(OMe)Me \qquad (2)$$



(6)



(7)

The key synthetic routes for Fischer carbenes fall into one of three general categories, illustrated by equations (1–3). In equation (2) an acyl or similar species (often but not always formed by a nucleophilic attack on a CO or a similar ligand) is treated with an electrophile to give a Fischer carbene. In equation (3), an H^- (Fischer case) or an H^+ (Schrock case) is abstracted from the α-position of an alkyl and in equation (5) a traditional carbene source is used.

$$L_nM\text{–}CHR_2 - H^+ \longrightarrow [L_nM{=}CR_2]^- \qquad (3)$$

$$L_nM\text{–}CHR_2 - H^- \longrightarrow [L_nM{=}CR_2]^+ \qquad (4)$$

$$L_nM + N_2CR_2 \longrightarrow [L_nM{=}CR_2] + N_2 \qquad (5)$$

As an example related to equation (1), isonitriles are very sensitive to nucleophilic attack, and a wide range of bis-heteroatom stabilized carbenes can be obtained (equation 6).[10]

$$[(MeNC)_4Pt]^{2+} + 4Me_2NH \longrightarrow [Pt\{{=}C(NHMe)_2\}_4]^{2+} \qquad (6)$$

Chugaev[11] obtained carbene complexes like these as early as 1915, but the right structure was only assigned much later.[12] Acetylides $L_nM\text{–}C{\equiv}CR$ are unexpectedly good bases[13] via their resonance form $L_nM^+{=}C{=}C^-\text{–}R$. They can react with acid in alcohol solution to give the carbenes shown in equations (7) and (11). An intermediate vinylidene cation probably undergoes nucleophilic attack by the alcohol.[14] In this case, the usual order of attack of equations (1) and (2) – nucleophile, then electrophile – is inverted.

$$ClL_2M\text{–}C{\equiv}CR + HOEt = [ClL_2M{=}C{=}CHR]^+ + {}^-OEt$$
$$= ClL_2M{=}C(OEt)\text{–}CH_2R \qquad (7)$$

Electrophilic abstraction from an alkyl complex (equation 4) is illustrated in the reactions of equations (8) and (9); equation (9) is driven by the high Si–F bond strength.

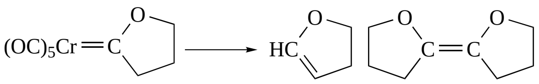
$$Cp(CO)_2FeCH_2OMe + H^+ \longrightarrow \text{‘}Cp(CO)_2Fe{=}CH_2{}^+\text{'} \downarrow \text{other products} \qquad (8)$$

$$Cl(CO)(MeCN)L_2RuCF_3 + Me_3SiCl \longrightarrow Cl_2(CO)L_2Ru{=}CF_2 + Me_3SiF \qquad (9)^{15}$$

Alkylidenes can sometimes be made from organic carbene precursors such as diazomethane[16] or R_2CCl_2.[17]

In ^{13}C NMR spectroscopy, the carbene carbon resonates at ca. 140–400 ppm to low field of $SiMe_4$. This is probably a result of the existence of low-energy electronic excited states for the complex, which leads to a large ‘paramagnetic’ contribution to the shift. A proton substituent at the carbene carbon resonates from +10 to +20 ppm.

Thermal decomposition of carbene complexes usually leads to one or both of two types of alkenes:[18] one type is formed by rearrangement, and the other by dimerization of the carbene. Equation (10)[19] shows both types of products. The reaction does not go via the free organic carbene, because cyclobutanone, which is known to be formed in the rearrangement of the free carbene, was not detected in the products.



(10)

Fischer carbenes without a heteroatom substituent are very reactive.[20] The protonation of vinyl complexes is one route to such species (equation 11):

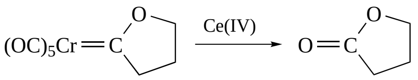
$$Cp(CO)_2Fe\text{–}CH{=}CH_2 + H^+ = Cp(CO)_2Fe{=}CH\text{–}CH_3{}^+ \qquad (11)$$

the addition of base reverses the reaction by a nucleophilic abstraction. The ethylidene complex readily gives a 1,2-shift of the β-proton to give the thermodynamically more stable alkene complex. Even carbenes which lack β-hydrogens are unstable: $[Cp(CO)_2Fe{=}CH{-}CMe_3]^+$ and $[Cp(CO)_2Fe{=}CH{-}CMe_2Ph]^+$ both rearrange by a 1,2-shift of a methyl or a phenyl group, respectively, to the electron-deficient carbene carbon (equations 11 and 12).[21] This reaction, analogous to the Wagner-Meerwein rearrangement in carbonium ions, is fast because of the electron-deficient character of the carbene carbon in this complex.

$$Cp(CO)_2Fe{=}CH{-}CMe_2Ph + H^+ = [Cp(CO)_2Fe(PhCH{=}CMe_2)]^+ \quad (12)$$

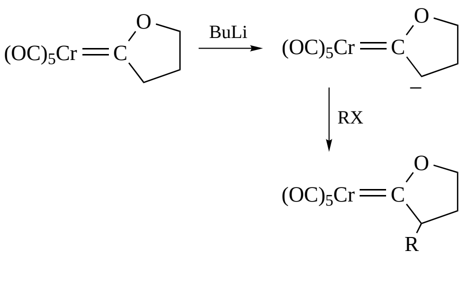
$[Cp(Ph_2PCH_2CH_2PPh_2)Fe{=}CH{-}CMe_3]^+$ does not rearrange, however, probably because the increased back donation by the more electron-rich phosphine-substituted iron center decreases the electron deficiency at the carbene carbon.[22]

Oxidative cleavage of a carbene ligand can be achieved with reagents such as Ce(IV) compounds, pyridine N-oxide, dmso, or even with air. The product is normally the ketone corresponding to the starting carbene. This reaction is not only useful for synthetic purposes but also for characterizing the original carbene (equation 13).[23]



(13)

The synthesis of equation (14) illustrates another useful reaction of Fischer carbenes, the abstraction of a proton β to the metal by a base such as an organolithium reagent. The resulting negative charge can be delocalized on to the metal,[24] and is therefore stabilized. The anion can be alkylated by carbon electrophiles as shown.



(14)

Fischer carbenes readily undergo nucleophilic attack at the carbene carbon, as shown in equation (15).[25] The attack of amines can give the zwitterionic intermediate shown, or by loss of methanol, the aminocarbene. Mentally replacing the $(CO)_5Cr$ group by an oxygen atom, shows the relation of this reaction to the aminolysis of esters to give amides.

$$(OC)_5Cr{=}C(OMe)Me + H_2NR \longrightarrow (OC)_5Cr{=}C(NHR)Me + HOMe \quad (15)$$

Schrock carbenes are obtained by α-elimination. High-valent metal alkyls, especially of the early metals, can undergo proton abstraction at the α-carbon to give nucleophilic Schrock[26] carbenes. The first high oxidation state carbene was formed in an attempt to make TaR_5 ($R = CH_2CMe_3$, or neopentyl), by the reaction of TaR_3Cl_2 with LiR – interestingly, Wittig was trying to make Ph_3PMe_2 when he discovered $Ph_3P{=}CH_2$. In fact the product is $R_3Ta{=}CH(t\text{-}Bu)$ (equation 16). The reaction probably goes via TaR_5, which then loses neopentane by an α-proton abstraction from one possibly agostic (*see* ***Dihydrogen Complexes & Related Sigma Complexes***) R ligand by another.[4,27]

$$R_3TaCl_2 + 2LiR \longrightarrow R_3TaR_2 \longrightarrow R_3Ta{=}CH\text{-}t\text{Bu} \quad (16)$$

One of the requirements for this α-elimination is that the molecule be crowded. Substitution of a halide in R_2TaCl_3 with a Cp group (equation 17)[28] is enough to do this, for example, as is addition of a PMe_3 (equation 18).[2] The corresponding benzyl complexes require one of the more bulky pentamethylcyclopentadienyls, Cp* (equation 19),[29] or two plain Cp groups (equation 20).[28]

$$R_2TaCl_3 + TlCp \longrightarrow CpCl_2Ta{=}CH\text{-}t\text{Bu} + t\text{Bu{-}Me} \quad (17)$$

$$R_2TaCl_3 + 2PMe_3 \longrightarrow [(Me_3P)Cl_2Ta{=}CH\text{-}t\text{Bu}(\mu\text{-Cl})]_2 \quad (18)$$

$$(PhCH_2)_3TaCl_2 + 2LiCp^* \longrightarrow Cp^*ClTa{=}CH\text{-}t\text{Bu}(CH_2Ph) \quad (19)$$

$$(PhCH_2)_3TaCl_2 + 2LiCp \longrightarrow Cp_2Ta{=}CH\text{-}t\text{Bu}(CH_2Ph) \quad (20)$$

By adding two PMe_3 ligands, the α-proton of a benzylidene can now undergo abstraction to give a benzylidyne (equations 11 and 25).

$$Cp^*ClTa{=}CH\text{-}t\text{Bu}(CH_2Ph) + 2PMe_3 \longrightarrow Cp^*Ta({\equiv}CPh)(PMe_3)_2Cl + PhCH_3 \quad (21)$$

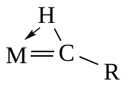
The methyl group is so sterically undemanding that it does not α-eliminate under the same conditions (equation 22). The synthesis of a methylene complex requires a deprotonation of a methyl complex by a strong base. A net positive charge on the complex activates the methyl for this reaction. Equations (23) and (24) show how this can be done by an electrophilic abstraction of Me^-.

$$Me_3TaCl_2 + 2LiCp \longrightarrow Cp_2TaMe_3 \quad (22)^{26}$$

$$Cp_2TaMe_3 + Ph_3C^+ \longrightarrow [Cp_2TaMe_2]^+ + Ph_3CMe \quad (23)^{30}$$

$$[Cp_2TaMe_2]^+ + CH_2PMe_3 \longrightarrow Cp_2TaMe({=}CH_2) + [PMe_4]^+ \quad (24)^{31}$$

Early metal complexes often avoid the 18e configuration – Me_3TaCl_2 is ostensibly 10e, for example. This can provide coordinative unsaturation at the metal: Schrock carbene complexes with <18e commonly have agostic C–H bonds (*see* ***Alkane Carbon–Hydrogen Bond Activation***; ***Dihydrogen Complexes & Related Sigma Complexes***). When

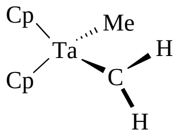


(8)

this happens, the proton on the carbene carbon bends back toward the metal, the M=C bond becomes shorter, and the C–H bond becomes longer (**8**).

Agostic binding leads to a high-field shift for this proton and a lowering of the C, H coupling constant in the ^{1}H NMR spectrum, together with a lowering of ν(C–H) in the infrared (IR). In 18e carbene complexes, such protons are not agostic and usually appear at 12δ with a J(C,H) of 105–130 Hz; in the complexes with <18e, they can come as high as -2δ with a J(C,H) of 75–100 Hz. At the same time, a ν(C–H) band appears in the IR at a position indicating that it has been weakened by the interaction, for example, at 2510 cm^{-1} for CpTa{CH(t-Bu)}Cl_2. Crystal structures[32] show that the M=C–R angle can open up to as much as 175°, while the M=C–H angles fall to as little as 78°. The M=C bond length is always short (at least 0.2 Å shorter than an M–C single bond) in all cases studied, but is even shorter in the complexes with <18e. Interestingly, the oxo alkylidene $Cl_2(PEt_3)_2W(=O)(=CHCMe_3)$ has a much less distorted alkylidene group. This is probably because the lone pairs on the oxo group are more basic and so more available for the metal than the C–H bonding pair.[33]

In the structure of $Cp_2TaMe(=CH_2)$ (**9**, by neutron diffraction), the orientation of the methylene group is not the one predicted on steric grounds, with the CH_2 lying in the mirror plane of the molecule, but nearly at right angles (88°) to this plane, with the proton substituents pointing in the direction of the Cp groups. A countersteric conformation like this often indicates that an electronic factor is at work. Here, the filled p_z-orbital of the CH_2 group is interacting with one of the empty orbitals on the metal. Since these orbitals are in the mirror plane of the molecule, this fixes the orientation of the CH_2. The larger CHR alkylidenes deviate only slightly from the orientation shown by CH_2, and so the two Cp groups become inequivalent. The ^{1}H NMR spectrum of the complexes shows this inequivalence but the resonances for the two Cp groups coalesce on warming. In the transition state, the alkylidene probably lies in the mirror plane and has no π-interaction with the metal. The rotation barrier deduced from the data, 25 kcal mol^{-1}, therefore gives an estimate of the strength of the Ta=C π-bond.



(9)

Reactions of Schrock carbenes illustrate their nucleophilic character. For example, they form adducts with the Lewis acid $AlMe_3$ (equation 25).

$$Cp_2TaMe(=CH_2) + AlMe_3 \longrightarrow Cp_2TaMe(\text{–}CH_2\text{–}AlMe_3) \quad (25)$$

They also react with ketones in the same way as a Wittig reagent (equation 26).[34]

$$R_3Ta(=CH\mathit{t}\text{-Bu}) + Me_2CO \longrightarrow Me_2C{=}CH\mathit{t}\text{-Bu} + \text{‘}R_3TaO_x\text{’} \quad (26)$$

Alkenes react with carbenes to give metalacycles. The alkene may coordinate to the metal first, if only transiently. The carbene carbon then attacks the coordinated alkene to give the product. The metalacycle can decompose in several ways (equations 11 and 30), either by reversal of the formation reaction to give alkene and a carbene, by reductive elimination to give a cyclopropane, or by β-elimination to give an alkene.[26] As might be expected, the more electropositive Ti forms even more nucleophilic carbene complexes. One of the most interesting species of this class is Tebbe's reagent, formed from Cp_2TiCl_2 and $AlMe_3$ (equation 27).[35]

$$Cp_2TiCl_2 + AlMe_3 = Cp_2Ti(Cl)(CH_2)AlMe_2 \quad (27)$$

This is an example of a bridging carbene, but in its reactions it almost always loses Me_2AlCl first to give the mononuclear 16e $Cp_2Ti{=}CH_2$; a base like NEt_3 is sometimes added to help remove the aluminum fragment by complexation. This reagent even gives a Wittig type product with esters, substrates that are not methylenated with $Ph_3P{=}CH_2$. In addition, Tebbe's reagent does not racemize enolizable ketones as do the phosphorus ylids.[36]

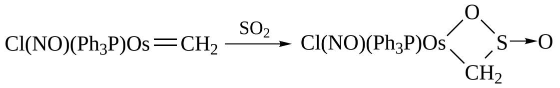
$$\text{‘}Cp_2Ti{=}CH_2\text{’} + PhCOOMe \longrightarrow Ph(OMe)C{=}CH_2 \quad (28)$$

Acyl halides, on the other hand, do not methylenate, but give an enolate.[37] Tebbe's complex reacts with alkenes to give stable metalacyclobutanes (equation 29), which are more convenient precursors for the '$Cp_2Ti{=}CH_2$' carbene than is Tebbe's reagent itself. The metalacycles undergo a number of useful reactions.[36] Protonation gives the propanes. Bromination gives the 1,3-dibromides. Oxidation with I_2 leads to net reductive elimination to give the cyclopropane.

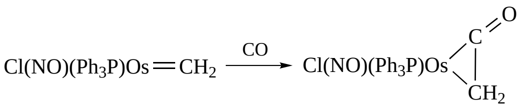
$$\text{‘}Cp_2Ti{=}CH_2\text{’} + CH_2{=}CMe_2 \longrightarrow Cp_2Ti(\text{–}CH_2\text{–}CMe_2\text{–}CH_2\text{–}) \quad (29)$$

Intermediate cases between Fischer and Schrock character are known. In the Os complex of equations (30) and (31), Roper[15] has a carbene with intermediate character between the Fischer and Schrock extremes because it reacts both with electrophiles like SO_2 (equation 30), or H^+ and with nucleophiles (e.g. CO, equation 31), or CNR. This is

reasonable based on the bonding picture. The osmium has π-donor (Cl), as well as π-acceptor (NO) ligands, the metal is in an intermediate oxidation state (Os(II) if we count the carbene as a Fischer, Os(IV) if a Schrock type), and the carbene carbon has non π-donor substituents (H).

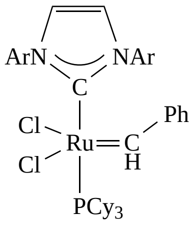


(30)



(31)

N-Heterocyclic carbenes (or NHCs, **5**), a class of Fischer carbenes, deserve closer attention. Arduengo[38] (1991) isolated a series of stable carbenes by deprotonation of N,N'-disubstituted imidazolium salts with bulky substituents. These were stable enough for crystal structures to be obtained. This finding reignited interest in carbene complexes derived from the imidazolium ring system that were discovered in the period 1968–1973 by Wanzlick,[39] Öfele,[40] and Lappert.[41] Herrmann[42] showed that these ligands are not only excellent for stabilizing a variety of transition metals but that the resulting complexes are active in a variety of homogeneous catalytic reactions such as Heck and Suzuki coupling. Many more catalytically active complexes have been discovered since, of which perhaps the most striking example is the greatly improved Grubbs metathesis catalyst,[43] $[(NHC)(PR_3)Cl_2Ru{=}CHR]$ (**10**, Ar = mesityl), obtained by replacing one phosphine in the classic catalyst by an NHC.



(10)

IR studies of metal carbonyls show that the NHCs are very strongly donating groups, much more so than even the most basic phosphine. NHCs have sometimes been compared with phosphines. It is true that NHCs, like phosphines, stabilize a wide range of complexes and promote catalytic activity in these complexes but there are as many differences as similarities in the behavior of the two classes. One difference, for example, is that carbenes are firmly attached and do not dissociate from the metal significantly, while phosphines can do so with much greater ease.

The synthesis of these NHCs has most often been carried out by first deprotonating the imidazolium salt with nBuLi and then introducing the metal salt. This can be unsatisfactory for systems such as chelating and pincer carbenes which require milder conditions. To cover such cases, direct metallation, transmetallation, and oxidative addition have all proved satisfactory. In direct metallation, the imidazolium salt is treated with a metal precursor having a leaving group, such as an acetate salt. The acetate would then deprotonate the imidazolium salt after initial binding has activated the 2CH bond.[44] For transmetallation, the imidazolium salt is often treated with Ag_2O to give the silver carbene[45] which undergoes subsequent transmetallation to the metal of interest.[46] Oxidative addition can be carried out with Pd(0) to give bis-carbene species, for example.[47] Occasionally, there are surprises, such as in the attempted direct metallation of $IrH_5(PPh_3)_2$, where metallation took place, not at the normal C2 position but at the C4(5) position.[48] These abnormal carbenes are even more strongly electron donating than their normal counterparts. NHCs derives from triazole, oxazole, and other heterocyclic carbenes have also been studied and show distinct differences in behavior from the imidazole versionsm.

4 CARBYNES: SYNTHESIS, SPECTRA, AND REACTIVITY

Fischer[49] first prepared carbyne complexes (1973) by electrophilic abstraction of methoxide ion from a methoxy methyl carbene.

$$\begin{aligned} &L(CO)_4M{=}C(OMe)Me + BX_3 \\ &\longrightarrow [L(CO)_4M{\equiv}CMe]^+BX_4^- + BX_2(OMe) \\ &\qquad\downarrow \\ &X(CO)_4M{\equiv}CMe \end{aligned} \quad (32)$$

If L is CO, then the halide ion (Cl, Br, or I) displaces the CO trans to the carbyne in the intermediate cationic complex; this shows the high trans effect of the carbyne. On the other hand, if L is PMe_3, then the cationic species is the final product. Oxidation states for Fischer carbynes are normally assigned by considering CR as an LX ligand, CR^-, that is, $X(CO)_4M{\equiv}CMe$ is M(II). By carefully controlled oxidation, Mayr[50] has been able to remove the carbonyl ligands in a Fischer carbyne to give a Schrock carbyne, thus making a direct link between the two types. This also allows synthesis of Schrock carbenes and carbynes with substituents other than the ones which can be obtained by the standard methods. In equation (33), we can think of the Br_2 oxidizing the metal by two units. This destabilizes the metal d_π orbitals relative to the carbon p orbitals, and so switches the polarity of the metal–carbon multiple bond. Note how the coligands change on going from the soft carbonyls in the W(II) starting material to the hard dme ligand in the W(VI) product. Schrock carbynes

are nearly always d^0 (counting the carbyne as an X_3 ligand) as here.

$$\mathrm{Br(CO)_4\,W{\equiv}CMe \xrightarrow{Br_2,\ dme} Br_3(dme)W{\equiv}CMe}$$
$$\mathrm{(dme = MeOCH_2CH_2OMe)} \qquad (33)$$

Otherwise, Schrock carbynes can be made by deprotonation of an α-CH (equation 34), by an α-elimination, in which this CH bond in effect oxidatively adds to the metal (equation 35) or in rare cases by a remarkable metathesis reaction[51] (equation 36). This reaction fails for coligands other than t-butoxide, showing the sensitivity of the different reaction pathways to the electronic and steric environment of the metal. MeCN is cleaved in the same way to a carbyne and a nitride $(t\text{-BuO})_3W{\equiv}N$.

$$\mathrm{CpCl_2Ta{=}CHR \xrightarrow{i)\ PMe_3,\ ii)\ Ph_3P{=}CH_2} CpCl(PMe_3)Ta{\equiv}CR} \qquad (34)$$

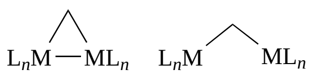
$$\mathrm{Cp^*Br_2Ta{=}CH}t\mathrm{\text{-}Bu \xrightarrow{i)\ dmpe,\ ii)\ Na/Hg} Cp^*(dmpe)HTa{\equiv}C}t\mathrm{\text{-}Bu} \qquad (35)$$

$$(t\text{-BuO})_3\mathrm{W{\equiv}W(O}t\text{-Bu})_3 + t\mathrm{BuC{\equiv}C}t\text{-Bu} \longrightarrow 2(t\text{-BuO})_3\mathrm{W{\equiv}C}t\text{-Bu} \qquad (36)$$

The structural and spectral characteristics follow the pattern of the carbenes. The carbyne ligand is linear, having sp hybridization and the M≡C bond is very short (1st row: 1.65–1.75 Å, 2nd and 3rd row: 1.75–1.90 Å). The ^{13}C NMR shows a characteristic low field resonance for the carbyne carbon at +250 to +400 ppm. Moving to reactivity, a carbyne can couple[52] with another carbyne to give an alkyne or alkyne complex.[53] For instance, $Br(CO)_4Cr{\equiv}CPh$ reacts with Ce(IV) to give free PhC≡CPh. Carbynes also have extensive photochemistry.[54] In the Fischer series, the carbyne carbon is electrophilic and subject to nucleophilic attack, for example, by PMe_3, pyridine RLi or isonitrile (=Nu) to give a carbene of the type $L_nM{=}CR(Nu)$.[49] Alternatively, the nucleophile may attack the metal in $L_n(CO)M{\equiv}CR$ and produce a ketenyl complex $L_n(Nu)M(\eta^2\text{-OC=CR})$ or $L_n(Nu)_2M(\eta^1\text{-OC=CR})$. On the other hand, Schrock carbynes are nucleophilic and subject to attack by electrophiles, for instance, $(t\text{-BuO})_3$ W≡C(t-Bu) reacts with HCl to give $(t\text{-BuO})_2Cl_2$ W=CH (t-Bu).

5 BRIDGING CARBENES

Like CO, carbenes can act as bridging ligands,[55] usually accompanied by a metal–metal bond (**11**). In bridging, carbenes lose some of their unsaturation, and therefore the very high reactivity of their mononuclear analogs. Fischer methylenes are very reactive and barely isolable, while bridging methylenes are well known and relatively stable. This is reflected in the ^{13}C NMR resonance positions of the carbene carbon for terminal and bridging cases: terminal groups resonate at 250–500δ, while bridging groups appear at 100–210δ if an M–M bond is present and at 0–10δ, if not; for comparison, simple metal alkyls resonate at −40 to 0δ. These values probably reflect the change in hybridization required by the carbon atom to form bonds at the angles required by the geometry of the complex. If no M–M bond is present (**12**), then these will be close to 109°, appropriate for sp^3 C. If an M–M bond is present, the M–C–M angle closes to 75–85° and for a terminal carbene, the angle is 0° and an sp^2 C is needed.



(11) **(12)**

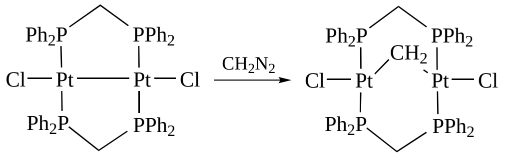
One of the most valuable synthetic routes to bridging carbenes involves the use of diazomethane (equation 37) and related free carbene precursors;[56] the product of equation (37) has a type (**11**) structure.

$$\mathrm{CpMn(CO)_2(thf) + CH_2N_2 = [\{CpMn(CO)_2\}_2(\mu\text{-}CH_2)] + N_2} \qquad (37)$$

Diazomethane adds not only to monomeric metal complexes but also to compounds containing metal–metal double bonds (equation 38), a reaction that has analogy with the addition of a free carbene to a C=C double bond to give a cyclopropene.[57]

$$\mathrm{[Cp^*{}_2Rh_2(\mu\text{-}CO)_2] + CH_2N_2 = [Cp^*{}_2Rh_2(\mu\text{-}CO)(\mu\text{-}CH_2)] + CO} \qquad (38)$$

The product retains the Rh=Rh double bond in what is really a substitution of CO by CH_2. Insertion of CH_2 into a metal–metal single bond is seen in the synthesis of the platinum 'A-frame' complex shown in equation (39),[58] a rare example of a bridging methylene complex without an M–M bond (structure of type (**12**)).

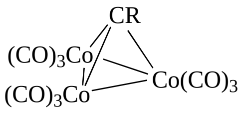


(39)

Comparison of the ^{13}C NMR resonance positions of the carbene carbon for terminal and bridging carbenes reflects the greater unsaturation of the terminal type. Terminal groups resonate at 250 to 500δ, while bridging groups appear at 100 to 210δ if an M–M bond is present, and at 0 to 10δ if not; for comparison, simple metal alkyls resonate at −40 to 0δ. These values probably reflect the change in hybridization required for the carbon atom to form bonds at the angles required by the geometry of the complex. If no metal–metal bond is

present (**12**), then these angles will be close to 109° apart and no special rehybridization is required. If an M–M bond is present, the two M–C bonds are usually 75–85° apart. In a terminal carbene, the two bonds are of course formed with the same metal atom.

Carbynes can also bridge three metals, as in the long-known and very stable tricobalt complex (**13**).



(13)

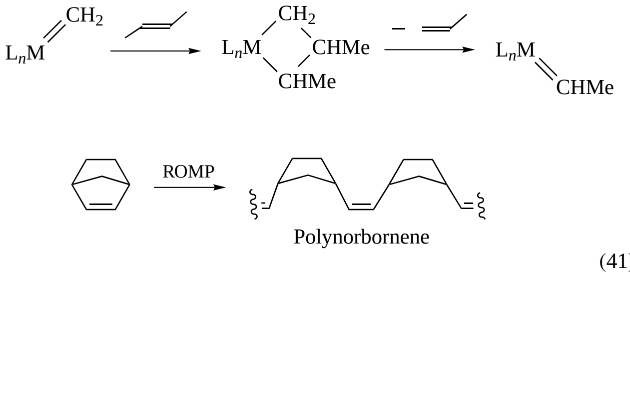
6 ALKENE METATHESIS

The alkene metathesis reaction[41] (*see Alkene Metathesis*) exchanges alkylidene groups between different alkenes, and is catalyzed by a variety of high oxidation state, early transition metal species (equation 40). The reaction is of interest because it is the strongest bond in the alkene, the C=C bond, that is broken during the reaction. It is also commercially important in the Shell higher olefins process and in the polymerization of cycloalkenes. It is relevant to this article because carbenes are the key intermediates, and the best-known catalyst, (**1**), is a carbene complex.

$$\mathrm{RCH{=}CHR} + \mathrm{R'CH{=}CHR'} \rightleftharpoons \mathrm{RCH{=}CHR'} \qquad (40)$$

The availability of a very recent monograph[2] means that the topic will not be covered in full detail here.

The mechanism of the reaction remained mysterious for many years. Several early papers, the first by Chauvin,[59] suggested the correct solution, but this was not generally accepted until much later. The question was whether the two alkenes bound to the metal and underwent rearrangement (called the pairwise mechanism), or whether the alkenes reacted one at a time (the nonpairwise mechanism). The *Chauvin Mechanism*, equation (41), is now the accepted pathway, and was a particularly imaginative suggestion at a time when both the required metalacyclobutane formation and fragmentation reactions and nonhetroatom substituted carbenes were unknown.



(41)

Metathesis catalysts also have important applications in alkene polymerization via *Ring Opening Metathesis Polymerization*, or ROMP, which leads to the formation of an unsaturated polymer, which means it can be vulcanized, or cross-linked, for greater strength. Commercial norbornene polymerization (mol. wt. $> 2 \times 10^6$) dates from 1976 (CdF Chimie, France). Both Schrock[60] and Grubbs[61,62] have shown that carbene complexes can be active in ROMP. Very good control of chainlength is achieved, and a block copolymer (. . .AAABBB. . .) can be made by adding a second cycloalkene when the first has been consumed. Catalysts that keep their activity even after the substrate has been consumed are *living systems*. Poly(1,4-phenylenevinylene), (p-C_6H_4–CH=CH–)$_n$, obtained in a similar way, has high conductivity when doped, and has useful optical and photochemical properties but is too insoluble to be processable.

$({}^i\text{Pr})_2\text{ATI}^-$ = N,N'-diisopropyl-aminotroponiminate; Trip = 2,4,6-triisopropylphenyl; Ar = 2,6-diisopropylphenyl; $\text{Pz}^{\text{R,R}'}$ = 3-R-5-R′-pyrazole.

1 INTRODUCTION

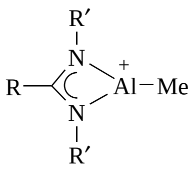
Low-coordinate group 13 complexes have received great attention in the last decade because the often quite electrophilic metal center in these species may be the source of unusual reactivity and thus mediates new chemical transformations. The use of appropriately designed and thus very crowded chelate ligands (*see Chelating Ligands*) has shown a major way to access such low-coordinate compounds because the resulting steric protection of the metal center may strongly limit exchange/redistribution reactions and avoid the formation of aggregates, which are well-known features in group 13 chemistry.[1]

This article mainly focuses on the two major and recent breakthroughs in the area of low-coordinate group 13 chelates: (1) tri-coordinate cationic group 13 chelates and (2) monovalent group 13 chelates. Recent advances in homogeneous catalysis involving more ‘classical’ tri-coordinate Al(III) complexes are also briefly mentioned.

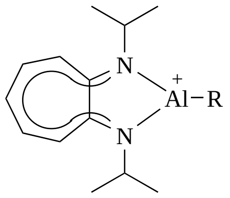
2 TRI-COORDINATE CATIONIC GROUP 13 CHELATES

2.1 Aluminum, Gallium, and Indium Chelates

Although various types of four- to six-coordinate cationic Al chelate species have been developed in the last twenty years and have found applications in catalysis due to their enhanced Lewis acidity (*see Lewis Acids & Bases*),[2] the synthesis and structure of the first tri-coordinate chelate Al cation $\{\text{HC(CMeNAr)}_2\}\text{AlMe}^+$ (**1**) was only recently reported by Jordan.[3] Cation (**1**) can be cleanly obtained as a $\text{B(C}_6\text{F}_5)_4^-$ salt by the reaction of the β-diketoiminate neutral precursor $\{\text{HC(CMeNAr)}_2\}\text{AlMe}_2$ with the trityl salt $[\text{Ph}_3\text{C}][\text{B(C}_6\text{F}_5)_4]$, which proceeds by Me^- abstraction at the metal center (Scheme 1). A weak interaction between the cationic metal center and one meta fluorine of $\text{B(C}_6\text{F}_5)_4^-$ (Al−F contact = 2.151(1) Å) is observed in the solid-state structure of the (**1**) $[\text{B(C}_6\text{F}_5)_4]$ salt (*see Noncoordinating Anion or Cation*). As a result, the geometry at Al is slightly distorted from planar to pyramidal. The Al–N and Al–C bond distances in (**1**) are slightly shorter than those in the neutral precursor that was ascribed to the increased ionic character of these bonds resulting from the cationic charge (*see Ionic Character*).



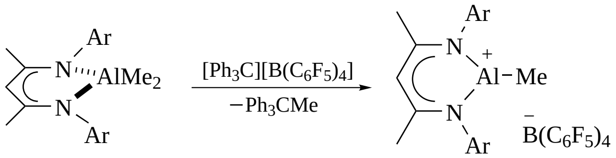
(**2**)
RC(NR′)$_2$AlMe$^+$
R = R′ = ^{t}Bu
R = 2,6-(2,4,6-Me$_3$Ph)$_2$Ph, R′ = ^{i}Pr



(**3**)
(ATI)AlR$^+$
R = Et, Pr

Thorough studies on various tri-coordinate $\{\text{L-X}\}\text{AlR}^+$ species (**1–3**) bearing dinitrogen-based bidentate ligands ($\text{L-X}^- = \text{RC(NR}')_2^-$,[4–6] HC(CMeNAr)_2^-,[1,7] and $({}^i\text{Pr})_2\text{ATI}^-$ [8–10]) concluded that such species, which combine a low-coordination number and a charge at Al are highly electrophilic and can be obtained provided two key requirements are fulfilled: (1) the use of a crowded L-X^- bidentate ligand that forms a stable Al chelate moiety and (2) the use of an inert counterion (*see Noncoordinating Anion or Cation*).[5,10]

In general, the reactivity of tri-coordinate $\{\text{L-X}\}\text{AlR}^+$ chelate cations is dominated by their potent Lewis acid character as they form robust four-coordinate cationic $\{\text{L-X}\}\text{Al(R)(L)}^+$ with Lewis bases such as NMe_2Ph, acetone, and



Ar = 2,6-^{i}Pr$_2$Ph (**1**)

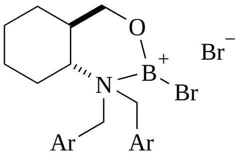
Scheme 1

acetonitrile. A PhCl adduct $\{(^i\mathrm{Pr})_2\mathrm{ATI}\}\mathrm{Al(Et)(PhCl)}^+$ was also X-ray characterized.[11] This high Lewis acidity is probably responsible for the excellent activity of $\{(^i\mathrm{Pr})_2\mathrm{ATI}\}\mathrm{AlR}^+$ cations in the polymerization of isobutene, propene oxide and, in some cases, of methyl methacrylate. In contrast, studies on the $\{(^i\mathrm{Pr})_2\mathrm{ATI}\}\mathrm{AlR}^+$ species have revealed a poor insertion reactivity in the Al–C bond. In fact, in this regard, these cations appear less reactive than neutral AlR_3 species. Rather, they show a selective and exclusive preference for β-hydride transfer to unsaturated substrates such as ethylene and acetone.[10] The reactivity trends observed for these cations versus those of the AlR_3 neutral species agree with theoretical calculations.[12,13] Apart from this, it is also noteworthy that $\{(^i\mathrm{Pr})_2\mathrm{ATI}\}\mathrm{AlEt}^+$ catalytically dimerize ^{t}BuC≡CH via an insertion/σ-bond metathesis cycle (*see σ-Bond Metathesis*).[10]

The synthesis of the Ga and In tri-coordinate chelates $\{(^i\mathrm{Pr})_2\mathrm{ATI}\}\mathrm{MMe}^+$ (M = Ga, In) was also reported.[11,14] These cations, which both crystallize as weakly four-coordinated PhCl adducts, exhibit an enhanced Lewis acidity versus that of the corresponding MMe_3.

2.2 Boron Chelates

A significant contribution in the area of low-coordinate boron chemistry was realized by Corey with the synthesis of chiral tri-coordinate and cationic oxaborolidine complexes such as (**4**), for use in asymmetric catalysis.[15,16] These compounds can be obtained by reaction of the desired chiral aminophenol with BBr_3, and they are highly effective catalysts for enantioselective Diels–Alder reactions. Smith also reported the generation of the tri-coordinate boron cation $\{\mathrm{HC(CMeNAr)_2}\}\mathrm{BMe}^+$, obtained by a Me^- abstraction reaction of $\{\mathrm{HC(CMeNAr)_2}\}\mathrm{BMe_2}$ by $B(C_6F_5)_3$.[17] This boron cation appears to be much less Lewis acidic than its Al counterpart.



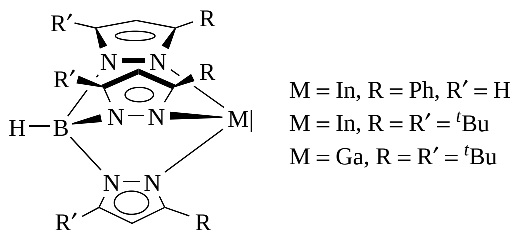
Ar = 3,5-Me_2Ph

(**4**)

3 LOW-COORDINATE MONOVALENT GROUP 13 CHELATES

3.1 Tri-coordinate Monovalent Group 13 Chelates

Nearly unknown 10 years ago, stable monovalent and monomeric group 13 species have been the subject of a few reports since then. In 1994, Piggott reported that the reaction of the bulky tridentate hydroboratotris(pyrazolyl) $\mathrm{HB(Pz^{Ph,H})^-}$ (*see Tris(pyrazolyl)borates*) with InI yields the air-stable, three-coordinate In(I) complex $\{\mathrm{HB(Pz^{Ph,H})_3}\}\mathrm{In}$ (**5**), which is the first monomeric and monovalent group 13 complex (Tl excluded).[18] In this complex, the arrangement of the tridentate ligand-phenyl rings forms a pocket about the In center and its lone pair of electrons, which may be crucial for its stabilization. The closely related tri-coordinate Ga(I) complex $\{\mathrm{HB(Pz^{Ph,H})_3}\}\mathrm{Ga}$ and several other tri-coordinate hydroboratotris(pyrazolyl) In(I) species were subsequently synthesized.[19,20]

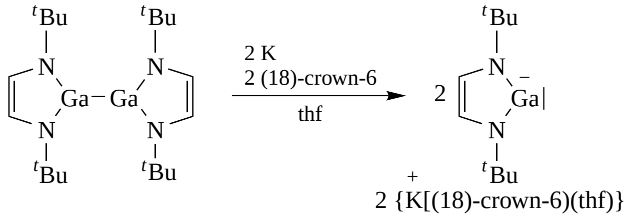


(**5**)

3.2 Two-coordinate Monovalent Group 13 Chelates

There has recently been an increasing interest in the design and synthesis of stable monovalent two-coordinate bidentate group 13 complexes, which are isoelectronic to carbene species. The use of bulky bidentate L-X^- or X_2^{2-}-type ligands combined with the appropriate synthetic methodology has opened the way to these unique species whose structural and reactivity studies remain an ongoing effort.

In 1999, Schmidbaur reported that the reduction by potassium metal of the dinuclear Ga(II) compound (**6**), previously synthesized by Cowley,[21] affords the two-coordinate Ga anion (**7**) as a $\mathrm{K(18\text{-}crown\text{-}6)(THF)_2}^+$ (*see Crown Ethers*) salt (Scheme 2).[22] This anion is the first two-coordinate chelate group 13 complex and was X-ray characterized. The $4s^2$ lone pair of electrons on the Ga atom and the two-electron pairs donated by the nitrogen



(**6**) (**7**)

Scheme 2

(**8**)

Scheme 3

atoms make up for a sextet configuration. In the present case, the Ga anion may be stabilized by the steric bulk of the bidentate combined with the 6π-electrons system of the heterocycle.

More recently, Roesky and Power showed that the very crowded β-diketoiminate $HC(CMeNAr)_2^-$ was suitable for the preparation of the neutral two-coordinate monovalent Al and Ga species. While the Ga derivative $\{HC(CMeNAr)_2\}Ga$ was directly accessible via a salt metathesis reaction (*see Metathesis*) between $[HC(CMeNAr)_2]Li$ and GaI, the Al derivative $\{HC(CMeNAr)_2\}Al$ (**8**) was obtained by reduction of the Al(III) di-iodo precursor $\{HC(CMeNAr)_2\}AlI_2$ with potassium (Scheme 3).[23,24] The work on Al has been very recently reviewed.[25] X-ray diffraction and theoretical studies on (**8**) suggest that its excellent stability most likely results from the significant steric protection afforded by the Ar groups and the presence of an sp-like hybrid lone pair of electrons at the metal center pointing outside the chelate ring. The Al–N bond distances are longer in $\{HC(CMeNAr)_2\}Al$ than those in the related Al(III) species, which was ascribed to the less Lewis acidic Al(I) versus Al(III).

Reactivity studies of two-coordinate chelate group 13 species have just begun and appear particularly interesting because such species may exhibit both a Lewis acid character (due to the sextet configuration at the metal center) and a Lewis base one (due the lone pair of electrons at the metal center) (*see Lewis Acids & Bases*). For instance, the two-coordinate Ga chelate $\{HC(CMeNAr)_2\}Ga$ reacts with $B(C_6F_5)_3$ to form the gallium–boron donor-acceptor complex $\{HC(CMeNAr)_2\}Ga \rightarrow B(C_6F_5)_3$, showing that such low-coordinate species can behave as effective Lewis bases.[26] Alternatively, the Al(I) and Ga(I) complexes $\{HC(CMeNAr)_2\}M$ (M = Al, Ga) behave like Lewis acids when reacted with the bulky azide compound $TripN_3$ to yield, along with N_2 formation, the first monomeric Al and Ga imide complexes $\{HC(CMeNAr)_2\}M{-}N(Trip)$ with M = Al and Ga, respectively.[27] In the case of the Ga imide complex (**9**), experimental data and theoretical calculations support a multiple bond character for the exocyclic Ga–N bond.

4 RECENT ADVANCES IN HOMOGENEOUS CATALYSIS BY NEUTRAL TRI-COORDINATE Al CHELATES

The use of Al(III) complexes as catalysts in Lewis acid–mediated reactions has been known for years.[28] However, recent years have witnessed interesting developments in this area with the use of ingeniously designed neutral tri-coordinate Al(III) chelates. Representative examples involving such chelates as catalysts include: (1) asymmetric acyl halide-aldehyde cyclocondensations,[29–31] (2) asymmetric Meerwein–Schmidt–Ponndorf–Verley reduction of prochiral ketones,[32] (3) aldol transfer reactions[33] and (4) asymmetric rearrangement of α-amino aldehydes to access optically active α-hydroxy ketones.[34] It is important to point out that, in most cases, the use of a chelating ligand appears critical for effective catalytic activity and enantioselectivity.

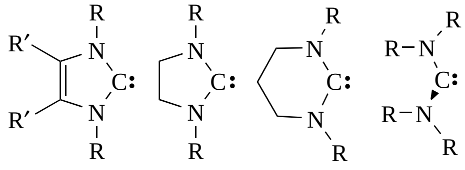
1 INTRODUCTION

There has been considerable interest in main group carbene complexes since 1993. Many fascinating advances have been made particularly concerning the solid-state structure of these carbene complexes, which has resulted in an understanding of their electronic structure. Undoubtedly, the isolation of stable crystalline carbenes (**1–4**) has enabled the chemistry of these compounds to be investigated,[1–5] and owing to their high nucleophilicity they can be used as ligands in the formation of both transition and main group complexes.[6,7] These carbenes even form stable complexes with metals that normally show no tendency for π back-donation. Carbenes (**1–4**) represent carbon compounds in oxidation state II and as such are good reducing agents. Generally, the singlet carbene acts as a two-electron donor in a similar manner to tertiary phosphines (*see* ***P-donor Ligands***). Thus, N-heterocyclic carbenes (**1–4**) are reported to complex with around 50 elements, as highlighted in a review by Herrmann and Köcher.[7]

Recently, significant progress has been made in the characterization of main group adducts of these carbenes.[8] This chapter will deal only with carbene compounds of the main group elements reported since 1993 and excludes transition metal carbene compounds (such compounds may be found in the article ***Carbene Complexes***).

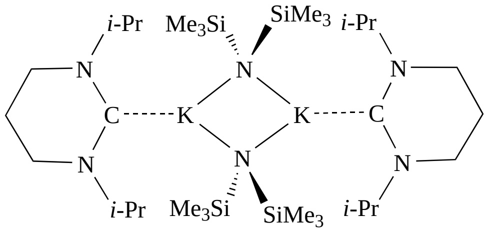


(**1**) (**2**) (**3**) (**4**)

2 GROUPS 1 AND 2

2.1 Complexation of Stable Carbenes with Alkali Metals

There are few examples of carbene complexes of group 1 metals. This is surprising since N-heterocyclic carbenes, such as compounds (**1–4**), are generally synthesized via the C-deprotonation of formamidinium using bases with alkali metal counterions, for example, KO-*t*-Bu.[1–5] The structural characterization of alkali metal carbene complexes would give information on the interactions between carbenes and alkali metals and thus lead to some understanding of the reactivity properties of these complexes in solution. The first example of an alkali metal–carbene complex (**5**) was isolated from the reaction of (**3**) (R = *i*-Pr) with $KN(SiMe_3)_2$.[9] The structure of (**5**) showed that dimeric molecules are present with the $N(SiMe_3)_2$ groups acting as bridging ligands. The K–carbene interaction is largely of an electrostatic ion–dipole nature as suggested by the K···C distance of 3.00 Å.

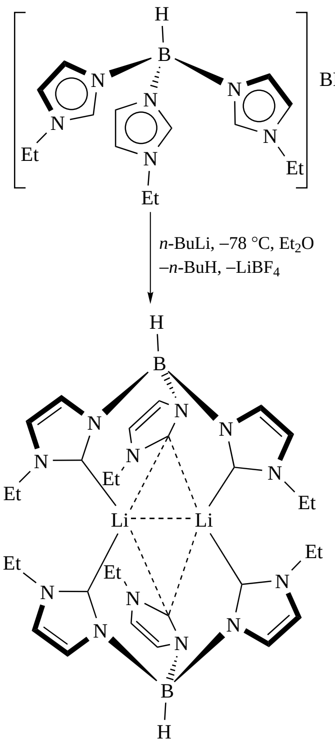


(**5**)

The interaction of $[MN(SiMe_3)_2]$ (M = Li, Na, K) and LiTMP with carbenes (**1**) (R = *i*-Pr, R′ = Me), (**3**) (R = *i*-Pr) and (**4**) (R = Me) in solution was also reported.[9] Evidence of complexation of these carbenes with the Li, Na, and K species in solution was given by the ^{13}C NMR shifts for the relevant carbene center. Recently, the reaction of carbene (**1**) with lithium 1,2,4-tris(trimethylsilyl)cyclopentadienide was reported to result in monomeric carbene complexes with 1:1 stoichiometry (R′ = H; R = *t*-Bu (**6**), adamantyl (**7**), or 2,4,6-trimethylphenyl(**8**)).[10] The crystal structure of (**6**) showed that the cyclopentadienyl ring is coordinated in an η^5-fashion to the lithium center (*see* ***Alkali Metals: Organometallic Chemistry***) and there is a single σ-interaction present between the lithium and the carbene center (Li–C(carbene) 2.155 Å).

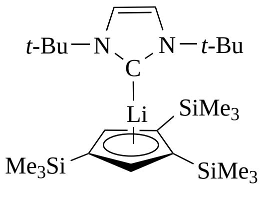
Recently, a novel homoleptic carbene–lithium complex (**9**) was isolated from the deprotonation of a monoanionic,

tridentate hydrotris(3-methylimidazolin-2-ylidene)borate carbene ligand with *n*-BuLi (equation 1).[11] An X-ray structure determination of compound (**9**) showed an unusual solvent-free complexation of each lithium atom by four carbene carbon atoms. Thus, terminal binding to the lithium centers of two carbon atoms from each hydrotris(3-methylimidazolin-2-ylidene)borate anion occurs, with the third carbene carbon atom adopting a bridging mode of coordination. The Li–C bonds to the terminal carbene atoms are 2.138(4) and 2.147(4) Å, which are similar to those observed in compound (**6**). In contrast, the Li–C bond distances to the bridging carbon atoms vary and are much longer (2.210(4) and 2.311(4) Å).



(1)

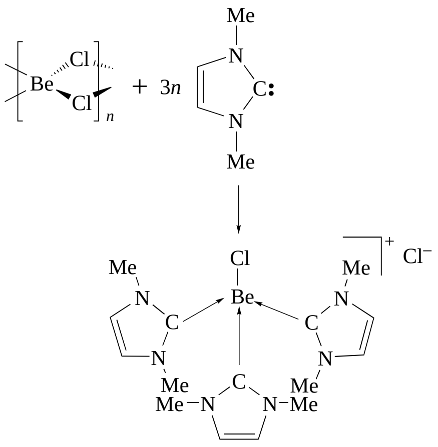
(**9**)



(**6**)

2.2 Carbenes Complexes of Alkaline Earth Metals

The reaction of polymeric beryllium chloride $(BeCl_2)_n$ with nucleophilic carbene (**1**) (R = Me, R′ = H) is reported (equation 2) to yield a cationic carbene complex (**10**).[12] The structure of the cation in (**10**) consists of the beryllium center adopting a distorted tetrahedral coordination. Although the Be–Cl bond distance (2.083 Å) is long when compared with other tetravalent complexes (*see* ***Beryllium: Inorganic Chemistry***), the addition of excess carbene failed to displace the second chloride ion. The Be–C(carbene) bond distances observed are similar to Be–C single bond distances and all the ring distances of the carbene correspond to those found in the free carbene.[1]

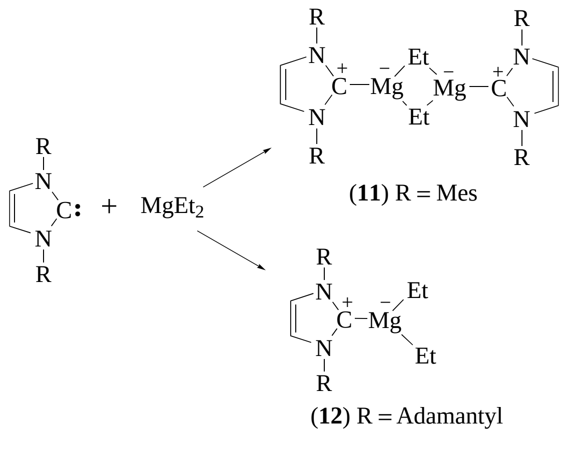


(2)

(**10**)

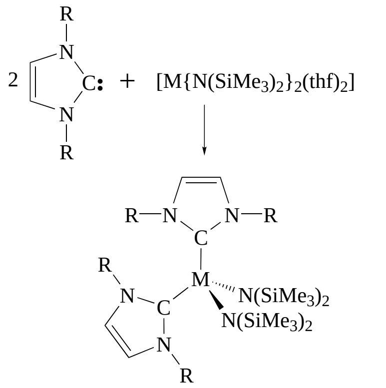
Reaction of carbene (**1**) (R = Mes or adamantyl, R′ = H) with one equivalent of diethyl magnesium resulted in the formation of the 1:1 adduct, that is, (**1**)·$MgEt_2$, as shown in Scheme 1.[13] The solid-state structure of (**1**)·$MgEt_2$ (**11**, R = Mes) is dimeric via bridging ethyl groups. However, due to greater steric protection provided by adamantyl groups, the structure of (**1**)·$MgEt_2$ (**12**, R = adamantyl) is monomeric with the Mg center adopting a trigonal planar coordination geometry.[13]

Carbene complexes of alkaline earth metal amides[7] and metallocenes have also been reported.[14,15] Reaction of calcium, strontium, and barium bis(trimethylsilyl)amides $[M\{N(SiMe_3)_2\}_2(thf)_2]$ (M = Ca, Sr, Ba) with two equivalents



Scheme 1

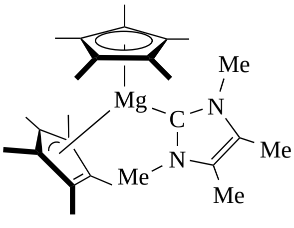
of (**1**) (R = Me or t-Bu, R′ = H) resulted in the displacement of two thf molecules (equation 3) to yield the biscarbene adducts (**13**).[7] The solubility and stability of the adducts was observed to decrease Ca to Ba.



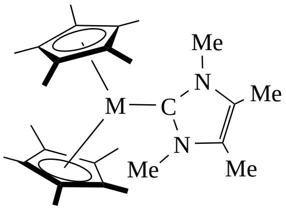
(3)

(**13**) M = Ca, Sr, Ba; R = Me, t-Bu

Carbene adducts of alkaline earth metallocenes may be prepared by the 1:1 reaction of carbene (**1**) (R = R′ = Me) with Cp^*_2M (M = Mg, Ca, Sr, Ba).[14] The structure of the magnesium adduct (**1**)·$MgCp^*_2$ (**14**) revealed two different bonding modes for the Cp* ligands (*see* ***Alkaline Earth Metals: Organometallic Chemistry***). Thus, one is coordinated in a η^5-manner (av. Mg–C 2.477(20) Å), whereas the second Cp* ring exhibits a 'slipped' geometry (three carbon atoms closest to Mg have an av. Mg–C distance of 2.460(85) Å). Interestingly, the closest Mg–C interaction is with the carbene center (2.192(2) Å). The Mg center in (**14**) adopts a trigonal planar geometry. In contrast to the magnesium adduct, the structures of carbene adducts of the heavier analogues (Ca and Ba) show that both Cp* ligands adopt an η^5-coordination (**15**). Unfortunately, the structure of the Sr analogue is not available. Overall, the carbene ligands show a preference for σ-bonding to the alkaline earth metal center and the metal–carbene distance is always smaller than the M–C(Cp*) distance irrespective of whether the ligand is π- or σ-bonded.

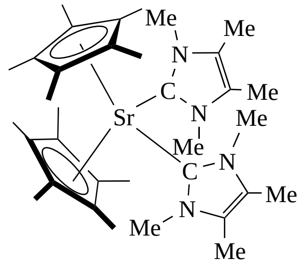


(**14**)



(**15**)

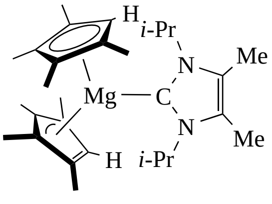
The heavier alkaline earth metals can also form bis(carbene) adducts, of the type $(\mathbf{1})_2 \cdot MgCp^*_2$ (M = Sr, Ba; R = R′ = Me).[14] An X-ray structure determination of the strontium adduct (**16**) showed that the strontium center adopts a pseudotetrahedral geometry with two carbenes and two Cp* ligands (Sr–C(carbene) 2.854(5) and 2.868(5) Å; av.



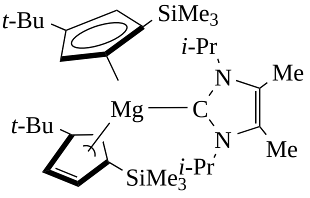
(**16**)

Sr–C(Cp*) 2.917(12) Å). The coordinated carbene ligands show a geometry that is similar to unligated carbene.

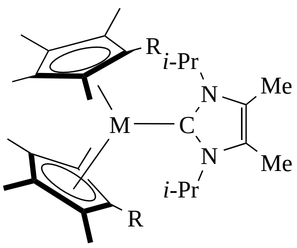
Recently, a series of carbene complexes of new metallocenes of group II elements were reported.[15] Thus, reaction of carbene (**1**) (R = i-Pr, R′ = Me) with Cp'_2Mg or $[(C_5Me_4R'')_2M(L_x)(L_y)]$ (M = Ca: R″ = H, $L_x = NH_3$, Ly = THF or R″ = i-Pr, L_x = THF; M = Ba, R″ = t-Bu, $L_x = L_y$ = THF; M = Sr, R″ = Me, $L_x = L_y$ = THF) afforded the 1:1 adducts (**1**)·$MgCp'_2$ (Cp′ = C_5Me_4H (**17**) or C_5H_3-1-($SiMe_3$)-3-t-Bu (**18**)) and (**1**)·$M(C_5Me_4R'')_2$ (**19**). The structures of (**17**) and (**19**) are similar to (**14**) and (**15**) described above, such that the metal center adopts a pseudo-trigonal planar geometry and both Cp′ ligands are coordinated in an η^5-fashion, except with magnesium where one Cp′ ligand is slipped to an η^3 bond. The M–C(carbene) distances are also comparable to (**14**) and (**15**) and confirm that the bond strength of these bonds are dependent on the alkaline earth metal size. As expected, bulky Cp ligands result in longer metal to carbene carbon bonds.



(**17**)



(**18**)



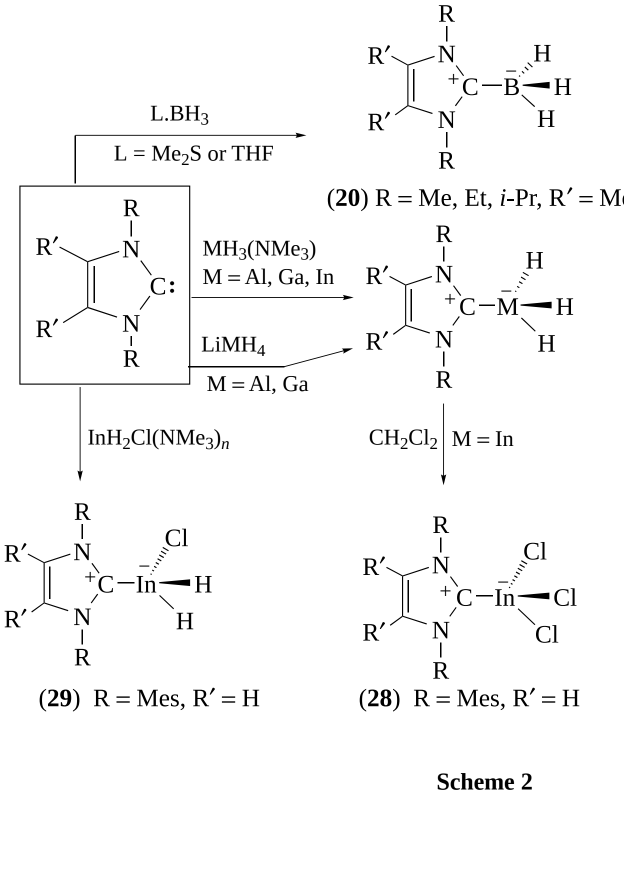
(**19**: M = Ca: R″ = H or i-Pr; M = Ba, R″ = t-Bu; M = Sr, R″ = Me)

3 GROUP 13

3.1 Carbene Adducts of Group 13 Hydrides

Aluminum and gallium trihydrides and their adducts with N−, P− or O− donor Lewis bases have been extensively studied (*see* ***Aluminum: Inorganic Chemistry*** and ***Ammonia & N-donor Ligands***).[16] Recent interest in these complexes is the result of their potential applications in a wide range of areas such as organic synthesis[17] and chemical vapor deposition (*see Chemical Vapor Deposition*) of 13−15 semiconductors.[18] Complexation of carbenes with the heavier group 13 trihydrides have only been studied recently.[19–25] However, the chemistry of borane adducts of carbenes have been investigated and when (**1**) (R = Me, Et, *i*-Pr, R′ = Me) was allowed to react with $Me_2S{\cdot}BH_3$, the first carbene−BH_3 adduct (**20**) was isolated, as shown in Scheme 2.[26] Both the X-ray structure and ab initio calculations (*see Ab Initio Calculations*) on (**20**) indicate that weak π-interactions between the C=C unit and the N–C–N moiety and within the ring are present with alternating bond lengths. Accordingly, the electronic structure for the imidazole fragment can be described as intermediate between that of a fully delocalized imidazolium ion and a free carbene. The ^{11}B NMR chemical shifts for (**20**) were typical of a ylide-borane adduct ($\delta = -35$) and the $^1J(^1H,^{11}B)$ coupling constant is similar to that of an anionic complex, that is, $[(C_6H_5)BH_3]^-$. Recently, the reaction of carbene (**1**) and $BH_4{\cdot}THF$ was reported to also yield a carbene−BH_3 adduct (**20**, R = Mes, R′ = H).[27] The structure of (**20**) revealed head-to-tail alignment of (**1**)·BH_3 in the solid state with the closest intermolecular contact occurring through a [C–H···H–B] hydrogen bond.

A range of carbene−metal trihydride complexes (**21–27**) were formed from the reaction of (**1**) (R = *i*-Pr, R′ = Me; R = Mes, R′ = H; also when M = Al, R = 2,6-*i*-$Pr_2C_6H_3$, R′ = H) with $[MH_3(NMe_3)]$ (M = Al, Ga, In) or $[LiMH_4]$ (M = Al, Ga), as shown in Scheme 2.[19–24] Although 2:1 adducts of *N*-heterocyclic carbene with indium halides have been isolated (Section 3.2),[28] attempts to form 2:1 adducts via the addition of two equivalents of carbene to $[InH_3(NMe_3)]$ failed. This is presumably due to the fact that InX_3 (X = Cl, Br) is more Lewis acidic than InH_3. The crystal structures of (**21–25**) and (**27**) are all similar and showed that the complexes are monomeric. The group 13 metal center adopts a distorted tetrahedral environment with long M–C(carbene) bond lengths when compared to typical M–C single bonds. As for compound (**20**), the carbene ligand in (**21–25**) and (**27**) exhibits a degree of delocalization somewhere between that of the free carbene and the fully delocalized imidazolium cation. The thermal stability of (**21–27**) was found to decrease in the order (**21**) > (**22**) > (**23**) > (**26**) > (**24**) > (**27**) > (**25**). Moreover, the indane complex, (**25**), is unstable in solution above −20 °C and decomposes in the solid state above −5 °C, depositing indium metal and generating a gas.[20–22] In contrast, compound (**27**) is stable in the solid state (under an inert atmosphere) up



(**20**) R = Me, Et, *i*-Pr, R′ = Me; R = Mes, R′ = H

(**21**) M = Al, R = Mes, R′ = H
(**22**) M = Al, R = 2,6-*i*-$Pr_2C_6H_3$, R′ = H
(**23**) M = Al, R = *i*-Pr, R′ = Me
(**24**) M = Ga, R = *i*-Pr, R′ = Me
(**25**) M = In, R = *i*-Pr, R′ = Me
(**26**) M = Ga, R = Mes, R′ = H
(**27**) M = In, R = Mes, R′ = H

(**29**) R = Mes, R′ = H

(**28**) R = Mes, R′ = H

Scheme 2

to 115 °C.[23] In solution, the stability of (**27**) is dependent on the solvent. For example, toluene solutions of (**27**) are stable at room temperature for over three months. However, CH_2Cl_2 solutions of (**27**) are unstable and chloride abstraction from the CH_2Cl_2 solvent takes place at 25 °C and the adduct (**1**)·$InCl_3$ (**28**) is formed in moderate yield, as shown in Scheme 2. The high thermal stability of (**27**) is probably a result of a combination of the large steric bulk and high nucleophilicity of carbene (**1**) (R = Mes, R′ = H). Indeed, the high nucleophilicity of the N-heterocyclic carbene is shown by the alane and gallane complexes, (**21–24**) and (**26**), which have much greater stability than normally observed for Lewis base adducts of the group 13 trihydrides (*see* ***Aluminum: Inorganic Chemistry*** and ***Gallium: Inorganic Chemistry***). Such complexes usually decompose cleanly to the metal, hydrogen, and ligand.[19–24] The greater stability of (**27**) versus (**25**) is thought to be due to (**25**) decomposing via a different pathway that involves metallation of the isopropyl carbene substituents by InH_3 with concomitant loss of H_2. However, compound (**27**) decomposes via ligand loss or dihydroimidazole formation.

The carbene adduct (**1**)·InH_3 (**27**, R = Mes, R′ = H), has been used as a selective reducing agent for unsaturated organic functionalities.[29] In addition, the reactivity of (**27**) toward a variety of transition metal complexes has been reported.[30] In general, InH_3 acts as a carbene and/or a hydride transfer reagent to transition metal centers rather than forming heterobimetallic complexes.

A mixed indium hydride halide complex, (**1**)·InH_2Cl (**29**) has been prepared from the 1:1 reaction of $[InH_2Cl(NMe_3)_n]$ with carbene (**1**) (R = Mes, R′ = H), as shown in Scheme 2.[23] The structure of (**29**) is monomeric with the geometry at the In center close to tetrahedral. The In–C distance (2.244(6) Å) is similar to those observed in (**28**) (2.200(7) Å) and (**25**) (2.253(5) Å). A related mixed gallium hydride iodide complex (**1**)·GaH_2I (**30**) has been isolated from the reaction of (**26**) with 'GaI', with concomitant deposition of gallium metal.[24] Complex (**30**) is isostructural with the related indium complex (**29**) and has a Ga–C bond distance of 2.022(4) Å.

Bidentate N-heterocyclic carbene complexes of group 13 hydrides have been reported recently.[25] Treatment of carbene (**31**) with two equivalents of $[MH_3(NMe_3)]$ (M = Al, Ga, In) or $LiInH_4$ (equation 4) resulted in the formation of the 1:2 adducts (**32–34**). The Al and Ga analogues are moderately thermally stable (*dec.* 122–124 and 168–171 °C) but less stable than compounds (**21–24**) and (**26**). In contrast, the indane adduct (**34**) decomposes at 10–12 °C. The structures of (**32**) and (**34**) were determined and found to be isostructural. Both (**32**) and (**34**) are monomeric and the bidentate carbene ligand (**31**) bridges two MH_3 fragments in a similar manner to bisphosphine complexes.

It is worth noting that recently a novel biscarbene complex of a polyhedral borane was reported.[31] Hydration of the known dicarbonyl $B_{12}H_{10}(CO)_2$ resulted in the formation of the bis(dihydroxy-carbene) complex $B_{12}H_{10}[C(OH)_2]_2 \cdot 4H_2O$ (**35**). Bond order calculations show negligible π-bonding between the cluster and the carbene diol groups (B–C 1.589(1) Å).

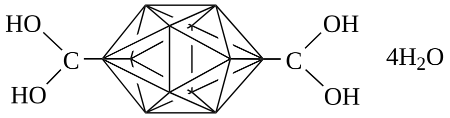
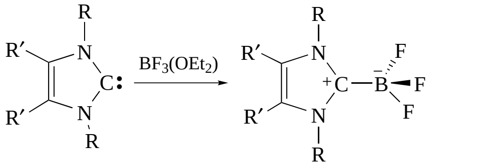
(**33**) M = Ga
(**34**) M = In



(**35**)

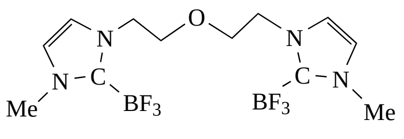
3.2 Carbene Complexes of Group 13 Halides

Reaction of (**1**) (R = Me, Et, *i*-Pr, R′ = Me; R = Mes, R′ = H, Cl) with $BF_3(OEt_2)$ (equation 5) resulted in the isolation of the 1:1 adduct with BF_3 (**36**).[26,32,33] Usually, carbene ligands cannot be stabilized by electron-poor coordination fragments because traditional carbenes show a pronounced tendency toward metal-to-ligand π back-donation. However, N-heterocyclic carbenes do not rely on back-donation for stabilization because of the delocalization of the nitrogen lone pair in these carbenes (e.g. carbene **1**). Thus, compound (**36**) was found to be thermally stable and could be sublimed without decomposition. The structure of (**36**) (R = R′ = Me; R = Mes, R′ = H, Cl) was determined and the geometry was found to be similar to the borane (BH_3) adduct (**20**), except that the B–C(carbene) bond distance was longer (B–C(carbene): 1.635(5) Å (R = Mes, R′ = H), 1.669(6) Å (R = Mes, R′ = Cl), and 1.603(3) Å for **20**).[26,33] The longer B–C(carbene) bond distance when R′ = Cl versus R′ = H, suggests that the boron–carbon bond is weaker due to the electron-withdrawing chlorine atoms.[33]

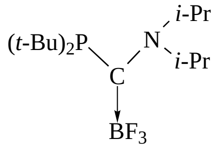


(5)

(**36**) R = Me, Et, *i*-Pr, R′ = Me
R = Mes, R′ = H or Cl



(**37**)



(**38**)

Two further carbene adducts of BF_3 have been reported recently.[34,35] A boron trifluoride adduct (**37**) of a bidentate nucleophilic heterocyclic carbene was obtained as a by-product from the reaction of di-silver-bis-[bis-(2-(3-methylimidazolin-2-yliden-1-yl))ethyl]ether di-tetrafluoroborate with $ZrCl_4$.[34] The geometry at each boron center is similar to that observed in (**36**) and the B–C(carbene) distance is 1.644(2) Å. An acyclic (i-Pr_2N)(t-Bu_2P)C·BF_3 adduct (**38**) has been prepared from the reaction of a (amino)(phosphino)carbene with $BF_3(OEt_2)$.[35] Compound (**38**) was characterized by NMR spectroscopy. Both the ^{11}B ($\delta = -14.6$) and ^{19}F ($\delta = -62.0$) NMR signals appear as quartets ($^1J_{BF} = 43$ Hz) without any coupling with phosphorus, showing that the BF_3 group is only interacting with the carbene center. Interestingly, the softer Lewis acid BH_3 interacts selectively with the phosphorus lone pair rather than the carbene center.[35]

Recently, a series of complexes between indium(III) halides and carbene (**1**) have been reported, as shown in Scheme 3.[22,28,36] The reaction of carbene (**1**) with one equivalent of InX_3 (X = Cl, Br) resulted in the isolation of 1:1 adducts with InX_3 (X = Cl, R = i-Pr, R′ = Me (**39**); X = Br: R = i-Pr, R′ = Me (**40**); R = Mes, R′ = H (**41**), R = 2,6-i-$Pr_2C_6H_3$, R′ = H (**42**)). The X-ray structures of (**40–42**) (X = Br) showed that all the compounds are monomeric and the indium center adopts a distorted tetrahedral geometry, with the In–Br bond distances almost equivalent. The In–C(carbene) bond lengths range from 2.195(2)–2.212(8) Å and are relatively long compared to single In–C bond distances. The bond lengths and angles within the carbene heterocycle indicate a degree of delocalization within the ring, for example, the N–C–N angle of ∼106° lies between the normal value for free carbenes (∼102°) and imidazolium cations (∼108°).[1] For the synthesis of the adduct (**1**)·$InCl_3$ (**28**: R = Mes, R′ = H), see Section 3.1 and Scheme 2.[23]

Biscarbene adducts of indium(III) halides (**43–44**) can be prepared from the reaction of InX_3 with two equivalents of carbene (**1**) (R = i-Pr, R′ = Me), according to Scheme 3.[28] The crystal structure of (**43**) and (**44**) showed that in both structures the indium center adopts a distorted trigonal bipyramidal geometry. In previously reported neutral 2:1 adducts of InX_3, the halides occupy the equatorial sites (*see **Indium: Inorganic Chemistry***), however, in complexes (**43**) and (**44**), one halide and the carbon atoms of (**1**) are present in the equatorial sites, with two halides occupying the apical

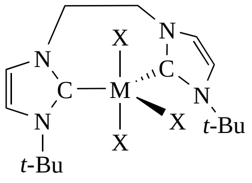
Scheme 5

positions. It is unclear why (**43**) and (**44**) adopt this sterically unfavorable arrangement of the ligands. The In–C(carbene) distances in (**43**) (*av.* 2.228 Å) and (**44**) (*av.* In–C 2.230 Å) are slightly longer than in (**40–42**), as expected, with the geometries within the planar heterocyclic rings being similar.

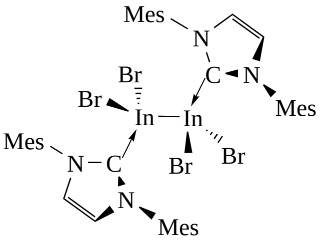
An ionic compound is formed when the 1:1 reaction between InX_3 and (**1**) (R = *i*-Pr, R′ = H) is carried out in the presence of water (**45**, X = Cl; **46**, X = Br).[28] The anion comprises a carbene adduct of $[InX_4]^-$, which illustrates the high nucleophilicity of the carbene ligand. The mechanism of the formation of (**45**) and (**46**) is thought to involve the adduct $[InX_3(thf)_n]$ in equilibrium with its ionic isomer in thf solution, as shown in Scheme 4. The other product of the reaction is believed to be an indium hydroxide, $[InX_2OH]$, although this compound was not isolated.

A number of stable carbene–thallium(III) complexes have been prepared via the reaction of carbene (**1**) with TlX_3 (R = Mes: X = Cl, R′ = H or Br (**47**); X = Br, R′ = H (**48**)), as shown in Scheme 5.[37] The structure of (**47**) (R′ = H) is monomeric with a distorted tetrahedral geometry at the thallium center. The geometry of the heterocycle is similar to the indium analogue (**28**) with a Tl–C bond distance of 2.154 Å. The formation of a bis(carbene) adduct of $TlCl_3$ (**49**) was achieved via the reaction of (**47**) with carbene (**1**) (R = R′ = Me). Unfortunately, no structural data for (**49**) is available but it is assumed that the geometry about the thallium center is trigonal bipyramidal with the chloride ligands in the equatorial positions.[37]

Bidentate N-heterocyclic carbene complexes of $InBr_3$ and $TlCl_3$ have been described recently.[25] Reaction of carbene (**31**) with one equivalent of MX_3 resulted in the formation of the 1:1 adducts (**50**, M = In, X = Br; **51**, M = Tl, X = Cl). The isolation of 1:1 adducts rather than a similar 2:1 adduct

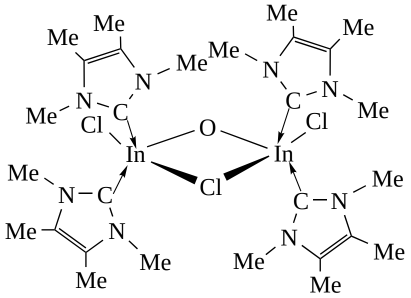


(**50**) M = In, X = Br
(**51**) M = Tl, X = Cl



(**52**)

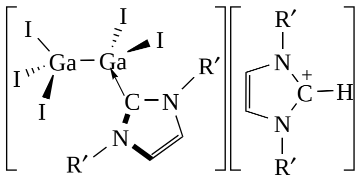
observed for MH_3 (**32–34**) gives further evidence that $InBr_3$ is a stronger Lewis acid than InH_3. An X-ray structure determination of compound (**50**) shows that the molecule is monomeric with the carbene ligating the indium center in a chelating mode. The geometry at the indium center is distorted trigonal bipyramidal with the carbenes residing in two equatorial positions, similar to the biscarbene–indium halide complexes (**43** and **44**).[36]



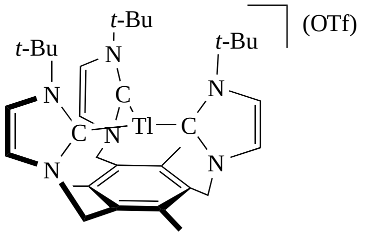
(**53**)

The reactivity of N-heterocyclic carbenes with group 13 metal(I) halide complexes has been studied to a limited extent (*see* ***Low Oxidation State Main Group***).[38–40] The reaction of 0.5 or 1 equivalent of carbene (**1**) (R = Mes, R′ = H) with InBr resulted in the isolation of a thermally robust carbene–indium(II) bromide complex (**52**) with concomitant deposition of indium metal.[38] The mechanism for the formation of (**52**) is thought to involve the intermediate complex (**1**)·InBr, which undergoes a disproportionation reaction to yield (**52**) and indium metal. In the solid state, compound (**52**) is dimeric and both indium centers adopt a distorted tetrahedral geometry with the two [(**1**)·$InBr_2$] fragments staggered with respect to each other. All bond lengths and angles are in the normal range. Reaction of a less sterically hindered N-heterocyclic carbene (**1**) (R = Me, R′ = Me) with InCl afforded the oxo-bridged dimer (**53**) in low yield, due to adventitious oxidation.[39] In contrast, reaction of a very hindered carbene (**1**) (R = 2,6-*i*-$Pr_2C_6H_3$, R′ = H) with 'GaI' resulted in the deposition of gallium metal and the formation of a ionic complex (**54**). The presence of only one coordinated carbene in (**54**), in comparison to the two carbene ligands in (**52**), may be due to the greater steric bulk of the carbene ligand and the smaller covalent radius of the metal atom in the former complex.[38,39] The structure of (**54**) showed that both gallium centers have distorted tetrahedral coordination geometries with a long Ga–Ga bond distance (2.4739(12) Å).

The synthesis and characterization of a thallium(I) triscarbene complex has been described.[40] The reaction of a chelating tripodal carbene ligand 1,3,5-{tris(3-*tert*-butylimidazol-2-ylideno)methyl}-2,4,6-trimethylbenzene with Tl(OTf) resulted in the formation of the triscarbene thallium(I) complex (**55**). An X-ray structural determination showed that the tripodal carbene ligand coordinates with the thallium(I) ion in (**55**) in the expected tridentate conformation. All three imidazole rings are almost perpendicular to the mesitylene moiety, however, the three carbene centers in (**55**) are bound asymmetrically (Tl–C 2.893(4), 2.979(4) and 2.985(5) Å). This is thought to be due to steric or crystal packing effects rather than electronic reasons.



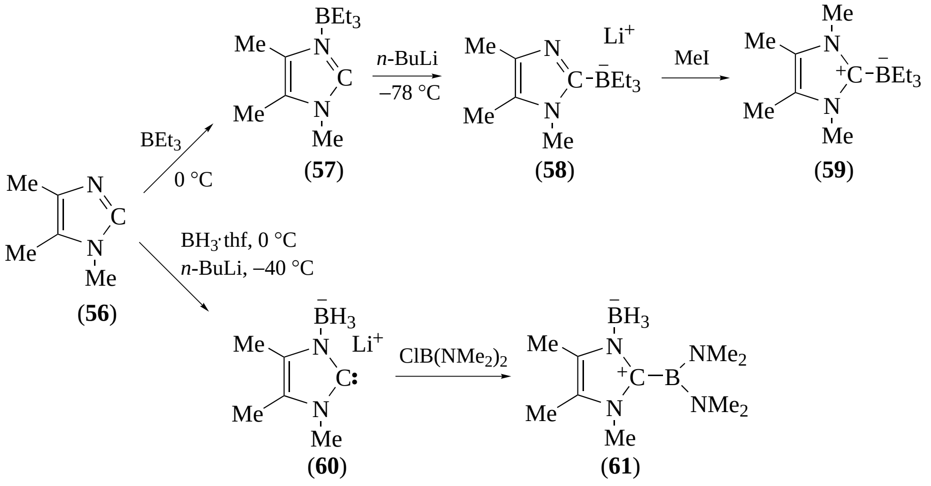
(**54**, R′ = 2,6-*i*-$Pr_2C_6H_3$)



(**55**)

3.3 Carbene Adducts of Organo and Amido Group 13 Complexes

Trialkylboron–carbene adducts have been prepared via a novel synthetic route, as shown in Scheme 6.[41] The initial first step involves reaction of BEt_3 with 1,4,5-trimethylimidazole (**56**) to afford the BEt_3 adduct (**57**), followed by deprotonation and rearrangement to give an ionic species (**58**). The triethylboron–carbene adduct is generated in the final step by way of

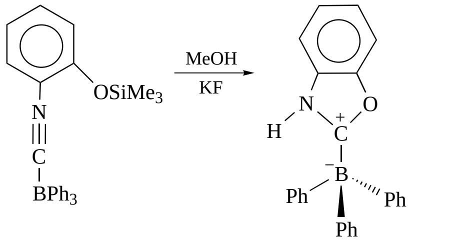


Scheme 6

a methylation with MeI (**59**). Compound (**59**) was characterized by NMR (^{1}H-, ^{13}C- and ^{11}B) and mass spectroscopy; the ^{11}B NMR chemical shift observed for (**59**) was δ −12.6.

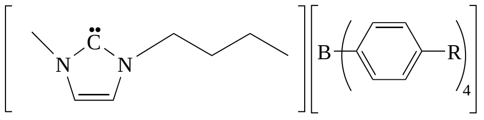
Compound (**56**) can also be used to synthesize an amidoboron–carbene adduct.[41] Thus, the intermediate carbene (**60**) was formed by reaction of BH_3·THF with (**56**), followed by deprotonation using *n*-BuLi. Addition of $ClB(NMe_2)_2$ to (**60**) results in the ylidene (**61**), the ^{11}B NMR of which had chemical shifts of δ−21.8 (BH_3) and δ 27.8 ($BNMe_2$). In the solid state, compound (**60**) is dimeric.[42] The synthesis of a range of transition metal complexes with the anion in compound (**60**) have been reported recently, demonstrating that (**60**) is a suitable reagent for introducing the carbene ligand.[43]

N,O–heterocyclic carbenes have also been shown to form adducts with triorganoboron complexes.[44] Triphenylboron–carbene adducts (**62**) were isolated from the reaction of an isocyanide adduct of BPh_3 with methanol (equation 6), in the presence of a catalytic amount of KF. An X-ray structural determination showed that (**62**) consists of a tetrahedrally coordinated boron atom with all four B–C bond distances equal (within experimental error).

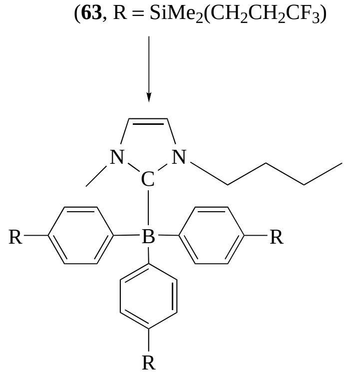


(**62**) (6)

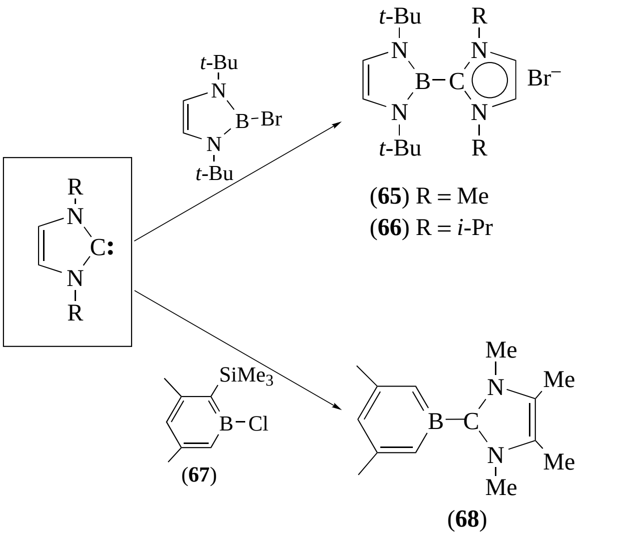
A related triarylboron–carbene adduct (**64**) was isolated from the attempted recrystallization of the 1-butyl-3-methylimidazolium tetraarylborate salt (**63**) in warm MeOH/H_2O (equation 7).[45] The solid-state structure of (**64**) comprises a distorted tetrahedral boron center with all four B–C bond distances similar, as observed in compound (**62**).[44]



(**63**, R = $SiMe_2(CH_2CH_2CF_3)$)

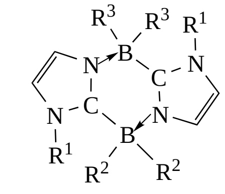


(**64**) (7)



Scheme 7

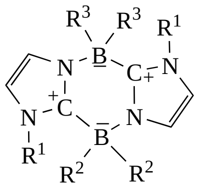
The reactivity of nucleophilic carbenes with 2-bromo-2,3-dihydro-1*H*-1,3,2-diazaborole has also been described.[46] Reaction of a benzene solution of (**1**) (R = Me, *i*-Pr; R′ = H) with *t*-BuNCH=CH(*t*-Bu)BBr (Scheme 7) resulted in the formation of an ionic compound (**65**, R = Me; **66**, R = *i*-Pr). The halide displacement observed in the aforementioned reaction is similar to those previously reported in the reactions of carbenes with Me_3SiI.[47] The crystal structure of (**65**) was determined and showed that both heterocyclic rings are planar with an interplanar angle of 92.9°; the B–C(carbene) bond distance of 1.580(11) Å corresponds to that found in (**20**) (1.603(3) Å). A carbene adduct of borabenzene has also been reported, as shown in Scheme 7.[48] Treatment of the highly reactive silylated chloroborabenzene (**67**) with carbene (**1**) (R = R′ = Me) afforded an immediate precipitation of the carbene–borabenzene adduct (**68**). The structure of (**68**) consists of a planar borabenzene and carbene ring with an interplanar angle of 34.75(6)°. The B–C(carbene) bond distance of 1.596(2) Å is comparable to that observed in (**65**).[46]



dimeric N-borane adduct (**69a**)

A range of imidazabole derivatives have been described recently.[49] These compounds may be considered as aza- (**69a**) or carbene–borane (**69b**) adducts. However, NMR and X-ray diffraction data of these compounds (**69**) indicate that they are dimers of carbene–borane adducts rather than dimers of

N–borane adducts, as shown by the geometry of the imidazole ring, which is consistent with the former.

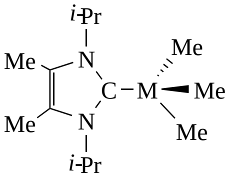


dimeric carbene-borane adduct (**69b**)

$R^1 = CH_3$, $R^2 = R^3 = H$, F, Cl or CH_2CH_3

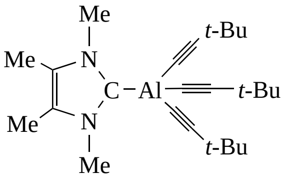
$R^1 = CH_2C_6H_5$, $R^2 = R^3 = H$

$R^1 = CH_3$, $R^2 = F$, $R^3 = H$



(**70**) M = Al

(**71**) M = Ga

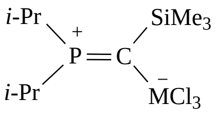


(**72**)

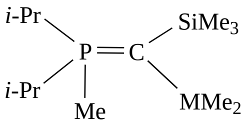
Reports of triorgano group 13 carbene adducts involving the heavier group 13 elements are limited to carbene complexes of $AlMe_3$, $GaMe_3$, and Al(C≡C-*t*-Bu)$_3$.[50,51] Thus, when (**1**) (R = *i*-Pr, R′ = Me) was allowed to react with MMe_3, stable 1:1 adducts of Me_3M (**70**, M = Al; **71**, M = Ga) were formed. X-ray structural determinations showed that the group 13 metal centers in (**70**) and (**71**) are tetrahedrally coordinated with long M–C(carbene) bond lengths (**70**, Al–C(carbene) 2.124(6) Å *cf.* Al–C(methyl) 1.940(5) Å and 2.062(7) Å; (**71**), Ga–C(carbene) 2.13(2) Å *cf.* Ga–C(methyl) 1.95(1) Å and 2.08(2) Å). The Al–C(carbene) distance in (**70**) is much longer than that observed in the related alane complex (**23**) (2.034(3) Å), which is probably a result of greater steric hindrance of $AlMe_3$ versus AlH_3.[21] Similarly, the Ga–C(carbene) bond length in (**71**) is much longer than that found in the gallane complex (**24**) (2.071(15) Å).[21]

The first carbene adduct of a substituted aluminum ethynyl derivative (**72**) was isolated from the reaction of $AlBr_3$ with three equivalents of LiC≡C-*t*-Bu in the presence of carbene (**1**) (R = *i*-Pr, R′ = Me).[51] The structure of (**72**) is similar to compound (**70**), such that the aluminum atom adopts a tetrahedral coordination geometry.

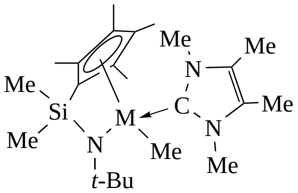
Phosphinosilylcarbene group 13 adducts have also been reported. Reaction of {$(R_2N)_2P$}(Me_3Si)C: with BEt_3 (R = cyclohexyl) or MCl_3 (M = Al, Ga or In; R = *i*-Pr) afforded the 1:1 adducts [{$(R_2N)_2P$}(Me_3Si)C:BEt_3] and [{$(R_2N)_2P$}(Me_3Si)C:MCl_3] (**73**).[52,53] However, reaction of {$(R_2N)_2P$}(Me_3Si)C: with MMe_3 resulted in the isolation of phosphorus ylids [{$(R_2N)_2P(Me)$}(Me_3Si)CMMe_2] (**74**), probably via the initial formation of the carbene–MMe_3 adducts.[53] Carbene adducts of constrained geometry aluminum and gallium complexes have been reported recently.[54] The bridged amidocyclopentadienide ligand [$Me_2Si(\eta$-$C_5Me_4)$(N-*t*-Bu)]$^{2-}$ was reacted with $MeMCl_2$ (M = Al, Ga), followed by treatment with carbene (**1**) (R = R′ = Me), to yield the adducts [$Me_2Si(\eta$-$C_5Me_4)$(N-*t*-Bu)]MMe.(**1**) (**75**).



(**73**) M = Al, Ga, In



(**74**) M = Al, Ga



(**75**) M = Al, Ga

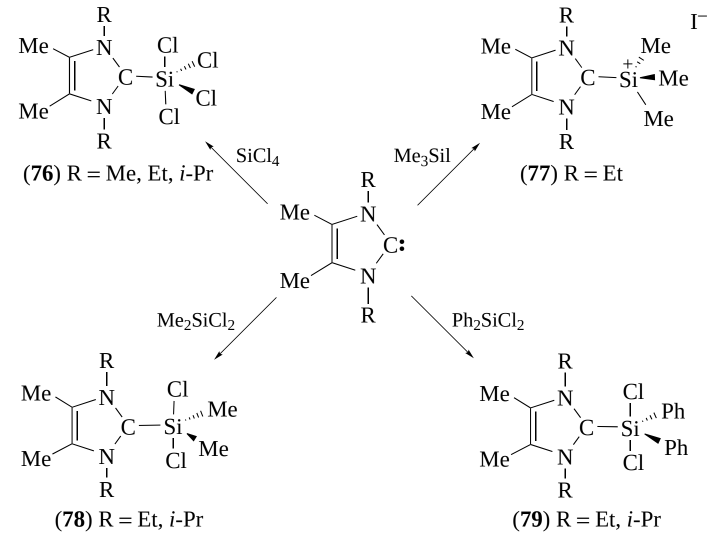
4 GROUP 14

Nucleophilic carbenes have been reported to react with Lewis acidic group 14 complexes with the isolation of neutral or ionic compounds via simple adduct formation or displacement of a halide ion.[47,55–60] The range of carbene complexes of silicon, germanium, tin, and lead, as well as some related cyclopropenylidene complexes are described below.

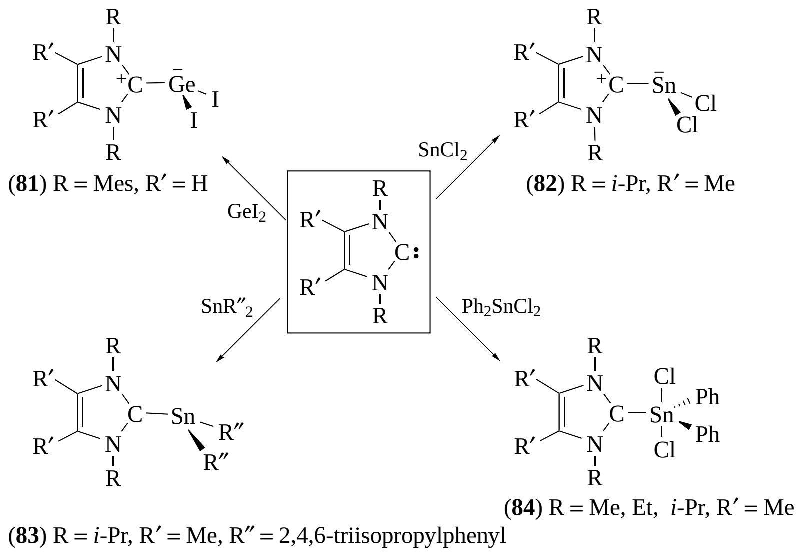
4.1 Carbene Complexes of Silicon

When tetrachlorosilane was allowed to react with (**1**) (R = Me, Et, *i*-Pr; R′ = Me), the somewhat labile 1:1 adduct with $SiCl_4$ (**76**) was formed, according to Scheme 8.[47] The solid-state structure of (**76**), when R = *i*-Pr, showed that the silicon center adopts an essentially trigonal bipyramidal geometry with the carbene ligand in an equatorial position. The bond lengths and angles within the carbene heterocycle indicate a degree of delocalization within the ring (N–C–N angle of 107.1(6)°) and the Si–C(carbene) bond distance is 1.9711(7) Å.

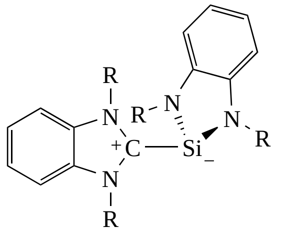
Pentavalent silicon adducts (**78,79**) can be isolated from the reaction of dialkyl- or diaryl-dichlorosilanes with (**1**) (R = Et, *i*-Pr; R′ = Me), whereas when Me_3SiI is reacted with (**1**), ionic imidazolium salts are formed (**77**).[47] Unfortunately, no information regarding the structure of these compounds is available. A crystalline carbene–silylene adduct 1,2-C_6H_4[N(R)]$_2$C-Si[N(R)]$_2C_6H_4$-1,2 (**80**, R = CH_2-*t*-Bu) has



Scheme 8



Scheme 9



(**80**) R = CH_2-*t*-Bu

been reported recently.[55] Compound (**80**) is a monomer with a long central bond of 2.162(5) Å between the carbene carbon and Si atoms. The carbene carbon is almost planar, however, the silicon is in a pyramidal coordination environment.

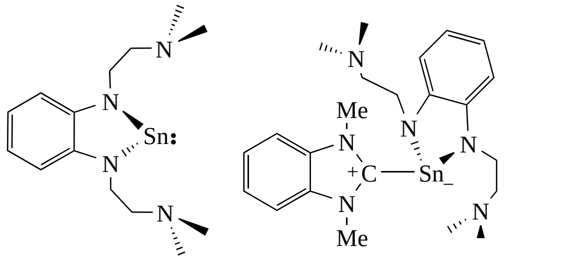
4.2 Carbene Adducts of Germanium and Tin

Carbene adducts of germanium and tin have also been reported, as shown in Scheme 9.[56–58] A model for the dimerization of singlet carbenes along a non-least-motion pathway was provided by the reaction of GeI_2 with carbene (**1**) (R = Mes, R′ = H).[56] The formation of a polarized Ge–C bond, rather than a true double bond, was indicated by the ^{13}C NMR chemical shift of the carbene atom ($\delta = 60.88$) in the resulting germene–carbene adduct (**81**). The solid-state

structure of (**81**) consists of pyramidal coordination geometry at the Ge center with a long Ge–C bond distance (2.102(12) Å). Interestingly, due to steric interaction between the iodine and mesityl substituents, the two halves of the adduct are twisted with respect to one another.

Stable carbene adducts of tin(II) may be prepared from the reactions of $SnCl_2$ or SnR''_2 (R″ = 2,4,6-triisopropylphenyl) with (**1**) (R = *i*-Pr; R′ = Me).[47,57] The crystal structure of the $SnCl_2$ adduct (**82**) is similar to (**81**), in that a pyramidal geometry is adopted at the Sn center with a Sn–C(carbene) bond distance of 2.290(5) Å. As expected, the Sn–C(carbene) bond distance in the SnR''_2 adduct (**83**, Sn–C(carbene) 2.379(5) Å) is longer than that observed in (**82**) and greater than Sn–C(aryl) bond lengths (2.321(2) Å and 2.308(2) Å). The long Sn–C(carbene) bond distances in (**82**) and (**83**) indicate that these complexes are examples of simple Lewis acid–Lewis base adducts.

Pentavalent tin adducts have also been reported and were isolated from the reaction of (**1**) (R = *i*-Pr, R′ = Me) with Ph_2SnCl_2.[47] An X-ray structure determination of the Ph_2SnCl_2 adduct (**84**) showed that the Sn(IV) center adopts a distorted trigonal bipyramidal geometry and the three organic substituents occupy the equatorial positions. The Sn–C(carbene) bond distance of 2.179(3) Å in (**84**) is shorter than the Sn–C(carbene) bond distances found in the Sn(II) adducts (**82** and **83**) but longer than the Sn–C(phenyl) bond lengths (2.122(5) Å and 2.139(3) Å).

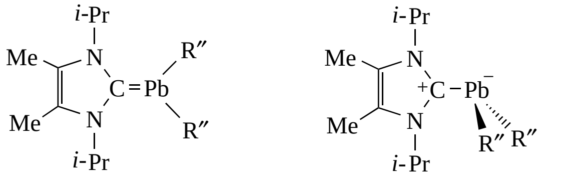


(**85**) (**86**)

A zwitterionic (*see Zwitterion*) carbene–stannylene adduct has been prepared via the cleavage of a dibenzotetraazafulvalene by a stannylene.[58] Thus, reaction of the tetraamine 1,2-C_6H_4-$[NHCH_2CH_2NMe_2]_2$ with bis(bis(trimethylsilyl)amido)tin(II) yielded the N-heterocyclic stannylene (**85**). Treatment of stannylene (**85**) with *N,N′N″N‴*-tetramethyl dibenzotetraazafulvalene results in C=C bond cleavage in the dibenzotetraazafulvalene to give the carbene–stannylene adduct (**86**). An X-ray structure determination showed that compound (**86**) is zwitterionic with a partially cationic carbene subunit and a partially anionic stannylene unit. The structure of (**86**) is similar to that of the carbene–silylene (**80**) such that the carbene plane and the stannylene plane are orientated in an almost perpendicular manner.

4.3 Carbene Adducts of Lead

There is only one report of a carbene–plumbylene adduct.[59] Addition of carbene (**1**) (R = *i*-Pr, R′ = Me) to a toluene solution of PbR''_2: (R″ = 2,4,6-*i*-$Pr_3C_6H_2$) afforded the 1:1 adduct (**87**). An X-ray structure determination revealed that (**87**) is monomeric with an unusually long Pb–C(carbene) distance of 2.540(5) Å. The structure of (**87**) is similar to the silylene– (**80**) and stannylene–carbene (**86**) adduct such that the carbene carbon is almost planar with a pyramidal lead atom. Therefore, of the two possible electronic forms of (**87**) (the plumbene (**87a**) and the zwitterionic (**87b**)), the latter dominates.



(**87a**, R″ = 2,4,6-*i*-$Pr_3C_6H_2$) (**87b**, R″ = 2,4,6-*i*-$Pr_3C_6H_2$)

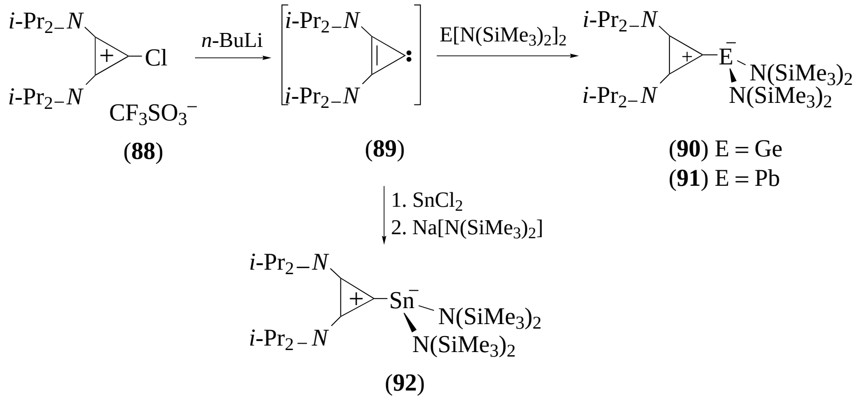
4.4 Cyclopropenylidene Complexes of Germanium, Tin, and Lead

Recently, cyclopropenylidene adducts of divalent germanium, tin, and lead have been reported.[60] Treatment of the cyclopropenylium salt (**88**) with *n*-BuLi afforded the bis(diisopropylamino)cyclopropenylidene (**89**), as shown in Scheme 10. For germanium and lead, cyclopropenylidene adducts of $E(N(SiMe_3)_2)_2$ (**90**, E = Ge; **91**, E = Pb) can be formed directly via the reaction of (**89**) with $E(N(SiMe_3)_2)_2$. In contrast, the analogous tin compound (**92**) is only accessible from the reaction of $SnCl_2$ with (**89**) followed by amidation of the intermediate carbene adduct. Compounds (**90–92**) are all isolated as thermally stable yellow crystals and have the same structures. Thus in each structure, the group 14 element is pyramidal with E–C(carbene) distances (**90**, Ge–C(carbene) 2.085(3) Å; **91**, Sn–C(carbene) 2.303(9) Å; **92**, Pb–C(carbene) 2.423(8) Å) that suggest a ylidic resonance structure corresponding to the imidazol-2-ylidene adducts described above.[56,57]

5 CARBENE ADDUCTS OF PHOSPHORUS, ARSENIC, AND ANTIMONY

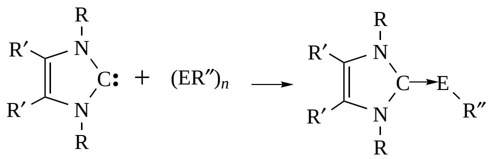
5.1 Carbene Complexes of Phosphorus(III) and Arsenic(III)

The first examples of p-block pnictinidenes were recently reported.[61,62] It was found that the N-heterocyclic carbenes are sufficiently nucleophilic to enable depolymerization of



Scheme 10

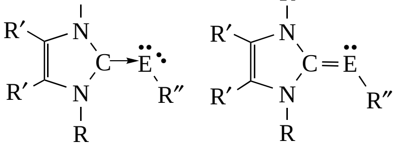
cyclopolyphosphines and cyclopolyarsines to occur (equation 8) with the isolation of carbene–pnictinidene (**93–97**) adducts.[61,62]



(8)

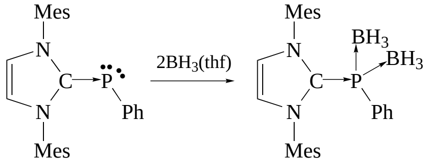
(**93**) R = R′ = Me; E = P; R″ = Ph; *n* = 5
(**94**) R = Mes; R′ = H; E = P; R″ = Ph; *n* = 5
(**95**) R = Mes; R′ = H; E = P; R″ = C_6F_5; *n* = 4
(**96**) R = Mes; R′ = H; E = P; R″ = CF_3; *n* = 4
(**97**) R = Mes; R′ = H; E = As; R″ = Ph; *n* = 6

The carbene–pnictinidene (**93–97**) adducts can be represented by two extreme canonical forms (**98** and **99**). The canonical form (**99**) represents a conventional phosphaalkene with a C=P double bond, whereas form (**98**) corresponds to a phosphinidene adduct of a carbene and features a C–P dative bond order of one. Structural data for compounds (**93–97**) showed that the E–C(Carbene) bond is ~4% longer than typical single bonds and that the E–C(R″) moiety is twisted out of the carbene plane by 26–46°.[61,62] These data, along with the high-field ^{31}P chemical shifts of (**93**,**94**) and (**96**), indicate the predominance of structure (**98**).



(**98**) (**99**)

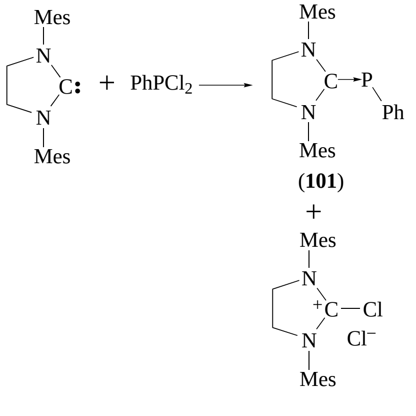
Further support for structure (**98**) was obtained from the reaction of BH_3·THF with compound (**94**) (equation 9), which resulted in the isolation of the bis(borane) adduct (**100**). The formation of (**100**) confirms the availability of two lone pairs on the phosphorus center in (**94**).[63]



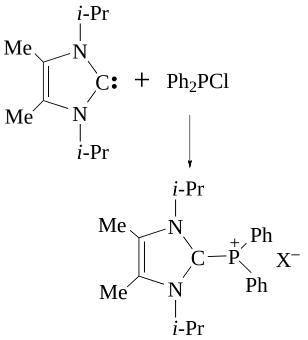
(**94**) (**100**)

(9)

The carbene–phosphinidene adducts described above were prepared from cyclopolyphosphines, which in turn are formed via reduction of higher-oxidation state phosphines, such as $PhPCl_2$. However, in some cases, carbene–phosphinidene adducts (**101**) can be prepared by direct reaction of a nucleophilic carbene with $PhPCl_2$ (equation 10) and a separate reduction step is not required.[61] In contrast, reaction of Ph_2PCl with carbene (**1**) (R = *i*-Pr, R′ = Me) resulted in the formation of the corresponding phosphino-imidazolium salt (**102**), which has been structurally characterized as (**103**) on treatment with $AlCl_3$ (equation 11).[64] The related phosphino-imidazolium salt (**104**) was isolated from the reaction of $[Ph_3PPh_2][OTf]$ with carbene (**1**) (R = *i*-Pr, R′ = H) with concomitant formation of Ph_3P.[65]



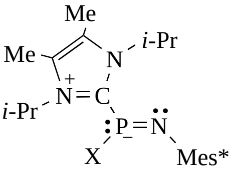
(10)



(11)

(**102**) X = Cl
(**103**) X = $AlCl_4$
(**104**) X = OTf

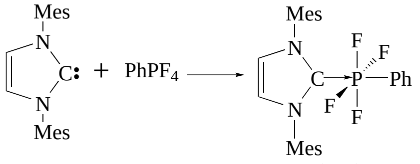
Carbene complexes of iminophosphines have also been reported.[66] Thus, treatment of carbene (**1**) (R = *i*-Pr, R′ = H) with Mes*PNCl or Mes*PNOTf affords the 1:1 adducts (**105**) and (**106**). The structures of (**105**) and (**106**) indicate that π-interaction between the nitrogen centers and the methylene center is favored over that between a planar phosphorus center and a methylene center.



(**105**) X = Cl
(**106**) X = OTf

5.2 Carbene Complexes of Phosphorus(V)

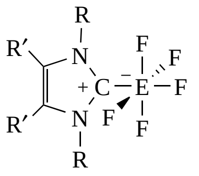
Recently, the formation of the first carbene complex of a phosphorus(V) center was reported.[67] The direct reaction of carbene (**1**) (R = Mes, R′ = H) with phenyltetrafluorophosphorane (equation 12) results in the formation of perphosphoranide (**107**) in quantitative yield. An X-ray structural determination showed that the phosphorus center in (**107**) adopts an octahedral geometry with a long P–C(carbene) bond length (P–C(carbene) 1.91 Å *cf.* P–C(phenyl) 1.84 Å). The ^{31}P resonance in (**93**,**94**) and (**96**) are at a substantially higher field than the value in (**107**), which is expected and reflects the change from a two-coordinate to a six-coordinate P center.



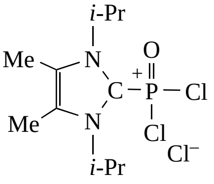
(**107**)

(12)

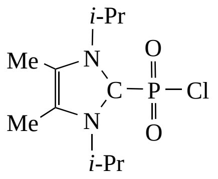
Carbene adducts of phosphorus pentafluoride have also been reported.[32] Reaction of carbene (**1**) (R = Mes, R′ = H) with PF_5 affords (**1**)·PF_5 (**108**) as a minor product with concomitant formation of 1,3-dimesitylimidazolium hexafluorophosphate, (**1**)·PF_6. However, treatment of carbene (**1**) (R = Mes, R′ = Cl) with PF_5 resulted in a 60% yield of the 1:1 adduct, (**1**)·PF_5 (**109**). The improvement in the yield of the adduct is thought to be due to moderation of the carbene's nucleophilic reactivity by the inductive effect of the two chlorine substituents in the formation of (**109**). An X-ray determination showed that the structure of (**109**) is similar to (**107**) with the phosphorus atom adopting an octahedral coordination geometry and a P–C bond distance of 1.893(3) Å.[32,67] Overall, the NMR and structural data support the valence bond structure of (**109**) as zwitterionic. Heterocyclic carbenes have also been used to stabilize metaphosphoric acid fragments.[68] Reaction of carbene (**1**) (R = *i*-Pr, R′ = Me) with $POCl_3$ resulted in the isolation of the corresponding $POCl_3$ carbene adduct (**110**). The metaphosphoric acid–carbene adduct (**111**) was subsequently obtained from the partial hydrolysis of (**110**). The X-ray structure of (**111**) revealed that it is monomeric with a long P–Cl bond (2.070 Å) and a P–C bond distance of 1.843(2) Å.



(**108**) E = P, R = Mes, R′ = H
(**109**) E = P, R = Mes, R′ = Cl
(**112**) E = As, R = Mes, R′ = Cl
(**113**) E = Sb, R = Mes, R′ = Cl



(**110**)



(**111**)

5.3 Carbene Complexes of Arsenic and Antimony

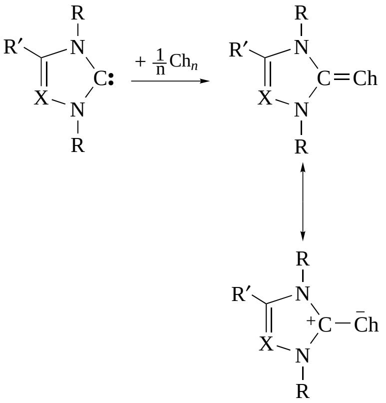
Carbene adducts of the heavier pnictogen pentafluorides have been reported.[32] Reaction of AsF_5 or SbF_5 with carbene (**1**) (R = Mes, R′ = Cl) in 1,3-bis(trifluoromethyl)benzene resulted in the isolation of (**1**)·AsF_5 (**112**) and (**1**)·SbF_5 (**113**). The crystallographic analysis for (**112**) and (**113**) reveals the expected octahedral geometry at the pnictogen center with a long As–C (2.009(5) Å) and Sb–C (2.175(5) Å) bond distance respectively. Recently, a novel hypervalent antimonide complex was reported.[69] The nucleophilic addition of carbene (**1**) (R = Mes, R′ = H) to $Sb(CF_3)_3$ (equation 12) resulted in the

formation of the 1:1 adduct with $Sb(CF_3)_3$ (**114**). An X-ray investigation of compound (**114**) showed that the antimony center adopts a pseudo-trigonal bipyramidal coordination geometry with a Sb−C(carbene) bond distance of 2.821 Å and *av.* Sb−C(CF_3) of 2.22 Å. Therefore, the average antimony−carbon distance to the CF_3 groups in (**114**) more closely resemble the Sb–C(carbene) distance in (**113**).

6 CARBENE COMPLEXES OF THE CHALCOGENS

N-heterocyclic carbene adducts of sulfur have been known for many years as a result of their industrial applications in catalysis. These complexes have been described in various reviews[6–8] and this section will be confined to carbene complexes of the chalcogenides reported since 1993.

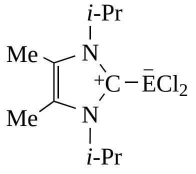
The reaction of imidazol-2-ylidenes with selenium and tellurium (equation 13) affords the selenones (**115**) and tellurones (**116**).[70–73] In general, tellurocarbonyl compounds, for example, telluroaldehydes, can only be isolated by stabilization with metals, however, compound (**116**) is relatively stable.[69] An X-ray investigation of (**115**) and (**116**) shows that rather than a formal double bond, an ylidic structure is adopted in both cases with long Ch−C(carbene) bond distances (**115** Se−C(carbene): 1.853(4) Å (R = *i*-Pr, R′ = Me), 1.884(9) Å (R = Me, R′ = H); (**116**) Te−C(carbene) 2.087(4) Å (R = *i*-Pr)). Further support for the ylidic structure for (**115**) and (**116**) was obtained by the ^{74}Se and ^{125}Te NMR spectra, in which the signals resonate upfield when compared to other chalcocarbonyl compounds. This shielding is accounted for by the presence of π-delocalization in the heterocyclic rings (**115** N–C–N 106.4° (R = *i*-Pr, R′ = Me), 106.8° (R = Me, R′ = H); **116** N–C–N 106.7°). It has also been reported that oxygen, sulfur, and selenium react with 1,2,4-triazol-5-ylidenes (equation 13) in a similar manner to give the 1:1 adducts (**117**).[75]



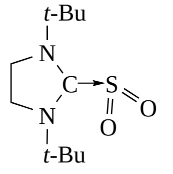
(**115**) Ch = Se, X = CR′, R = Me, Et, *i*-Pr, R′ = Me; R = Me, R′ = H
(**116**) Ch = Te, X = CR′, R = Me, Et, *i*-Pr, R′ = Me; R = Mes. R′ = H, Cl
(**117**) Ch = O, S, Se; X = N, R = R′ = Ph

(13)

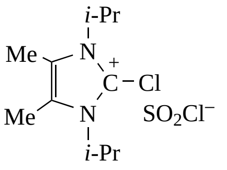
Carbene adducts of a range of sulfur compounds have also been isolated.[75–77] Carbene (**1**) (R = *i*-Pr, R′ = Me) reacts with sulfur dichloride or thionyl chloride to yield the hypervalent sulfur derivatives (**118**) and (**119**).[76] Similarly, reaction of carbene (**2**) (R = *t*-Bu) with SO_2 led to the formation of the 1:1 adduct (**2**)·SO_2 (**120**).[77] In contrast, reaction of carbene (**1**) (R = *i*-Pr, R′ = Me) with SO_2Cl_2 affords the 2-chloro-1,3-diisopropyl-4,5-dimethylimidazolium chlorosulfite salt (**121**).[74] A carbene adduct of SO_3 (**122**) can then be isolated through hydrolysis of (**121**) in the presence of cyanide.



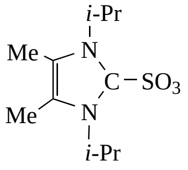
(**118**) E = S
(**119**) E = S=O



(**120**)

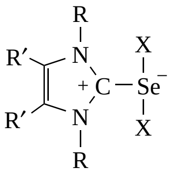


(**121**)

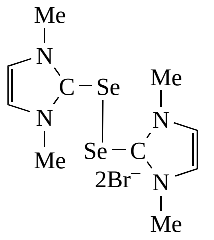


(**122**)

A carbene adduct of $SeBr_2$ (**123**) may be prepared via reaction of (**115**) (R = Me, R′ = H) with bromine.[71] However, if only half an equivalent of bromine is reacted with (**115**) (R = Me, R′ = H), the diselenide (**124**) is formed.



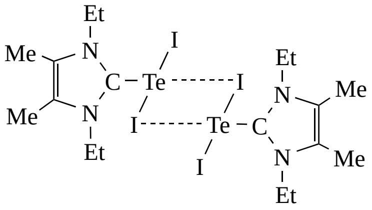
(**123**) X = Br, R = Me, R′ = H
(**125**) X = I, R = *i*-Pr, R′ = Me



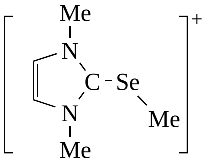
(**124**)

The reaction of iodine with seleno- and telluroimidazolines results in the formation of the adducts of SeI_2 (**125**) and TeI_2 (**126**) respectively.[78–80] X-ray diffraction of (**125**) showed that the molecule is monomeric, with the Se center adopting an equatorially vacant trigonal bipyramidal geometry.[78] The axial positions are occupied by the iodine atoms and the Se−I bonds are long (*av.* Se−I 2.811(1) Å; I−Se−I 175.4°). The Se−C(carbene) bond distance of 1.900(4) Å in (**125**) is longer than that observed in (**115**). In the solid-state structure of (**125**), weak iodine−iodine

interactions are present (I· · ·I 3.719(1) Å). An Se-methyl ionic compound (**127**) may be prepared by refluxing (**115**) (R = Me, R′ = H) with iodomethane.



(**126**)

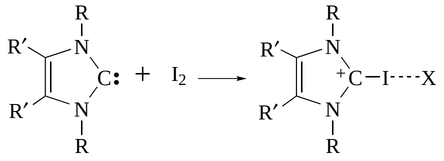


(**127**)

The solid-state structure of the tellurium analogue (**126**) is dimeric and a square-planar geometry is adopted by each tellurium atom.[78] The Te_2I_2 unit is planar and each tellurium has two short Te–I bonds (2.989(1) Å and 2.897(1) Å) and one long Te–I bond (3.564(1) Å). As expected, the Te–C(carbene) distance of 2.120(3) Å is longer than that observed in (**116**) (2.087(4) Å).

7 CARBENE ADDUCTS OF CHLORINE, BROMINE, AND IODINE

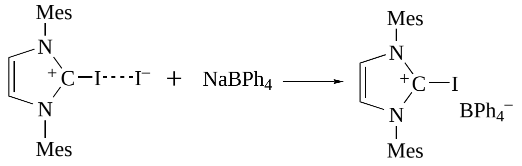
Carbene adducts of iodine have been published prior to 1993 and are described in a number of reviews.[7,8] More recently, nucleophilic carbenes, such as (**1**), have been shown to react with I_2 (equation 14) to form 2-iodoimidazolium salts (**128–130**).[80,81] Weak interactions in the solid state, between the iodine in the 2-position of the imidazole ring and the iodide counterion (**128**, I· · ·I 3.348 Å; **129**, I· · ·I 3.249 Å), are present in the imidazolium salts (**128**) and (**129**). The almost linear arrangement of the C–I· · ·I unit indicates a hypervalent central iodine atom and hence the C–I bond distances are long when compared to iodoarenes (**128**, C–I 2.104 Å, C–I· · ·I 176.0°; **129**, C–I 2.113 Å, C–I· · ·I 179.2°). The N–C–N angles of 109.3° and 107.0° in (**128**) and (**129**) respectively are typical of an imidazolium ion. The imidazolium salt (**130**) is similar with a weak interaction in the solid state between the triiodide counterion and the iodine bonded to the carbene (I· · ·I 3.310 Å, C–I 2.131 Å, C–I· · ·I 173.1°, N–C–N 109.5°).



(14)

(**128**) X = I^-, R = Et, R′ = Me
(**129**) X = I^-, R = Mes, R′ = H
(**130**) X = I_3^-, R = adamantyl, R′ = H

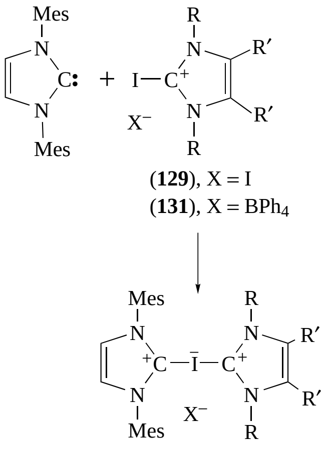
The iodide ion in (**129**) can be substituted by tetraphenylborate (**131**), presenting an interesting comparison to (**128–130**), because the anion is unable to interact covalently with the 2-iodoimidazolium cation (equation 15).[80] As expected, the C–I bond distance in (**131**) is shorter than in (**128–130**) at 2.042 Å and the N–C–N internal ring angle is smaller at 107.7°. It is interesting to note that in the crystal structure of (**131**), the C–I bond of the cation resides along a twofold crystallographic axis and the boron atom lies along this same axis at a distance of 4.42 Å from the iodine.



(15)

(**131**)

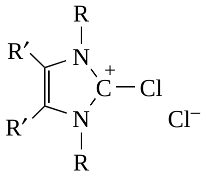
Cationic bis(carbene) adducts of the hypervalent iodine (**132** and **133**) may be prepared by reaction of the imidazolium salts (**128**) and (**130**) with carbene (equation 16).[81] The ^1H and ^{13}C NMR spectra of (**132**) and (**133**) are identical, indicating that the anions do not play an important role in the bonding of the hypervalent iodine cation. X-ray diffraction of (**133**) showed that the central C–I–C unit (177.5°) is almost linear with slightly longer C–I bond distances than those observed in (**128–130**) and (**133**, C–I 2.286 Å and 2.363 Å). The structure of (**133**) suggests that the C–I–C interaction in (**133**) is stronger than the C–I· · ·I interactions in (**128**) and (**129**).



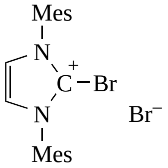
(16)

(**132**), X = I
(**133**), X = BPh_4

Recently, the reactivity of N-heterocyclic carbenes with bromine and some chloride sources were reported.[82,83] Imidazolium chloride salts are sometimes obtained as side products when carbene (**1**) is reacted with main group species to produce main group carbene adducts.[53,74] However, they can be prepared directly from the reaction of carbene (**1**) (R = Mes, R′ = H) with chloroalkanes, such as hexachloroethane in acetonitrile (**134**). Reaction of carbene (**1**) (R = Mes, R′ = H) with Br_2 or 1,2-dibromoethane affords the 2-bromo-1,3-bis(2,4,6-trimethylphenyl) imidazolium bromide (**135**).



(**134**, R = Mes, R′ = H;
R = *i*-Pr, Et, Me, R′ = Me)



(**135**)

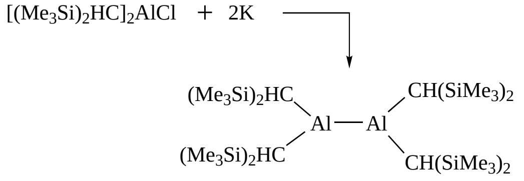
1 INTRODUCTION

The proposition of multiple bonding is, arguably, the most compelling concept throughout the whole of chemistry. While the general concept of multiple bonding is well established and easily embraced in organic chemistry, this is not the case for much of organometallic chemistry. In particular, multiple bonding involving homonuclear compounds of the heavier main group elements is a relatively recent phenomenon. The criteria that are routinely employed to assign double and triple bond character in organic compounds, that is, bond distance and bond strength, are of little significance in many cases involving the heavier main group elements. For example, the E=E (E = Sn, Pb) double bond is both *longer* and *weaker* than the corresponding E–E single bond. Quite obviously, such behavior stands in stark contrast to that of carbon and other lighter main group elements. This is most prominently manifested in the structure of the resulting compounds: 'trans-bent' geometries are preferred over linear structures where triple bonds of the heavier main group elements are concerned. Indeed, a compelling case can be made on the basis of the premise that the behavior of carbon is the exception, rather than the rule, where multiple bonding of many main group elements is concerned. This article will discuss some of the more significant recent discoveries in the chemistry of main group 13, 14, and 15 elements relative to the concept of homonuclear multiple bonding.

2 GROUP 13 MULTIPLE BONDS

2.1 Aluminum Multiple Bonds

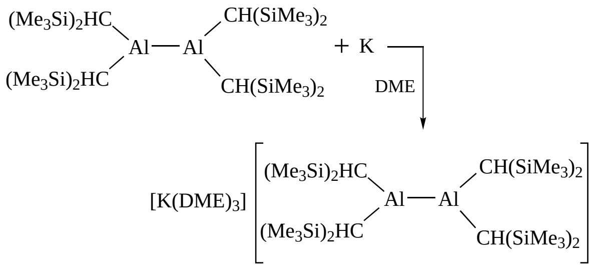
The first compound containing an Al–Al bond was reported in 1988 with tetrakis[bis(trimethylsilyl)methyl]dialane, $[(SiMe_3)_2CH]_2Al{-}Al[CH(SiMe_3)_2]_2$. This compound was prepared by the potassium reduction of bis[bis(trimethylsilyl)methyl]aluminum chloride (equation 1).[1]



(1)

The Al–Al bond distance is 2.660(1) Å. It is noteworthy that the aluminum atoms were shown to reside in trigonal planar environments about a nearly planar $C_2Al{-}AlC_2$ core.

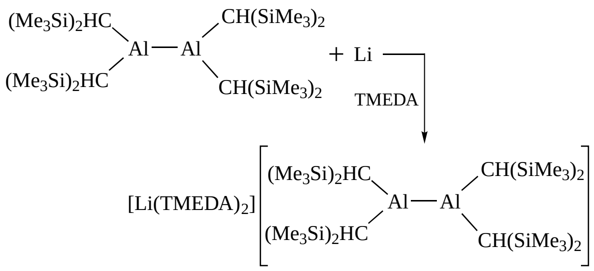
In an attempt to approach a measure of π-bonding between two aluminum atoms, Uhl *et al.* examined the alkali metal reduction of $[(SiMe_3)_2CH]_2Al{-}Al[CH(SiMe_3)_2]_2$. Specifically, sodium or potassium reduction of $[(SiMe_3)_2CH]_2Al{-}Al[CH(SiMe_3)_2]_2$ in dimethoxyethane (DME) afforded dark blue colored crystals of the $[(SiMe_3)_2CH]_2Al{-}Al[CH(SiMe_3)_2]_2^{\bullet -}$ radical anion (equation 2).[2]



(2)

This species, characterized by ESR, UV-VIS, and IR, demonstrated remarkable stability.

The lithium reduction of $[(SiMe_3)_2CH]_2Al{-}Al[CH(SiMe_3)_2]_2$, in the presence of TMEDA (tetramethylethylenediamine), gives an 'Al–Al one-electron π-bond' in the $[(SiMe_3)_2CH]_2Al{-}Al[CH(SiMe_3)_2]_2^{\bullet -}$ radical anion as fine black crystals (equation 3).[3]



(3)

The solid-state structure of $[(SiMe_3)_2CH]_2Al{-}Al[CH(SiMe_3)_2]_2^{\bullet -}$ is very interesting when compared with that of the neutral dialane. The C–Al–C bond angle of 111.9(2)° is smaller than that reported for the neutral dialane (116.7(1)°), while the Al–C bond distances in the radical anion (2.0420(5) Å) are lengthened compared to those of the

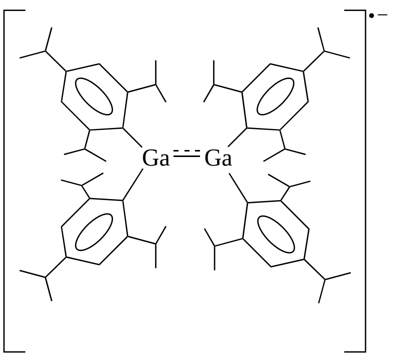
neutral dialane (1.982(5) Å). The Al–Al bond in the radical anion of 2.53(1) Å is considerably shorter than that observed in the neutral dialane (2.660(1) Å). Certainly, this decrease in the Al–Al bond distance (in going from the neutral dialane to the radical anion) is consistent with an interaction of some level of multiple bond character.

The radical anion $[Pr^i_3C_6H_2]_2Al–Al[C_6H_2Pr^i_3]_2^{\bullet-}$ was prepared by the lithium reduction of the neutral dialane. The Al–Al bond distance decreased from 2.647(3) Å in the neutral dialane, $[Pr^i_3C_6H_2]_2Al–Al[C_6H_2Pr^i_3]_2$, to 2.470(2) in the radical anion, $[Pr^i_3C_6H_2]_2Al–Al[C_6H_2Pr^i_3]_2^{\bullet-}$, thus providing evidence of multiple bond character.[4]

The evidence substantially supports a one-electron π-bond between two aluminum atoms. However, a RAl=AlR compound containing a two-electron π-bond has not been reported.

2.2 Gallium Multiple Bonds

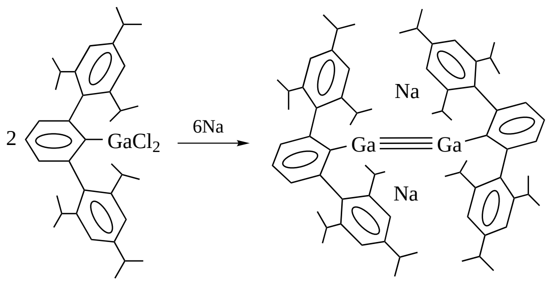
The first compound containing a Ga–Ga bond, $[(SiMe_3)_2CH]_2$ Ga–Ga$[CH(SiMe_3)_2]_2$, was prepared by the reaction of $Ga_2Br_4(dioxane)_2$ with $LiCH(SiMe_3)_2$.[5] The Ga–Ga bond distance was 2.541(1) Å in this yellow crystalline digallane. Reaction of $Ga_2Cl_4(dioxane)_2$ and $(Pr^i_3C_6H_2)MgBr$ affords $[Pr^i_3C_6H_2]_2$ Ga–Ga$[C_6H_2Pr^i_3]_2$, with a Ga–Ga bond distance of 2.515(3) Å.[6] Upon treatment of $[Pr^i_3C_6H_2]_2$ Ga–Ga$[C_6H_2Pr^i_3]_2$ with an excess of lithium powder, followed by the addition of 12-crown-4, dark brown-red crystals of [Li(12-crown-4)]$[Pr^i_3C_6H_2]_2$ Ga–Ga$[C_6H_2Pr^i_3]_2$ (**1**) were isolated.



(**1**)

A comparison of the neutral gallane with the radical anion reveals a number of intermolecular structural changes. The Ga–Ga bond was shortened to 2.343(2) Å, thus providing support for a Ga–Ga one-electron π-bond. In addition, the torsion angle between the two C_2Ga planes decreased to 15.5° compared to the neutral digallane. The nature of the radical anion was supported by a strong ESR signal.

The utilization of sterically demanding *m*-terphenyl ligands facilitated an interesting, if provocative, period in organogallium chemistry. The *m*-terphenylgallium dichloride compound, $[2,6\text{-}(Pr^i_3C_6H_2)_2C_6H_3]GaCl_2$, was prepared from reaction of $[2,6\text{-}(Pr^i_3C_6H_2)_2C_6H_3]Li$ with $GaCl_3$.[7] Sodium metal reduction of $[2,6\text{-}(Pr^i_3C_6H_2)_2C_6H_3]GaCl_2$ yields dark red (almost black) crystals of $Na_2[RGa{\equiv}GaR]$ (R = 2,6-$(Pr^i_3C_6H_2)_2C_6H_3$) (equation 4).[8]



(4)

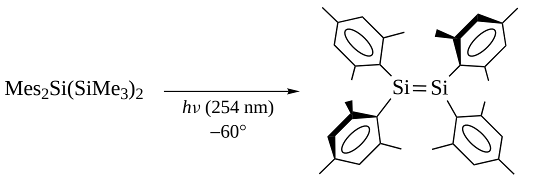
This provocative compound, with a Ga–Ga bond distance of 2.319(3) Å, was referred to as a 'digallyne', thus indicating the first compound containing a Ga–Ga triple bond, albeit a weak triple bond. The C–Ga–Ga–C backbone was decidedly nonlinear with bond angles about the gallium centers of 128.5(4)° and 133.5(4)°. Indeed, this geometry was described as 'trans-bent'. An alternative interpretation of the bonding as being closer to a Ga–Ga double bond was subsequently proposed by another group.[9] Importantly, bond order values for the –GaGa– interaction have been calculated ranging from 2.794[10] to 3.02,[11] clearly supporting the triple bond formulation. Studies by various research groups on the nature of the Ga–Ga interaction in the digallyne also provide compelling support for the triple bond formulation.[12–14] Indeed, few compounds in the realm of multiple bonding among heavier main group elements have been studied as extensively as the digallyne. This area has recently been reviewed.[15–17] It is important to note that the general mode of preparation employed for the gallyne, the trans-bent structure, and the premise that the heavier main group elements exhibit a different means of hybridization from carbon, have all been repeatedly, and consistently, observed in recent reports of triple bond stabilization for silicon and alkyne analogs for germanium, tin, and lead (vide infra).

3 GROUP 14 MULTIPLE BONDS

Multiple bonds involving the lightest member of group 14 are ubiquitous (i.e. alkenes and alkynes) and traditional chemical bonding theories such as Valence Bond Theory can adequately describe such interactions. The chemistry of compounds containing silicon–silicon multiple bonds, disilenes, and disilynes has not developed in parallel with that of carbon. Nonetheless, significant advances have recently been made, most prominently the report of the first example of a –Si≡Si– triple bond.

3.1 Silicon Multiple Bonds

The concept of multiple bonding becomes slightly more complicated concerning silicon. The first compound containing a Si=Si double bond, tetramesityldisilene, $Mes_2Si{=}SiMes_2$ (Mes = mesityl), was reported in 1981 (equation 5).[18]

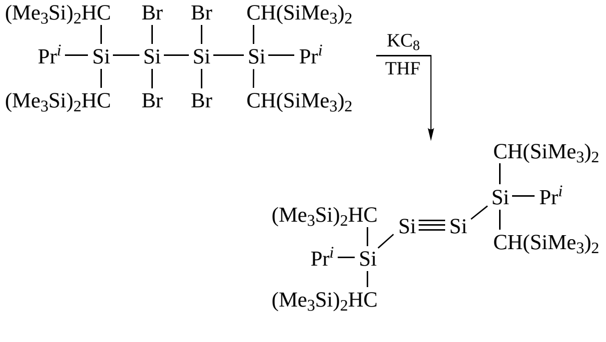


(5)

This seminal compound was isolated as yellow crystals in high yield. The X-ray crystal structure[19] of $Mes_2Si{=}SiMes_2$ revealed a Si=Si double bond distance of 2.15 Å (while typical Si–Si single bond distances approach 2.35 Å). Moreover, the geometry around the silicon atoms was not trigonal planar, as would be expected for carbon, but rather ‘trans-bent’ (with the silicon atoms residing in pseudopyramidal environments). This clearly suggests that multiple bonding involving heavier main group elements may behave differently than carbon.

The concept of a compound containing a Si–Si triple bond, R–Si≡Si–R, has fascinated chemists for decades. In particular, computational and theoretical chemists have long predicted that large bulky ligands will be necessary to stabilize the Si≡Si interaction and that the linear geometry is not a global minimum but the trans-bent geometry is favored.[20,21] Furthermore, it has been predicted that the bonding between two such silicon atoms would best be described as two dative (donor–acceptor) bonds and one π-bond. This bonding model is at odds with the traditional manner to describe a triple bond between two carbon atoms: one σ-bond and two π-bonds.

Quite recently, this most sought after prize was won: A group of workers succeeded in synthesizing a stable compound containing a –Si≡Si– triple bond. Sekiguchi and coworkers isolated 1,1,4,4-tetrakis[bis(trimethylsilyl)methyl]-1,4-diisopropyl-2-tetrasilyne from reaction of 2,2,3,3-tetrabromo-1,1,4,4-tetrakis[bis(trimethylsilyl)methyl]-1,4-diisopropyl-tetrasilane with four equivalents of potassium graphite in tetrahydrofuran (equation 6).[22]

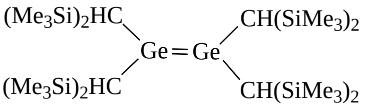


(6)

The air- and moisture sensitive disilyne was isolated as green crystals. The –Si≡Si– triple bond distance was shown to be 2.0622(9) Å via single crystal X-ray diffraction. Perhaps most importantly, the two silicon atoms engaged in the triple bond reside in a ‘trans-bent’ environment about a bond angle of 137.44(4)°.

3.2 Germanium Multiple Bonds

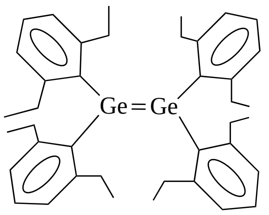
An early report discussed the synthesis and structure of a cyclotrigermane, hexakis(2,6-dimethylphenyl) cyclotrigermane, and its photoconversion to a digermene (which was not structurally characterized).[23] Reaction of $MgClR(OEt_2)$ ($R = CH(SiMe_3)_2$) with $GeCl_2$(dioxane) produced bright yellow crystals of $[(Me_3Si)_2HC]_2Ge{=}Ge[CH(SiMe_3)_2]_2$: the first solid-state compound containing a Ge=Ge double bond (**2**).[24]



(**2**)

The compound was reported to have C_{2h} symmetry about the Ge_2C_4 core with a fold angle of 32°. Furthermore, the germanium environment was described as being between pyramidal and planar. The Ge=Ge double bond distance was reported as 2.347(2) Å.

Masamune and coworkers subsequently reported the structure of tetrakis(2,6-diethylphenyl)digermene, isolated from the photoconversion of the corresponding cyclotrigermane (**3**).[25] The Ge=Ge bond distance of 2.213 Å in $[2,6\text{-}Et_2C_6H_3]_2Ge{=}Ge[C_6H_3\text{-}2,6\text{-}Et_2]_2$ is considerably shorter than that in (**2**) (2.347(2) Å).

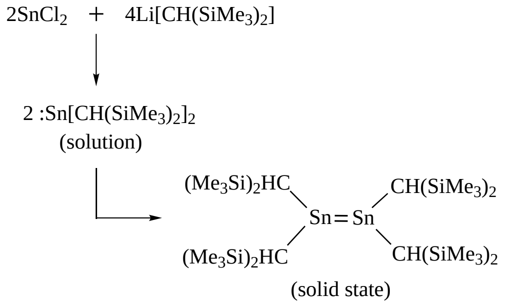


(**3**)

Recently, the $[2,6\text{-}Mes_2C_6H_3]_2Ge{=}Ge[C_6H_3\text{-}2,6\text{-}Mes_2]_2$ digermene has been reported utilizing a sterically demanding *m*-terphenyl ligand.[26] In addition, a germanium analog of an alkyne, albeit with significant electron lone-pair character on the metal atoms and ‘bond orders that are less than three’, has been reported.[27]

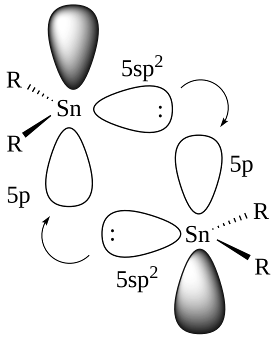
3.3 Tin Multiple Bonds

The first compound containing a Sn=Sn double bond was reported nearly three decades ago. Reaction of tin(II) chloride with bis(trimethylsilyl)methyllithium, Li[CH($SiMe_3$)$_2$], gave the diamagnetic species **:**Sn[CH($SiMe_3$)$_2$]$_2$ in solution. However, upon crystallization, the species dimerizes into [(Me_3Si)$_2$HC]$_2$Sn=Sn[CH($SiMe_3$)$_2$]$_2$ – the first distannene containing ‘a tin–tin (‘bent’ double) bond’ (equation 7).[28]



(7)

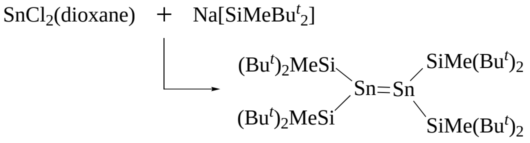
Again, the molecule resides in a ‘trans-bent’ configuration with the tin atoms in pyramidal geometries. The Sn=Sn double bond distance was shown to be 2.76 Å with the mean Sn–Sn–C bond angle of 115° and the C–Sn–C bond angle of 112°. The authors regarded the dimerization as ‘aggregation of two singlet bent monomers, whereby the approximately sp_xp_y [sp^2] lone-pair hybrid filled orbital on the tin atom of one of the partners overlaps with the vacant p_z orbital of the other’ (**4**). Concluding, the authors stated, ‘‘The molecule is thus considered as having a ‘bent’ and weak SnSn double bond, which also accounts for the relative disposition of the two sets of R groups with respect to each other.’’



(**4**)

The Sn=Sn double bond distance of 2.76 Å for [(Me_3Si)$_2$HC]$_2$Sn=Sn[CH($SiMe_3$)$_2$]$_2$ compares to a value of 2.770(4) Å for hexaphenyldistannane,[29] Ph_3Sn–SnPh_3: within experimental error the Sn=Sn double bond distance and the Sn–Sn single bond distance are equivalent.

Recently, a striking distannene, prepared from the reaction of Bu^t_2MeSiNa and $SnCl_2$(dioxane) in tetrahydrofuran (equation 8), in the form of [Bu^t_2MeSi]$_2$Sn=Sn[SiMeBu^t_2]$_2$ was reported.[30]



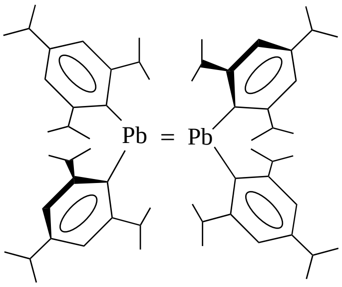
(8)

The most intriguing aspect of this compound is the fact that the Sn=Sn double bond remains intact both in solution and in the solid state. This behavior is in marked contrast to other distannenes that exhibit monomeric behavior in solution. As described by the authors, this compound serves up a number of interesting points structurally. The Sn=Sn bond distance of 2.6683(10) Å is the shortest of all distannenes. Continuing, the sp^2 Sn atoms reside in planar environments – this is in sharp contrast to all other distannenes that unambiguously display trans-bent environments. A last significant point concerns a twist angle of the Sn=Sn double bond of 44.62(7)°. It is most surprising that the Sn=Sn bond remains intact under such a twist angle.

Similar to the case for germanium, a stable tin ‘analog’ of an alkyne, albeit with significant electron lone-pair character on the metal atoms and ‘bond orders that are less than three’, has been reported in RSnSnR (R = 2,6-(2,4,6-$Pr^i_3C_6H_2$)$_2C_6H_3$) by the potassium reduction of RSnCl.[31] The Sn–Sn bond distance was reported as 2.6675(4) Å with a Sn–Sn–C bond angle of 125.24(7)°. The overall geometry is trans-bent. It should be noted that the general structure and description of the bonding in this compound is quite similar to the $RGaGaR^{2-}$ digallyne.

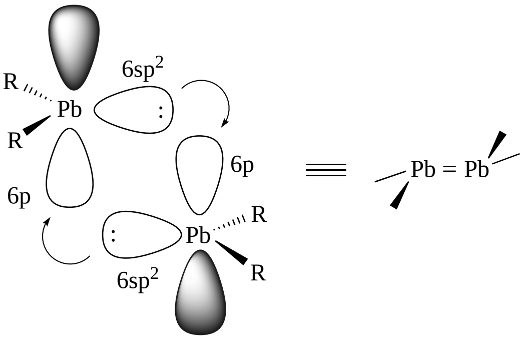
3.4 Lead Multiple Bonds

A compound containing an unambiguous example of a double bond between atoms of the heaviest member of group 14, lead, has only recently been reported. This compound, ($Pr^i_3C_6H_2$)$_2$Pb=Pb($C_6H_2Pr^i_3$)$_2$ (**5**), was prepared by reaction of lead(II) chloride with 2,4,6-triisopropylphenylmagnesium bromide at low temperature.[32] Reaction gave a violet solution, from which red crystals were isolated. The crystals were reported to be thermally stable, but light- and air-sensitive. The compound resides in a trans-bent geometry with a Pb=Pb double bond distance of 3.0515(3) Å.



(**5**)

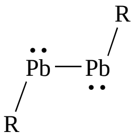
The Pb=Pb double bond distance of 3.0515(3) Å is easily compared to the Pb–Pb single bond distances of 2.83 Å for Ph_3Pb–$PbPh_3$ (Ph = phenyl)[29] or 2.8697(10) Å for Bp_3Pb–$PbBp_3$ (Bp = biphenyl).[33] Here again is an example of a heavier main group element engaging in multiple bond formation. However, the heavier main group atoms display a resistance to hybridize in the same fashion as carbon. Rather, the Pb=Pb double bond is depicted (**6**) showing the orbital overlap in two donor−acceptor interactions.



(**6**)

The authors pointed out that bond distances and bond strengths, unlike the case for carbon, are of little significance where multiple bonding of the heavier main group metals is concerned.

Reaction of $LiAlH_4$ with Pb(Br)R (R = 2,6-$(Pr^i_3C_6H_2)_2$ C_6H_3) has been reported to yield a lead analog of an alkyne.[34] The Pb–Pb bond distance of 3.188(1) Å for RPbPbR is longer than the Pb=Pb distance of 3.0515(3) Å for $(Pr^i_3C_6H_2)_2Pb{=}Pb(C_6H_2Pr^i_3)_2$. The fact that the C–Pb–Pb bond angle for RPbPbR is 94.26(4)° is perhaps suggestive that the most important contributing resonance structure should be the one with considerable lone-pair electron character on the two lead atoms (**7**).



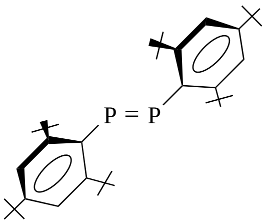
(**7**)

4 GROUP 15 MULTIPLE BONDS

The iconic molecule of multiple bonding of the group 15 elements is obviously dinitrogen, N_2. The **:**N≡N**:** triple bond and the chemistry that springs from it are ubiquitous. The chemistry of multiple bonds of the heavier group 15 elements is not as well developed. However, significant progress and important discoveries have recently been made in this area.

4.1 Phosphorus Multiple Bonds

Bis(2,4,6-tri-*tert*-butylphenyl)diphosphene, (2,4,6-Bu^t)$_3$ $C_6H_2P{=}PC_6H_2$(2,4,6-Bu^t)$_3$, the first compound with a formal P=P double bond, was prepared from the magnesium reduction of (2,4,6-Bu^t)$C_6H_2PCl_2$ (**8**).[35]



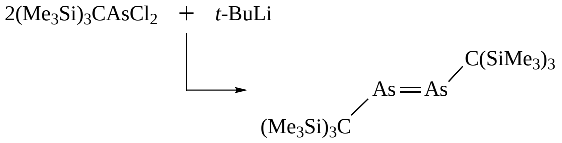
(**8**)

The P=P double bond distance of 2.03 Å for (2,4,6-Bu^t)$_3C_6H_2P{=}PC_6H_2$(2,4,6-Bu^t)$_3$ compares with the P–P single bond distance of 2.23 Å for P_4.

Even though great advances in the chemistry of the P=P double bond have taken place over the past two decades,[36] new and interesting diphosphenes, some utilizing sterically demanding *m*-terphenyl ligands continue to be reported.[37–39]

4.2 Arsenic Multiple Bonds

The chemistry of the As=As double bond is quite similar to that of phosphorus. Stabilization of the As=As double bond has been known for almost two decades. The As=As bond distance in bis[tris(trimethylsilyl)methyl]diarsene, $(SiMe_3)_3CAs{=}AsC(SiMe_3)_3$, prepared by reaction of $(Me_3Si)_3CAsCl_2$ and *tert*-butyllithium, is typical at 2.45 Å.[40]

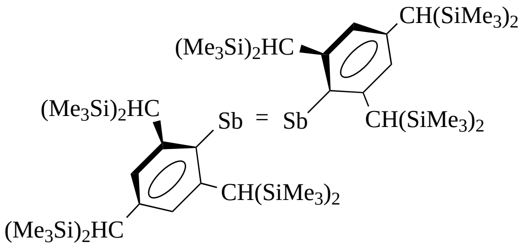


(9)

4.3 Antimony Multiple Bonds

The first stable compound containing an Sb=Sb double bond was only reported in 1998 with (Tbt)Sb=Sb(Tbt) (Tbt = 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl) (**9**).[41] The molecule was prepared in high yield as deep green crystals. The molecule has a trans-bent geometry.

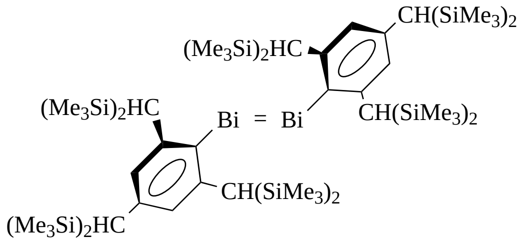
The Sb=Sb double bond was reported as 2.642(1) Å. Interestingly, (Tbt)Sb=Sb(Tbt) undergoes reaction with molecular oxygen to yield a di-μ-oxo dimeric species, (Tbt)Sb(μ-O)$_2$Sb(Tbt), while still maintaining the Sb–Sb bond (although considerably lengthened at Sb–Sb**:** 3.039(1) Å).[41]



(**9**)

4.4 Bismuth Multiple Bonds

The synthesis of the first stable compound containing a Bi=Bi double bond, (Tbt)Bi=Bi(Tbt) (Tbt = 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl), (**10**),[42] was achieved by a rather involved procedure concerning the deselenation of triselenatribismane with a phosphine reagent.[43] The key intermediate in this synthesis a triselenatribismane. The synthetic procedure continued with the treatment of this intermediate with an excess amount of hexamethylphosphorus triamide and heating for 12 h. Finally, the dibismuthene was isolated as deep purple single crystals. This was a significant discovery: a homonuclear double bond involving the heaviest stable (i.e. nonradioactive) element on the periodic table.



(**10**)

The Bi=Bi double bond distance in (Tbt)Bi=Bi(Tbt) of 2.8206(8) Å compares to the Bi–Bi single bond distance of 2.990(2) Å for $Ph_2Bi–BiPh_2$.[43]

1 INTRODUCTION

The copper enzymes covered in this article span a wide range in terms of both their structural and reactivity properties. Yet the copper centers in each share similar coordination geometries and have been designated 'Type 2 (or II)' copper proteins. Type 2 copper proteins lack the unique spectroscopic or magnetic signatures that typify the so-called Type 1 and Type 3 copper proteins, and the unique tetranuclear cluster found in nitrous oxide reductase (*see* ***Copper Proteins with Dinuclear Active Sites***; ***Copper Proteins: Oxidases***; ***Copper Proteins with Type 1 Sites***, and ***Copper Enzymes in Denitrification***). Indeed, the basis for classifying proteins as Type 2 was that the EPR (Electron Paramagnetic Resonance) spectra of the oxidized (resting) forms of these proteins closely resembled the spectra of 'normal' tetragonal Cu^{II} complexes, with $g_{\parallel} > g_{\perp} > 2.00$, and $A_{\parallel} > 120$ G at X-band. It was generally surmised that the coordination environments of the copper sites in such enzymes were unexceptional, with five- or six-coordinate structures composed of N, O ligands. As is often the case in science, many fascinating and totally unexpected structural and chemical phenomena turned out to be concealed behind this deceptively 'normal' facade. Each of the Type 2 enzymes covered here (superoxide dismutase, amine oxidase, lysyl oxidase, galactose oxidase, dopamine-β-monooxygenase, peptidylglycine α-hydroxylating monooxygenase, and quercetinase) displays unique active-site properties.

Elucidating and elaborating structure/function relationships for these enzymes has been greatly aided by the availability of high-resolution crystal structures for one or more enzymes from each group: superoxide dismutase, galactose oxidase, amine oxidase, peptidyglycine α-hydroxylating monooxygenase, and quercetinase. These have generally corroborated the fairly detailed structural models that were developed from extensive spectroscopic studies. At the same time, the 3D structures have revealed many surprising details of the active sites. Indeed, the roles of copper in these 'normal' Type 2 copper centers are more diverse than ever imagined.

2 TYPE 2 COPPER PROTEINS: OVERVIEW

As noted above, a copper-containing protein could be classified on the basis of its EPR spectrum. Type 2 proteins display EPR spectra similar to that of bovine Cu, Zn superoxide dismutase (SOD) shown in Figure 1(a).[1] In the absence of additional chromophores, a Type 2 protein would display an absorption spectrum like that of Figure 1(b). These spectral features, particularly the lack of an intense, low-energy ligand-to-metal charge-transfer (LMCT) transition, immediately suggest the absence of cysteine in the first coordination shell of the enzyme Cu^{II}. A classic analysis of the EPR spectra of Cu^{II} proteins and model complexes, based on correlating $g_{\parallel}$ and $A_{\parallel}$ values with the identities of ligand donor atoms, also indicated that Type 2 copper sites were composed primarily of N, O ligands.[2] Using peptide and amino acid complexes of Cu^{II} as a guide (*see* ***Peptide–Metal Interactions***), the most plausible ligands for Type 2 centers are histidine imidazole, tyrosine phenolate, amide side chains, peptide carbonyl or nitrogen groups, and water or hydroxide. The basic spectroscopic properties of Type 2 sites[3] (Figure 1) further established that these centers contained magnetically isolated $S = 1/2$ Cu^{II} ions in tetragonal five- or six-coordinate geometries. In other words, such a copper site would be mononuclear with a set of four ligands that roughly define a plane, the so-called equatorial plane, with one or two ligands above or below the plane (the axial ligands). Cu^{II} sites with trigonal or tetrahedral coordination geometries, or that are multinuclear, are expected to have spectroscopic properties that differ substantially from those of Type 2 centers.[4] Cu^{II} with a tetragonal coordination geometry has a $d_{x^2-y^2}$ ground

state, that is, this would be the d orbital that is half-filled, and a ligand-field energy diagram (*see* ***Ligand Field Theory & Spectra***) that simply gives the relative energies of the five 3d valence orbitals, similar to that shown in Figure 2.

Many spectroscopic experiments strongly suggested that water (or hydroxide) was a Cu^{II} ligand in most Type 2 proteins.[5] Facile binding of exogenous ligands by Type 2

Cu^{II} centers is commonly observed and is consistent with the presence of a readily substituted group, for example, a nonprotein ligand, in the first coordination shell of the copper. This aspect of the reactivity of Type 2 copper sites has been previously reviewed.[6] The 3D structural data confirm that water binds to Type 2 coppers. In galactose oxidase, superoxide dismutase, and quercetinase, rapid ligand substitution (substrate binding) at Cu^{II} is involved in the catalytic cycle. Additionally, ligand substitution by tyrosine is part of the copper-catalyzed self-processing mechanisms that create redox-active organic cofactors in galactose oxidase, amine oxidase, and lysyl oxidase. For peptidylglycine α-hydroxylating monooxygenase, substrate has been proposed to be a part of the electron transfer pathway between the two Type II copper centers. More generally, oxygen activation via coordination at Cu^{I} may be an important process in Type 2 copper enzymes.

As discussed in the following sections, the catalytic diversity of enzymes containing Type 2 copper is striking. Much progress has been made in understanding how the protein environments modulate a tetragonal Cu^{II} site to achieve these varied activities. Key information has been obtained from NMR and/or X-ray structures of the Type 2 enzymes.

3 Cu, Zn SUPEROXIDE DISMUTASE

This protein is probably the most extensively studied copper-containing enzyme. Cu, Zn superoxide dismutase was the first copper protein to be structurally characterized via X-ray crystallography.[7] Cu, Zn SOD is a very widespread and homologous class [EC 1.15.1.1] of enzymes among eukaryotes. The enzyme has also been identified in several prokaryotes, although here there is considerable diversity in primary sequence and quaternary structure. In addition, Ni-, Mn-, and Fe-containing superoxide dismutases (SODs) are also known. Ni SOD and Fe SOD are found in prokaryotes whereas the Mn SOD is found in prokaryotes and in mitochondria. The Fe and Mn SODs are homologous but structurally unrelated to the Ni SOD, or the Cu, Zn SOD discussed here (*see* ***Iron Proteins with Mononuclear Active Sites***; ***Manganese Proteins with Mono- & Dinuclear Sites***, and ***Nickel Enzymes & Cofactors***). All four types of SOD catalyze the dismutation of superoxide (*see* ***Oxygen: Inorganic Chemistry*** and equation 1).

$$\bullet O_2^- + \bullet O_2^- + 2H^+ \longrightarrow O_2 + H_2O_2 \qquad (1)$$

The catalyzed reaction is extremely rapid with a second-order rate constant on the order of $10^9\ M^{-1}s^{-1}$ at ambient temperature and neutral pH.[8] This is well within the range of diffusion-controlled reactions in aqueous solutions under these conditions. Reaction (1) is generally regarded to proceed

in two steps involving cyclical reduction/oxidation of the active-site metal ion, as shown in equations (2) and (3).[9]

$$\text{E-Cu}^{II} + \bullet O_2^- \longrightarrow \text{E-Cu}^{I} + O_2 \quad (2)$$

$$\text{E-Cu}^{I} + \bullet O_2^- + 2H^+ \longrightarrow \text{E-Cu}^{II} + H_2O_2 \quad (3)$$

Kinetics studies have shown that the rates of the electron-transfer steps are faster than the encounter rate between $\bullet O_2^-$ and the enzyme. The encounter rate is independent of the copper oxidation state. K_M for $\bullet O_2^-$ is high ($\sim$3.5 mM),[10] which means that, under nearly all conditions, superoxide dismutase turnover is far from saturated.

The overall structure of Cu, Zn SOD is shown in Figure 3;[11] details of the oxidized and reduced forms of the active site are shown in Figure 4.[12] To date, crystal or solution structures are available for Cu, Zn SODs from human, bovine, yeast, spinach, frog, and Gram-negative bacterial sources, in oxidized, reduced, apo-, metal-substituted and/or amino acid mutant forms. (See PDB entries 1Q0E, 1P1V, 1PU0, 1PTZ, 1HL5, 1OAL, 1F1G, 1F1D, 1F1A, 1F18, 1N19, 1N18, 1KMG, 1L3N, 1IBH, 1IBF, 1IBD, 1IBB, 1IB5, 1E9Q, 1E9P, 1E9O, 1EQW, 1DSW, 1EJ8, 1YAZ, 1SXZ, 1SXS, 1QUP, 1P4T, 1B4L, 1FUN, 2JCW, 1MFM, 1BZO, 1CBJ, 1CB4, 2APS, 1BA9, 1ESO, 1AZF, 1SXW, 1YAI, 1YSO, 1JCV, 1SXA, 1SXB, 1SXC, 1XSO, 3SOD, 2SOD, 1SRD, 1SPD, 1SOS, 1SDY, 1SDA, and 1COB, and associated references.) The eukaryotic proteins are dimers composed of two identical 16 kD subunits. In contrast, the prokaryotic enzymes are isolated in either monomeric or dimeric forms, depending on the bacterial species. The principal structural features are highly conserved among the proteins. The overall protein fold is a cylindrical β-barrel composed of eight antiparallel β-strands with three external loops (Figure 3).[11,13] Two of these loops modulate zinc binding or substrate/anion access to the active site. Although the overall fold is conserved across species, the bacterial enzymes use internal β-strands to form the dimer interface whereas the eukaryotic proteins juxtapose the N- and C-terminal β-strands. In all cases, subunit interactions are due mainly to hydrophobic interactions. Additional differences among the two classes of SODs are evident in the loop responsible for electrostatic guidance of the substrate into the active site.

The ligands of the metal centers of Cu, Zn SODs are highly conserved across species and are identical in sequence order, coordination geometry, and intersubunit separation. Cu, Zn SODs are notable for several interesting

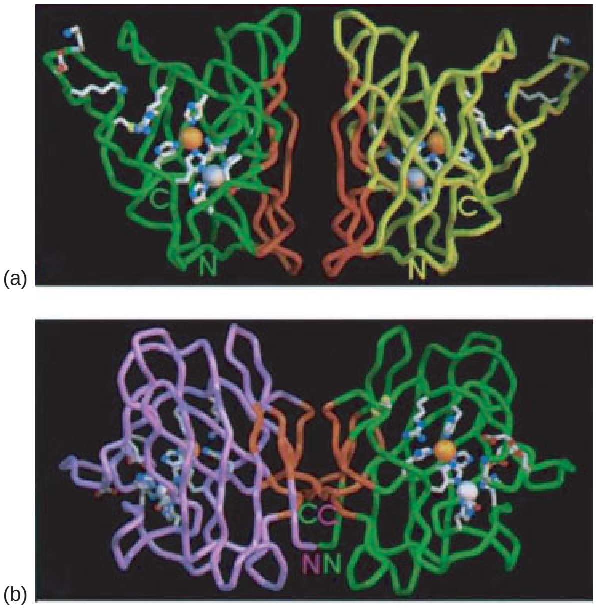

Figure 3 Comparison of the folds and dimer assemblies of (a) prokaryotic CuZnSOD with (b) bovine CuZnSOD. Functionally important side chains for the active site, disulfide cysteines, and electrostatic recognition residues are displayed with white bonds and atom-colored spheres. Dimer interface regions are highlighted in orange; metals are shown as spheres: copper (orange) and zinc (silver). (Reproduced from Y. Bourne, S.M. Redford, H.M. Steinman, J.R. Lepock, J.A. Tainer, and E.D. Getzoff, *Proc. Natl. Acad. Sci. USA*, 1996, **93**, 12774. © 1996 National Academy of Sciences, USA)

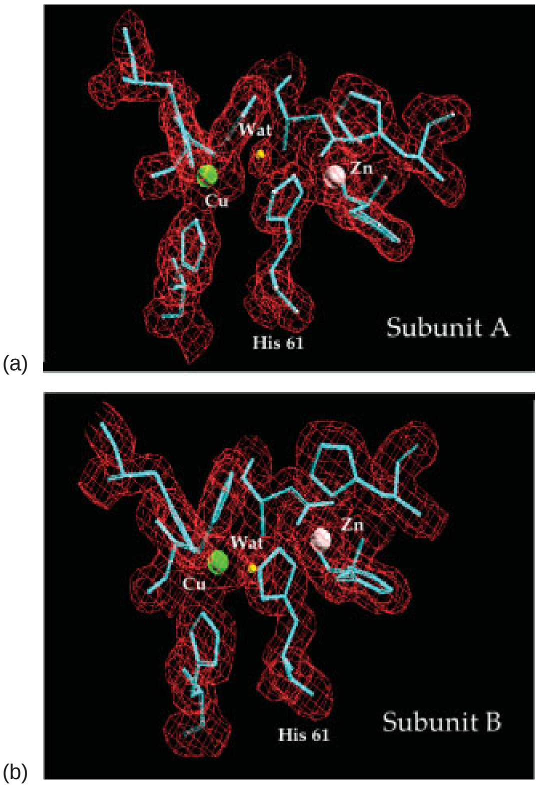

Figure 4 Close-up view of the Cu, Zn SOD active site in (a) reduced and (b) oxidized form. Copper is represented by the yellow spheres, zinc by the blue spheres. Water molecules are represented by the smaller, cyan, spheres. The shifts of water and the bridging His61 are clearly visible in (a), the reduced site. (Reprinted from Ref. 12. © 1999, with permission from Elsevier)

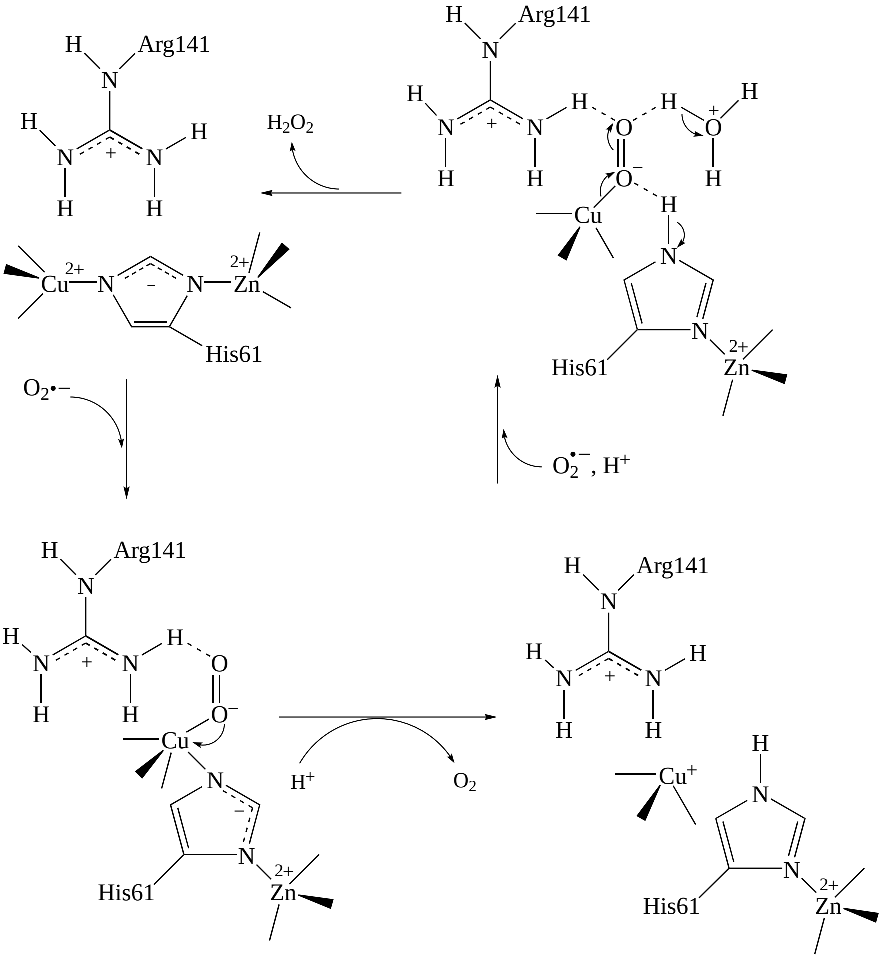
or novel aspects of their active-site structure and metal-ion coordination (Figure 4). The Cu^{II} ion is at the bottom of a deep channel; metal ion ligands form the floor of the channel. There is a potential binding site for superoxide positioned between the copper and a guanidinium side chain from a conserved arginine residue. A deprotonated imidazole group (imidazolate) from a histidine residue bridges the Cu^{II} and Zn^{II} ions in the oxidized form; the distance between the Cu^{II} and Zn^{II} is ~6 Å.[11–13] Not surprisingly, the Zn^{II} coordination geometry is approximately tetrahedral, but the Cu^{II} is in a distorted square pyramidal geometry with four coordinated histidine imidazoles at an average distance of 2.1 Å (including the bridging group) and a coordinated water molecule at about the same or a slightly longer distance. A reasonable way to formulate the structure is to think of the four imidazole nitrogens as roughly defining the equatorial 'plane', but with a pronounced tetrahedral distortion, and to assign the water molecule to an axial position. The coordinated water molecule exchanges very rapidly with solvent water.[5]

Numerous experiments have established that the copper center has the role of a redox catalyst, as shown in equations (2) and (3). A plausible mechanism, based on the premise that Cu^{II}/Cu^{I} cycling is important and emphasizing the role of the essential arginine, is presented in Scheme 1.[13] Recent structural studies[11,12] have confirmed spectroscopic observations that the bridging His ligand is broken upon copper reduction. The coordinating water is also displaced and the Cu(I) center becomes trigonal planar, as indicated in Figure 4(b). Zn^{II} does not appear to be catalytically important since a copper-containing, zinc-depleted form of SOD is nearly fully active.[14] Hence Zn^{II} appears to have primarily a structural role both in organizing the metal-binding region and stabilizing the native conformation. Consistent with a structural role, the Zn^{II} ion is not accessible to solvent and, with a tetrahedral four-coordinate geometry around a d^{10} metal ion, is effectively coordinatively saturated (*see* ***Coordination Numbers & Geometries***).

Since superoxide is a small anion, and since cells contain high concentrations of anions, the problem of substrate

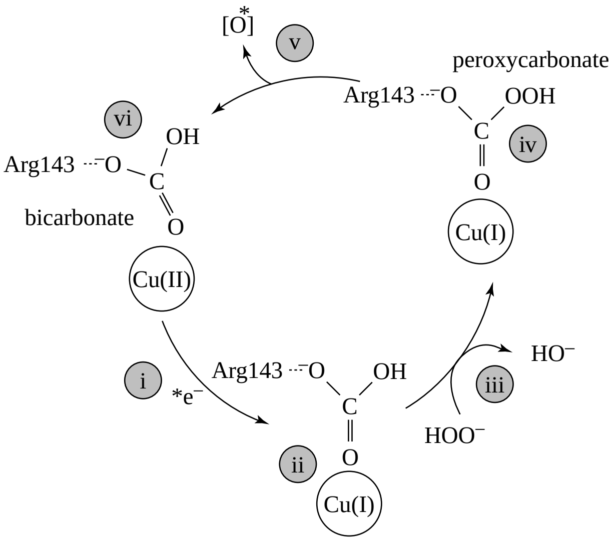


Scheme 1 A possible mechanism for superoxide dismutation catalyzed by Cu, Zn SOD, emphasizing Cu^{II}/Cu^{I} cycling. (Ref. 13. Reproduced by permission of Nature Publishing Group)

recognition by superoxide dismutase appears to be an intriguing one. An experimental indication of this may be the unusual ionic strength dependence of the SOD rate. Most Cu, Zn SODs have a net negative charge, as does superoxide. However, the reaction rate decreases with increasing ionic strength (at constant pH), in contrast to expectations based on simple diffusion models for encounters of ions with the same type of charge.[9,15] Superoxide substrate is electrostatically guided into the active site through interactions with charged amino acid side chains that line the substrate channel. The channel progressively narrows as it approaches the active site; the essential arginine residue and an active site threonine prevent the binding of large nonsubstrate anions.[15–17]

Several anions are known to bind to Cu^{II}, probably occupying the axial binding site between Cu^{II} and the arginine, thereby inhibiting the SOD activity. This chemistry has been thoroughly investigated because small anions may be regarded as substrate analogs; excellent reviews are available.[5,6] Of special interest is the reaction of SOD with bicarbonate, an anion that is present at high concentrations in the blood. Bicarbonate binding is associated with peroxidase activity, leading to the generation of reactive oxygen radicals as shown in Scheme 2.[17] It is postulated that initial formation of peroxycarbonate is followed by the production of a reactive oxygen radical species, O•. In turn, this species may interact with exogenous substrates that are too large to access the active site. Alternatively, oxidization of one of the histidyl copper ligands may occur, leading to loss of the copper ion and subsequent enzyme inactivation.

Over 90 mutations in human Cu, Zn SOD have been associated with familial amyotrophic lateral sclerosis (FALS), a fatal disease in which motor neurons are destroyed (*see* ***Metal-related Diseases of Genetic Origin***).[18] Several roles of SOD in FALS have been proposed; numerous reviews describe these in considerable depth.[19] Rather than the disease being caused by a decrease in SOD activity, it appears that FALS is associated with an as yet undefined gain of function by the SOD protein itself. Possible roles include higher peroxidase/oxidant reactivity and/or the formation of aberrant protein aggregates. Interestingly, the mutations are spread throughout the structure (Figure 5).[18] They may be classified into two groups based on their metal content and activity. More severe forms of FALS are associated with missense mutations in either the metal ligands or in the loops associated with electrostatic steering or zinc binding; these have compromised thermal stabilities as well as lower affinities for both copper and zinc. Hence, it is unlikely that this class of FALS mutants, termed metal-binding region mutants by Valentine *et al.*, causes oxidative damage, since this would require copper-loaded, active SOD. It is known that metal binding strongly influences the stability of the β-barrel. One hypothesis is that the lack of active-site metal ions leads to the unraveling of the edge strands of the β-barrel, which then form toxic aggregates.



Scheme 2 Proposed mechanism for bicarbonate-mediated peroxidation in SOD. After Cu(II) reduction (i), bicarbonate binds to the anion-binding site (ii). In (iii), HOO^- reacts with bicarbonate to form peroxycarbonate (iv). In (v), the oxygen radical species formed [O*] may oxidize endogenous or exogenous substrates. This leaves bicarbonate bound to the anion-binding site (vi). (Ref. 17. Reproduced by permission of American Society for Biochemistry & Molecular Biology)

In contrast, metal and structural analyses of the second group of FALS mutants show that these proteins are fully capable of binding metals and retain enzymatic activity, if they are properly folded. Thus, they have been termed wild-type-like. It is postulated that these mutants have higher prooxidant activity (possibly via bicarbonate-mediated inactivation, see Scheme 2). Self-inactivation could lead to metal loss and similar aggregation effects described for the metal-binding-region mutants.

In vitro, both metals in the active site of SOD can be reversibly removed. This behavior has been elegantly expanded to produce a variety of metal-substituted derivatives.[20] Co^{II}, Ni^{II}, and Ag^{I} derivatives, where the added metal ion may occupy the copper site or the zinc site (and in some cases both), have proven especially valuable in providing new spectroscopic probes of metal-site structure and reactivity in Cu, Zn SOD. Application of in vitro metal substitution to several of the FALS wild-type-like mutants has shown that these variants readily misfold and often exhibit altered metal ion binding.[21] In addition to the in vitro metal studies, recent work has centered on the mechanism of in vivo copper incorporation. CCS is a copper chaperone protein that forms a heterodimer with Zn-loaded SOD to insert copper and activate the enzyme (*see* ***Metallochaperones & Metal Ion Homeostasis***).

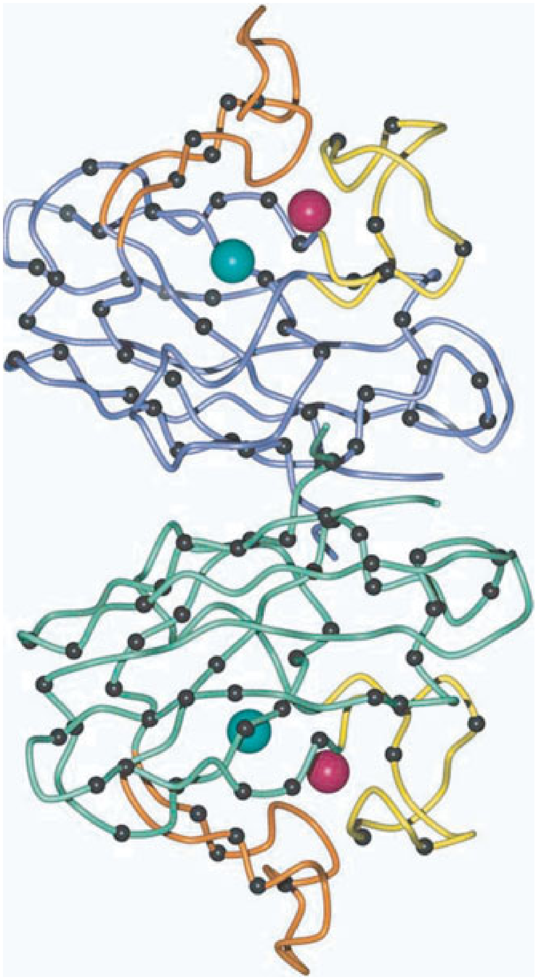


Figure 5 Backbone structure of CuZnSOD dimer showing zinc (red sphere), copper (green sphere), and the positions of FALS missense mutations (small black spheres). The β-barrel of the monomer is colored either green or blue. The electrostatic loop on each monomer is shown in orange while the zinc loop is colored yellow. (R.A. Steiner, K.H. Kalk and B.W. Dijkstra, *Proc. Natl. Acad. Sci. USA*, 2002, **99**, 16625. © 2002 National Academy of Sciences, USA)

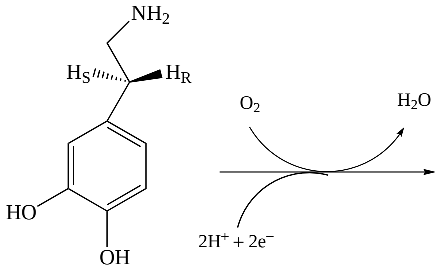
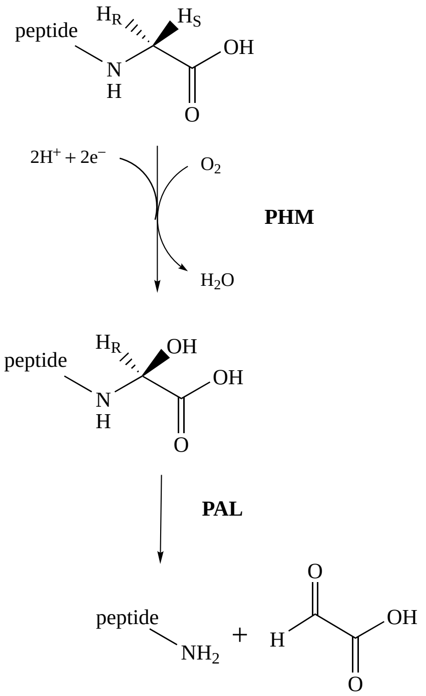
4 DOPAMINE-β-MONOOXYGENASE (DβM) AND PEPTIDYLGLYCINE α-AMIDATING MONOOXYGENASE (PAM)

Dopamine β-monooxygenase (DβM, EC 1.14.17.1) and peptidylglycine α-amidating monooxygenase (PAM, EC 1.14.17.3) are related enzymes of the central nervous system.[22,23] DβM (also known as dopamine β-hydroxylase) is the enzyme responsible for the hydroxylation of dopamine to form norepinephrine, as shown in equation (4). Both substrate and product are hormones/neurotransmitters. PAM is a bifunctional enzyme; one domain, called peptidylglycine α-hydroxylating monooxygenase (PHM, EC 1.14.17.3) catalyzes a mechanistically similar reaction to DβM–the hydroxylation of Gly-terminal peptides. The second domain contains peptidyl α-hydroxyglycine α-amidating lyase (PAL, EC 4.3.2.5) activity, which subsequently hydrolyzes the initially formed α-hydroxyglycyl derivative to produce an α-amidated, bioactive peptide and glyoxylate (equation 5). Despite the marked differences in substrate specificities, the two enzymes utilize the same general mechanism.[22–24] Hence, information gleaned about the structure and mechanism of one enzyme has often been applied to the other.



(4)



(5)

DβM is located in the chromaffin granules of the adrenal medulla and in synaptic vesicles of the sympathetic nervous system.[22] Owing to its critical role in neurotransmitter metabolism, DβM is of great pharmaceutical interest. DβM exists in both soluble and membrane-bound forms, with the membrane form retaining the amino-terminal signal peptide. The soluble enzyme is a tetramer with a total $M_r \approx 290$ kD; the subunit $M_r \approx 75$ kD. The subunits are arranged in disulfide-linked pairs. DβM is a glycoprotein, with approximately 4% carbohydrate by weight. PAM catalyzes the *C*-terminal amidation of peptides from the nervous and endocrine systems; over half of all bioactive peptides are processed in this way.[23] PAM activity appears to be restricted to neuronal and endocrine tissues. Multiple forms of PAM have been

identified in these tissues, resulting from alternative splicing that governs the presence of a transmembrane domain and/or a domain that triggers the cleavage of the PAL domain by endoproteases. When expressed as a 35-kDa monomer, the catalytic core of the PHM domain is fully active.

The active sites of DβM and PHM contain two catalytically essential copper ions. EPR spectra of the oxidized forms of these proteins are typical for Type 2 copper with N, O donor ligands.[24,25] The copper centers are not coupled and are at least 5 Å apart.[22,23] Note the stereochemistry of hydroxylation in equations (4) and (5); both reactions proceed with retention. ^{18}O tracer experiments for the enzymes provided direct evidence for the incorporation of molecular oxygen into the substrate, and both exhibit large deuterium kinetic isotope effects.[22,26,27] In both cases, ascorbate is the physiological reductant. These biochemical similarities are confirmed by sequence comparisons, which pinpoint a conserved catalytic domain.[23] The copper ligands of both the oxidized or reduced states of DβM and PHM are conserved; the H–X–L (L = His or Met) motif is a common copper-binding sequence.

A large body of work in the 1980s and early 1990s strongly suggested that bovine DβM uses a radical mechanism during catalysis.[22] The two copper ions are first reduced by ascorbate. The substrates O_2 and dopamine then bind at one of the copper centers. In the presence of the physiological activator fumarate, dopamine binds first in a preferred order mechanism, similar to the order of substrate binding for PHM.[23] Electron transfer from the second copper center is thought to produce an activated Cu(II)-oxygen species. This moiety abstracts an H atom from the organic substrate, cleaving the C–H bond. It has been shown that O–O bond cleavage occurs prior to the H−atom abstraction step. For many years, it was postulated that a tyrosine residue was involved in oxygen activation.[22]

The field was reenergized by the elucidation of the crystal structure of the catalytic core of PHM in 1997.[28] While that work and subsequent structures confirmed the spectroscopically derived models of copper coordination in the oxidized form (*see* ***Copper: Inorganic & Coordination Chemistry***), new questions and considerable debate arose about the structures of the reduced copper centers, the mechanism of electron transfer, and the nature of the reactive oxygen species.[23,29] These issues have been addressed by several groups and new catalytic mechanisms have emerged. Although there is not yet consensus on each catalytic step, there is general agreement that DβM and PHM are quite similar mechanistically.

The PHM crystal structure shown in Figure 6 corroborates that the copper centers are far apart (∼11 Å), being separated by a solvent-filled channel.[23] Cu_A (often referred to as Cu_H in PHM) is ligated by three His and water in the oxidized form; it has historically been assigned as the electron-transfer site. Oxidized Cu_B (Cu_M in PHM) is coordinated by two His and water, and has a long bond to the sulfur of Met. The latter site has long been identified with substrate binding and hydroxylation chemistry. As depicted in Figure 6(b), changes in copper site geometry or distance are not observed in reduced vs. oxidized PHM crystals.[29] Instead, the only significant difference occurs at the $Cu_{A/H}$ His108 ligand. In reduced PHM, His108 is H-bonded to Gln170, whereas a water molecule bridges the two residues in the oxidized form. The shortest electron transfer pathway connecting the copper centers via covalent and H-bonds is ∼80 Å, which is prohibitively long. No obvious electron transfer pathway across the channel exists in these structures (*see* ***Long-range Electron Transfer in Biology***).

The 3D structure of substrate-bound, oxidized PHM has also been determined.[29] The binding energy associated with the E·S complex is derived primarily from protein interactions with the peptide backbone of the substrate (*N*-α-acetyl-3,5-diiodotyrosylglycine); since few interactions with substrate side chains occur, PHM is able to amidate a diverse pool of peptides. The copper centers remain ∼11 Å apart. The hydrophobic residue of the substrate contacts the Met ligand of $Cu_{B/M}$ and a water molecule bridges the substrate carboxylate and Gln170 via H-bonding. The substrate carbon that undergoes hydroxylation is 4.4 Å from $Cu_{B/M}$; the H_S atom that is abstracted (see equation 5) points toward the solvent atom that is bound to $Cu_{B/M}$. These data support the hypothesis that $Cu_{B/M}$ is the center of substrate binding and hydroxylation. By comparing and combining the substrate/oxidized and reduced structures, Prigge *et al.* have offered a mechanism in which the substrate mediates electron transfer.[23] The proposed pathway is shown in Figure 7 and Scheme 3. The electron passes from $Cu_{A/H}$ through its His108 ligand to Gln170 via the H-bond that is present in the reduced form. From there, the electron moves through the bridging water molecule that is present between Gln170 and the substrate carboxylate in the substrate/oxidized form, through the substrate to $Cu_{B/M}$.

The reduced PHM structure contrasts strongly with the wealth of spectroscopic evidence for both DβM and PHM, which indicates that the coordination numbers of both sites decrease upon reduction to Cu(I).[30–32] The spectroscopically deduced model of the copper centers is presented in Figure 8;[33] both coppers lose their coordinated waters, and the long bond between $Cu_{B/M}$ and Met is considerably shortened. The spectroscopic data are sensible from an inorganic chemistry perspective: three-coordinate Cu^I complexes with N-donor ligands tend to be very reactive towards oxygen (*see* ***Copper: Inorganic & Coordination Chemistry***). In this light, it has been noted that crystallographic conditions can sometimes lead to the generation of photo-reduced species and/or metal centers that are trapped in intermediate geometries between the oxidized and reduced states.[34]

The discrepancy in the proposed reduced copper structures, along with the observation that under certain conditions both coppers of PHM are able to bind the O_2 analog carbon monoxide ($Cu_{A/H}$ only in the presence of substrate),[31,32,35]

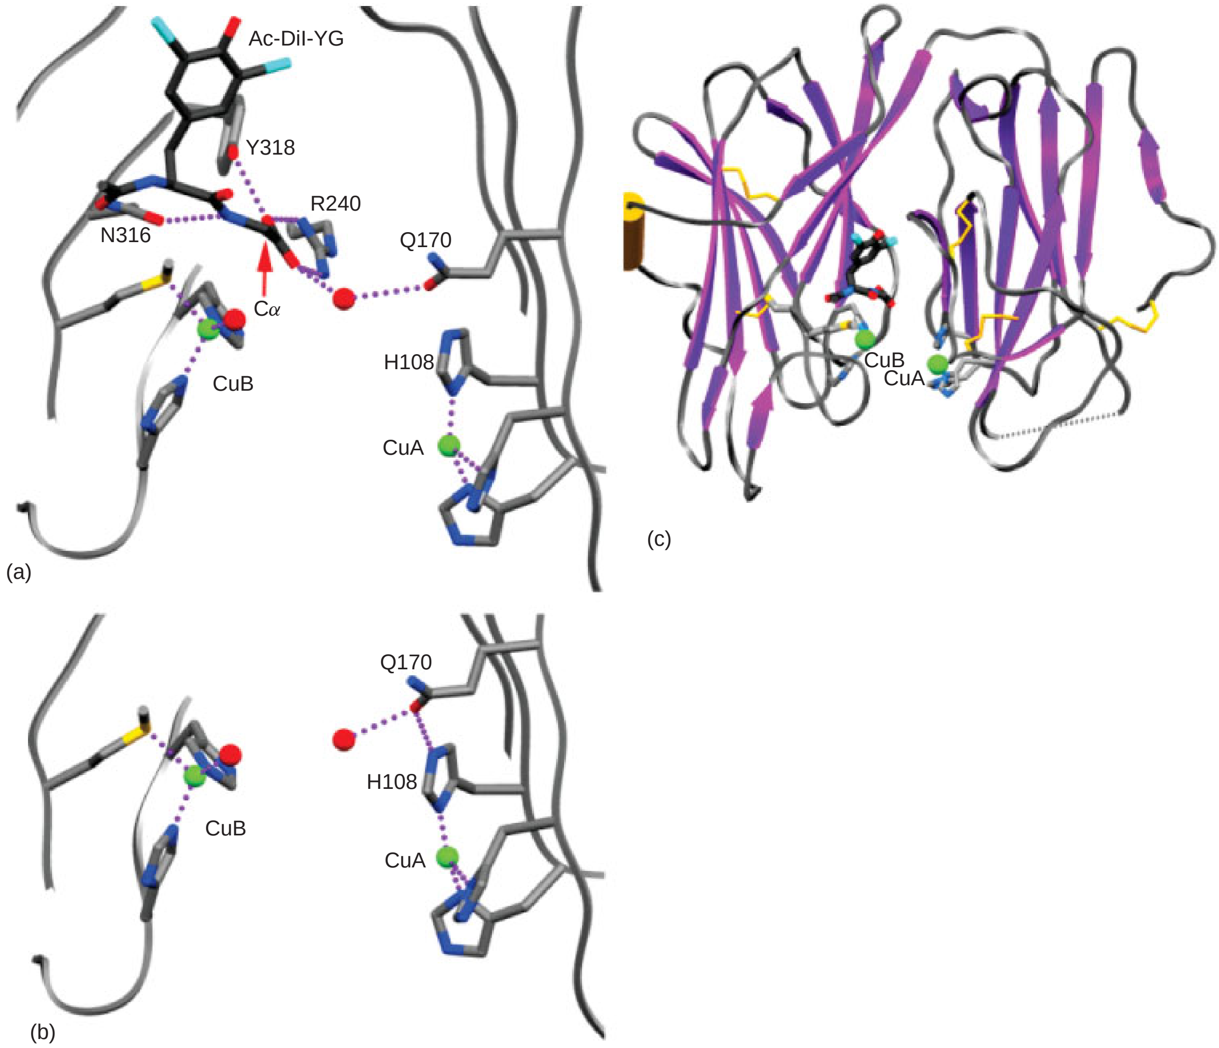


Figure 6 Structure of PHM: (a) active site in oxidized form with complexed peptide substrate, (b) active site in reduced form, (c) overall structure showing the large solvent cleft separating the two copper centers. (Ref. 23. Reproduced by permission of Birkhäuser Verlag AG)

has led to the development of other hypotheses to explain the oxygen activation and electron transfer pathway. These include the idea that O_2 initially binds at $Cu_{A/M}$, is reduced to superoxide and migrates across the channel.[35] Alternatively, it has been proposed that substrate also migrates from $Cu_{B/M}$ to $Cu_{A/H}$, and that the catalytic roles are reversed so that $Cu_{B/M}$ is the electron transfer site and $Cu_{A/H}$ becomes the site of O_2 activation and hydroxylation.[36] The latter hypothesis is based on the observation that mutation of Gln170 has little effect on PHM kinetics and so cannot mediate electron transfer.

Recent publications by Klinman and coworkers reevaluated older work in light of new experiments that (a) rule out Tyr as an activator of O_2 and (b) invoke nonclassical hydrogen tunneling to explain the observed isotope effects.[26,27,37] They have also expanded the mechanistic and kinetics data available for both DβM and PHM. In a key experiment with DβM and its very slow substrate 4-trifluoromethyl-phenethylamine, it was shown that O_2 and substrate activation are tightly coupled, and no paramagnetic species (Cu^{II} or a Cu^{I}-O-O• radical) is detectable by EPR.[27] These data have been used to support the formation of a spin-coupled, diamagnetic Cu^{II}-O_2^{-}• activated oxygen species that forms prior to electron transfer from the second copper. Klinman's working mechanism is depicted in Scheme 4. Note that the electron transfer pathway is proposed to occur over ~8 Å through H-bonded water molecules, which is predicted to be sufficiently fast even when substantial ligand reorganization of the copper sites is included (*see* ***Long-range Electron Transfer in Biology***), as suggested by the spectroscopically deduced models (Figure 8).[27,37] Moreover, this intriguing mechanism includes a role for Met ligand reorganization in mediating the reversibility of the first reduction step, thus contributing to the driving force for substrate oxidation.[27] Klinman also notes that this mechanism is compatible with substrate-mediated electron transfer for PHM (in lieu of the water molecules) and/or substrate migration. Although the

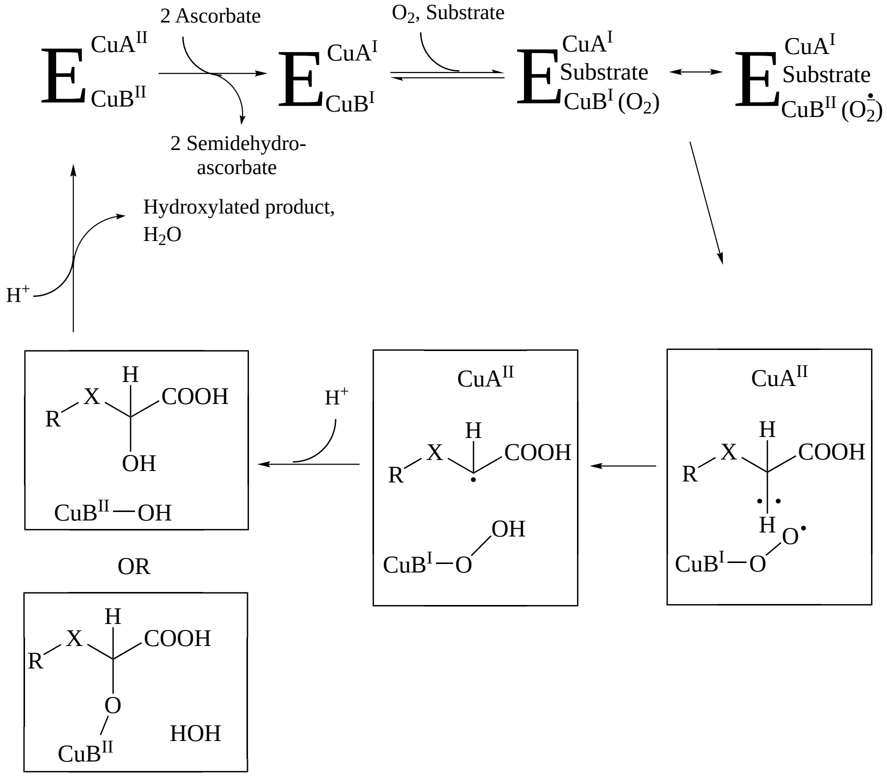
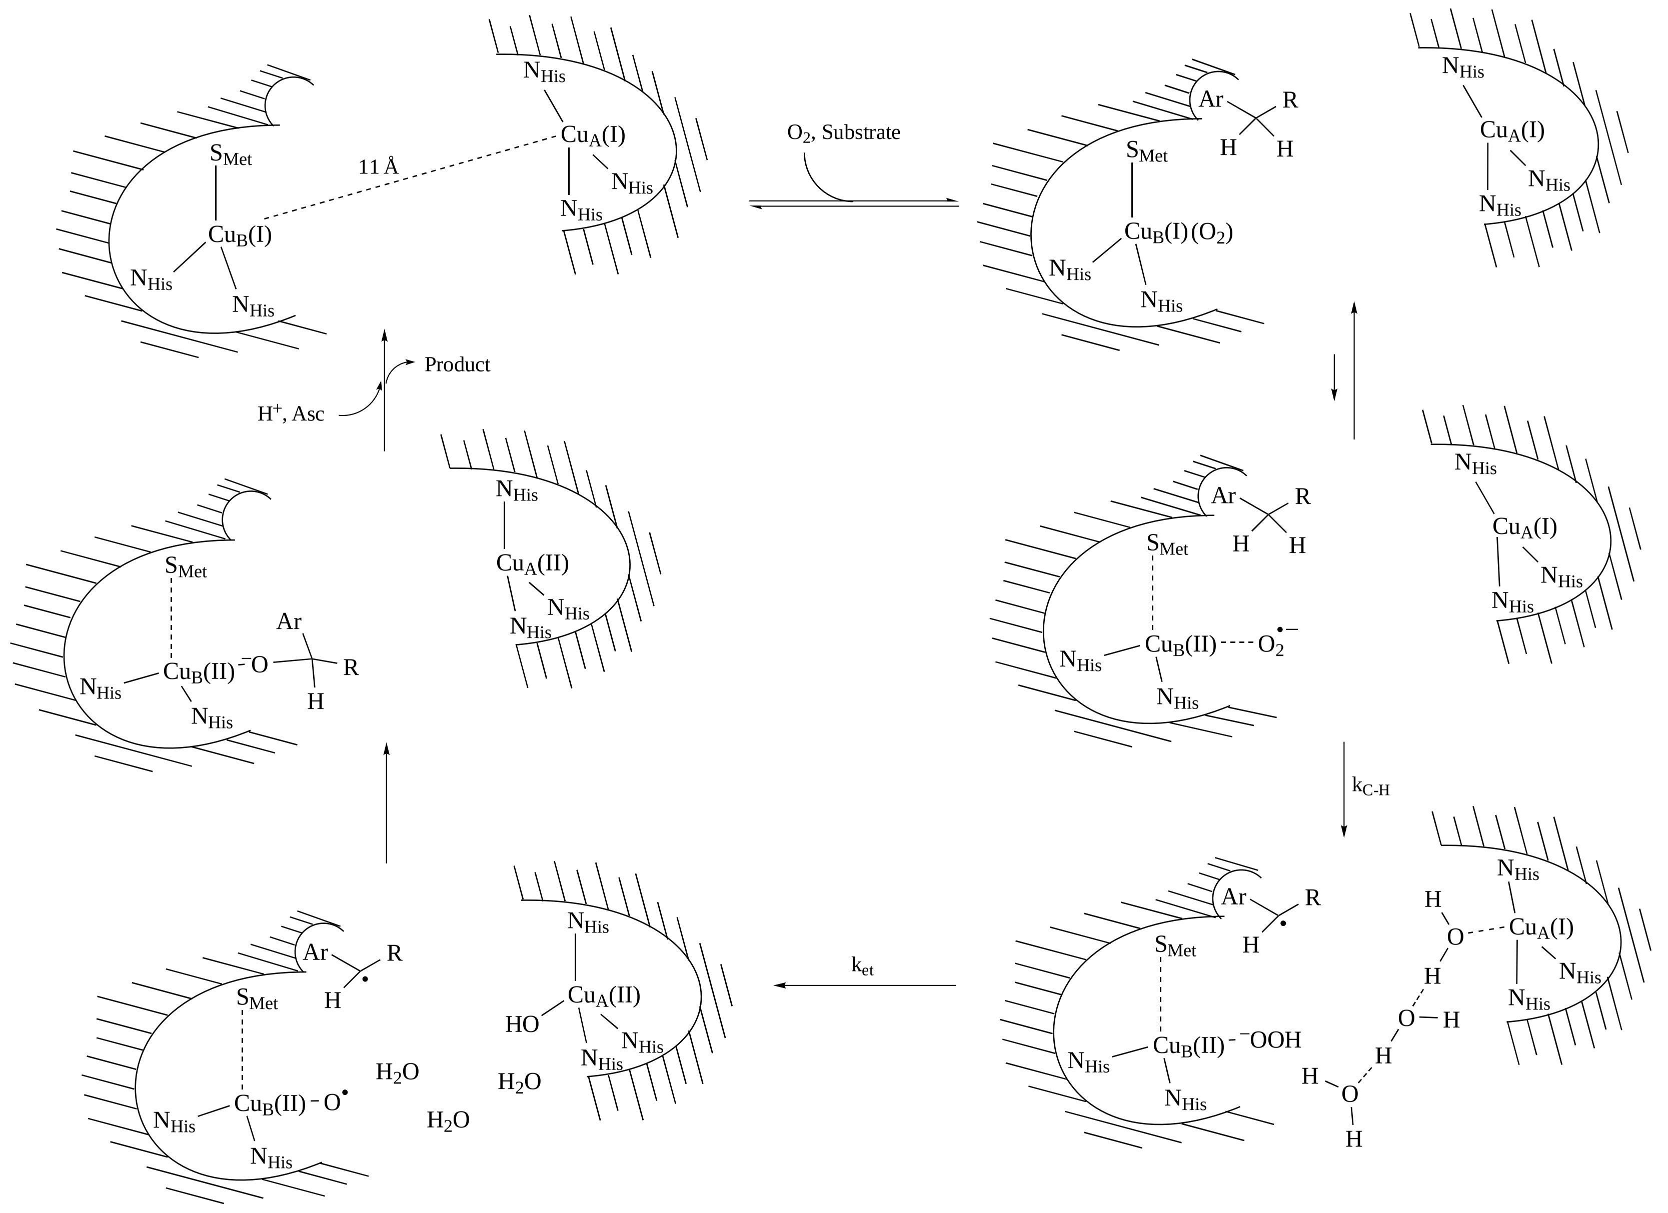


Scheme 3 Proposed catalytic mechanism of PHM involving substrate-mediated electron transfer. (Ref. 23. Reproduced by permission of Birkaüser Verlag AG)

mechanism does not require it, the roles of the two copper centers may also be reversed in Scheme 4.

In summary, the PHM structures have provoked new controversies over the details of substrate hydroxylation by PHM and DβM. It has become evident that the enzymes share a common catalytic mechanism, and that any proposed mechanism must account for the wealth of experimental data available for both proteins.



Scheme 4 Proposed catalytic mechanism of PHM and DβM showing the reactive ternary complex. Proposed structure of the intermediate formed after reaction of $Cu_B(II)-O_2^{\bullet}$ with substrate to form a substrate-derived free radical and $Cu_B(II)-OOH$. This illustrates a possible pathway for electron transfer from $Cu_A(I)$ to $Cu_B(II)-OOH$ through the solvent-filled cleft and the changes in copper ligation that accompany oxidation. With the exception of reactive intermediates, the water molecules complexed to the copper sites have been omitted. (Ref. 27. 5 QUERCETINASE

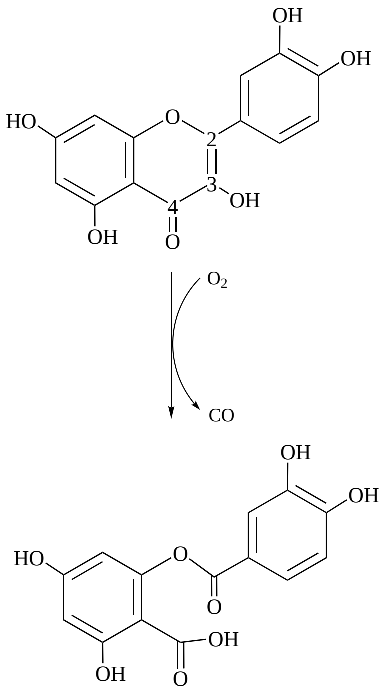
Quercetinase (quercetin 2,3-dioxygenase, 2,3QD, EC1.13.11.24) is the first noniron dioxygenase (*see* ***Iron Proteins with Dinuclear Active Sites*** and ***Iron Proteins with Mononuclear Active Sites***) to be structurally characterized. 2,3QD is a homodimeric enzyme of ~100–148 kDa and is heavily glycosylated.[38,39] 2,3QD catalyzes the cleavage of the O-heterocyclic ring of flavones such as quercetin, with concomitant production of carbon monoxide (equation 6).[38] Both atoms of molecular oxygen are incorporated into the reaction products.



(6)

Although 2,3QD has been isolated from several fungal species,[38–40] the enzyme from *Aspergillus japonicus* has been extensively characterized and will be described herein. A partially deglycosylated form of 2,3QD from *A. japonicus* has been crystallized in its resting form[40] and in anaerobic complexes with substrates or metal chelators.[41,42] The enzyme fold is shown in Figure 9. Each 2,3QD monomer

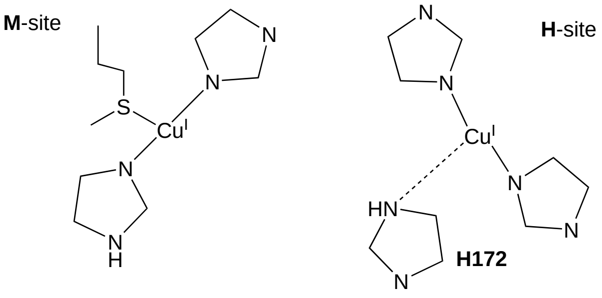


Figure 8 Model of the copper center geometries in reduced PHM, as determined spectroscopically[33]

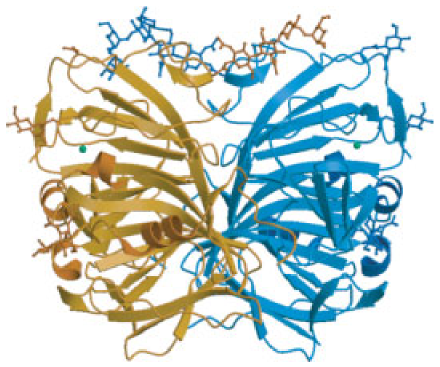

Figure 9 Ribbon diagram of quercetinase. The copper ions are shown as spheres; the carbohydrates are drawn in stick form. (Reprinted from Ref. 40. © 2002, with permission from Elsevier)

is composed of two structurally related β-sandwich domains (residues 1–145 and 206–350) that are connected by a 60-residue loop.[40] Whereas hydrophobic contacts mediate the interdomain interactions, H-bonds between loop residues and mediating waters largely comprise the dimerization interface. 2,3QD is a member of the cupin superfamily, which includes several nonmetalloenzymes, the manganese-containing enzyme oxalate oxidase (*see* ***Manganese Proteins with Mono- & Dinuclear Sites***), and the iron-containing homogentisate 1,2-dioxygenase (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***).[43] The metal centers of the metalloenzymes are quite similar in structure, supporting the hypothesis that Type 2 copper centers may have arisen from Mn- or Fe-containing ancestors.[40,44]

Each N-terminal domain of 2,3QD contains a mononuclear Cu(II) ion separated by ~40 Å.[40–42] As isolated, the copper coordination is modeled as two geometries, depicted in Figure 10. Approximately 70% of the copper is present in a distorted tetrahedral geometry with three His and one water molecule (W1) as ligands (Figure 10(b)). A trigonal bipyramidal coordination is also seen, in which a carboxylate oxygen from Glu73 becomes an axial ligand and the water shifts into the His plane (represented by W2) (Figure 10(c)). This is the first enzyme known in which a carboxylate oxygen from the side chain of Glu or Asp serves as a copper ligand.

As seen in Figure 11, EPR spectroscopy confirms that two states of Type 2 copper coordination exist in the resting enzyme at pH 6.[45] The minor species becomes dominant at pH 10. The EPR spectrum also changes upon the anaerobic addition of substrates or the metal chelator diethyldithiocarbamate (DDC), as indicated in the Peisach–Blumberg plot[46] in Figure 12. The spectrum of the DDC adduct indicates that copper has taken up a square pyramidal geometry with three His and two sulfurs from the chelator. This has been confirmed by X-ray crystallography.[41] The EPR,[45] X-ray,[41] and extended X-ray absorption fine structure (EXAFS)[47] data strongly suggest that substrate binds to copper in a monodentate manner during catalysis (Figure 13), replacing the water molecule. Glu73 is also a ligand in the substrate-bound form.[41] Peisach–Blumberg

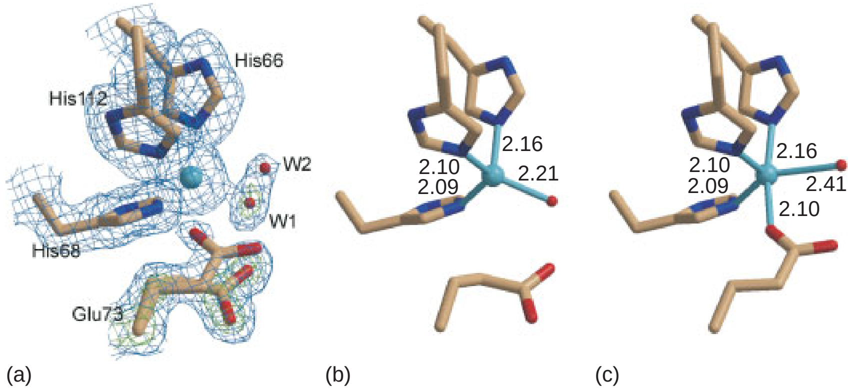

Figure 10 Copper coordination geometries in 2,3QD. (a) Experimental map contoured at the 1.0 r (blue) and 2.5 r (green, only for Glu73 and the solvent molecule) levels. (b) Major distorted tetrahedral coordination. (c) Minor trigonal bipyramidal coordination with a strong square pyramidal component. (Ref. 45. Reproduced by permission of Blackwell)

analysis of the EPR spectra of the anaerobic enzyme-substrate complex indicates that the copper center has undergone changes to a form intermediate between Type 1 and Type 2 centers. In the presence of dioxygen, an adduct ascribed to the copper-depside product is detected. It should be noted that for the *Aspergillus niger* enzyme, no changes in the EPR spectrum were observed upon substrate binding.[38]

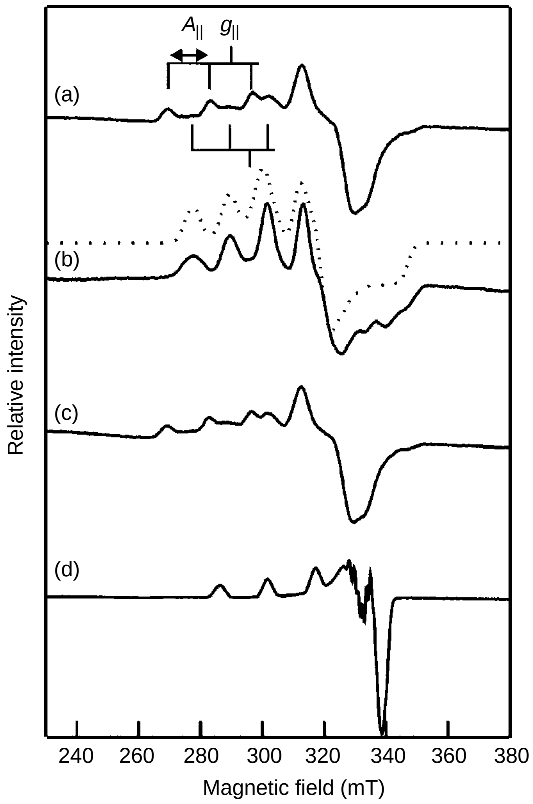

Figure 11 EPR spectra of 2,3QD. (a) 2,3QD at pH 6; (b) 2,3QD at pH 10 (dotted line is simulated data); (c) sample B after the pH has been brought back to pH 6; (d) DDC-inhibited 2,3QD at pH 6. (Ref. 45. Reproduced by permission of Blackwell)

The inherent flexibility in Glu73 ligation and its requirement for activity suggests that its coordination modulates the reactivity of the active site. Glu73 may serve as an active-site base to deprotonate the C3 hydroxyl group.[42] Alternatively, the noted flexibility in Glu73 ligation may modulate the redox potential of Cu(II). A Cu(I)-flavonol radical has been proposed to be a catalytic intermediate,[42] although no organic radical was detected by EPR at 77K, the only temperature examined.[38,45] This flavonol radical intermediate would be remarkably similar to the Cu(I)-TPQ semiquinolamine radical detected in amine oxidases (see Section 7); that radical is in a temperature-sensitive equilibrium with the Cu(II)-TPQ-quinolamine form and is only detectable near room temperature.

The structural and spectroscopic data along with biomimetic studies support the catalytic mechanism outlined in Scheme 5.[42,48,49] The flavonol substrate coordinates to Cu(II) in a monodentate manner, replacing water and shifting the metal center to a square pyramidal geometry (**2**). This is accompanied by the movement of several linker peptidyl residues, which sequesters the active site from solvent. The Glu73 residue may directly deprotonate the flavonol substrate, or it might store the proton for subsequent protononation of the depside product. A Cu(I)-flavonoxy radical tautomer of (**2**) is postulated, since its reaction with triplet O_2 (**2taut** → **3a**) is not spin-forbidden. Alternatively, O_2 may bind directly to the Cu(I) ion (**2taut** → **3b**). CO is released from the endoperoxide intermediate (**4**). Protonation of the depside product signals product release; the mouth of the substrate channel reopens.

6 GALACTOSE OXIDASE

Galactose oxidase [E.C. 1.1.3.9] is an extracellular fungal enzyme named for its ability to oxidize the C-6 position of galactose to an aldehyde (*see* ***Oxidation Catalysis by***

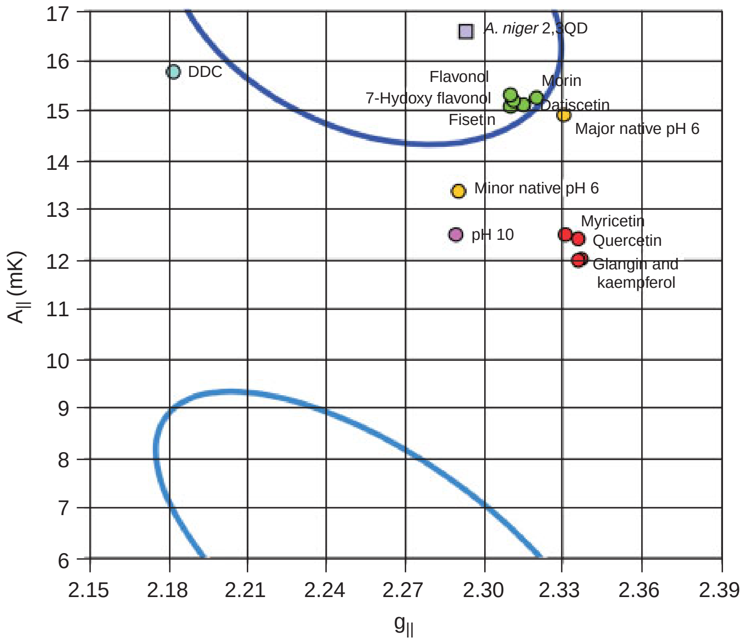

Figure 12 Peisach–Blumberg plot.[46] Plot of $g_{||}$ and $A_{||}$ values from EPR of various flavonol complexes. Area circled in dark blue: the region where Type 2 Cu sites in proteins are found; light blue, where Type 1 sites are found. (Ref. 45. Reproduced by permission of Blackwell)

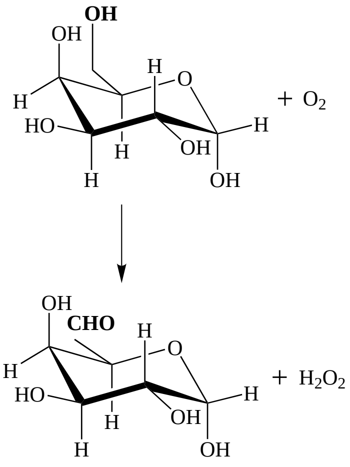
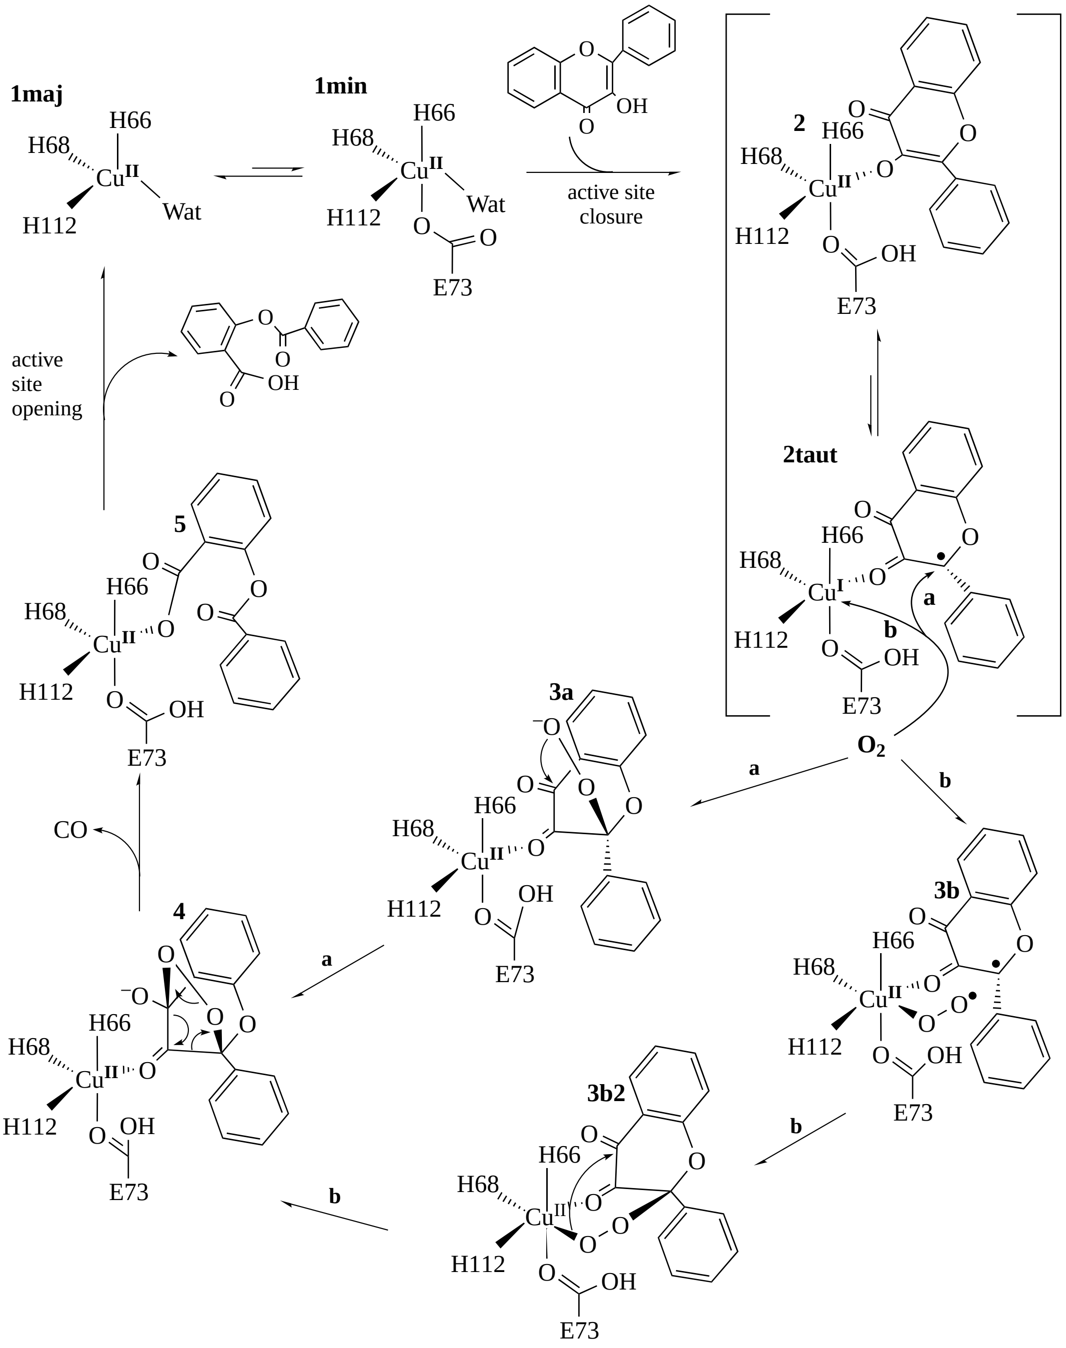
Protein copper ligands are represented by orange sticks, substrate is in gray, and the residues in van der Waals contact with the substrate are in green (Reproduced from R.A. Steiner, K.H. Kalk, and B.W. Dijkstra, *Proc. Natl. Acad. Sci. USA*, 2002, **99**, 16625. © 2001 National Academy of Sciences, USA)

Transition Metal Complexes), using oxygen as the oxidant and reducing it to hydrogen peroxide, as illustrated in equation (7). The enzyme acts on a broad range of alcohols and is not specific for galactose, which is actually only an average substrate. Several excellent reviews have recently been published and provide exceptional insight into the structure, catalytic mechanism, and cofactor biogenesis of galactose oxidase.[50–53]



(7)

The most extensively studied galactose oxidase is that secreted from the fungus *Fusarium* spp. (formerly known as *Dactylium dendroides* and *Polyporus circinatus*). Homologs include the fungal glyoxal oxidase and the putative prokaryotic FbfB protein, which is involved in *Stigmatella aurantiaca* fruiting body formation. The peroxide produced during the catalytic cycle of glyoxal oxidase fuels the peroxidases that degrade lignin.[53] However, the biological role of galactose oxidase has not been completely defined. Galactose oxidase



Scheme 5 Mechanism of 2,3-QD. (Ref. 42. Reproduced by permission of The National Academy of Sciences of the United States of America)

might also be involved in polysaccharide processing or act as a bacteriostat through its production of peroxide.

Galactose oxidase is a monomer composed of a single polypeptide chain ($M_r = 68$ kD), with two disulfide bridges, and a single copper ion that is essential for catalytic activity. A second redox center in the active site is provided by a tyrosyl radical (Tyr272).[50–53] The enzyme as isolated is a mixture of active and inactive forms. The inactive form of the enzyme has a typical Type 2 Cu^{II} EPR signal which is abolished by one-electron oxidation to the active form. These observations have led to a model that invokes oxidation of a tyrosine residue to a tyrosine radical on the active enzyme; the unpaired electron on the tyrosine radical is magnetically coupled to the odd electron on Cu^{II}, thereby producing an 'EPR-silent' state (see Figure 14).[54] If the active-site copper is removed, an EPR signal that is attributable to a modified tyrosine radical (Figure 15) can be detected.

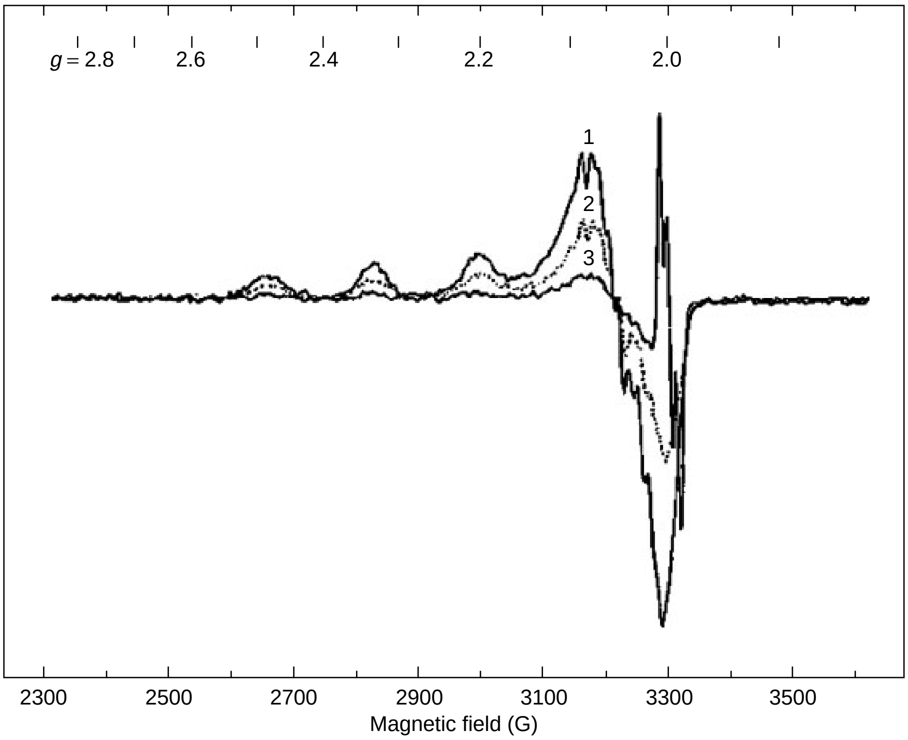


Figure 14 X-band EPR spectra of galactose oxidase at 30 K. 1, reductively inactivated; 2, native (as isolated); 3, oxidized. (Ref. 54. Reproduced by pemission of American Society for Biochemistry & Molecular Biology)

The three-dimensional structure of this enzyme has been solved at atomic resolution (1.7 Å).[55,56] The overall structure of galactose oxidase is shown in Figure 16(a). There are three domains, each composed mostly of β structure; the copper is located on the solvent-accessible surface of the second domain, opposite to the bulk of the third domain. Figure 16(b) provides details of the copper-site structure. Two histidine imidazoles (His496 and His581), a tyrosine (Tyr272), and water (acetate in pH 4.5 buffer conditions) make up the equatorial plane. A second tyrosine (Tyr495) is coordinated axially, with a bond length of 2.69 Å. The equatorial tyrosine (Tyr272) is covalently bonded to Cys228, which results from post-translational processing (vide infra; *see* ***Metal-mediated Protein Modification***). The aromatic ring of Trp290 stacks over the Tyr–Cys unit, shielding the Cys–Tyr cofactor from solvent.

Mutagenesis and spectroscopic studies have revealed much about the active-site structure, the roles of the active-site residues and the catalytic mechanism (see Scheme 6). Oxidized, active galactose oxidase has remarkable electronic absorption spectral features associated with its copper center, as seen in Figure 17. The band at 810 nm has been assigned as being an interligand charge transfer band (Y495 → Y272•) mediated by copper ion wave functions. These have been discerned from multiple detailed studies on the enzyme, mutants, and model compounds.[52]

Kinetic analyses indicate that the losses of catalytic activity in the mutants (see Table 1) is attributable to changes in k_{cat} with only minor perturbations in K_M for galactose.[52] The spectroscopic signatures of the radical present in apogalactose oxidase (resonance Raman, high-field EPR, and ENDOR) are consistent with a thio-substituted tyrosyl radical, establishing Tyr272 as the redox-active residue. Additionally, the Tyr495Phe mutant retains the ability to form a radical, despite being catalytically impaired. The reduction potential of the cofactor is quite low (~400 mV vs NHE) compared with normal tyrosyl radicals (800 – 1000 mV) and is largely controlled by the coordination of copper and the thio-ether linkage to Cys228, as shown in Table 1. Tyr495 and Trp290

Table 1 Properties of galactose oxidase and active-site mutants. (Adapted from Refs. 52, 57 and 58)

Enzyme form	Activity/Cu	Proton uptake	Radical formation/ E'^0 at pH 7.5 (mV)
Wild type	1.0	Yes	Yes/400
Wild type + azide	$K_I = 20\,\mu M$	Yes	Yes/393
Wild type Apo-enzyme	Copper-free	n.d.	Yes/570
Tyr272Phe	none	n.d.	No/ –
Tyr495Phe	0.001	No	Yes/450
Cys228Gly	0.0001	Yes	Yes/630
Trp290His	0.0005	Yes	Yes/730

also influence the potential. The Cu(II)/Cu(I) potential in wild-type enzyme is ~150 mV, which is similar to aqueous copper.

Spectroscopic studies of the Tyr495Phe mutant have suggested that the axial ligand Tyr495 functions as a general base, abstracting a proton from the substrate and activating it toward oxidation.[51,52] The Tyr495Phe mutant is not competent for proton uptake, as is normally observed for the wild-type protein in the presence of anions. Anions displace the solvent ligand from copper and are analogous to substrate binding. Both spectroscopic studies and computer modeling of enzyme–galactose interactions indicate that galactose can coordinate to Cu^{II} via O6 at the equatorial position occupied by solvent (see Scheme 6).[54,59]

These data have led to the development of a catalytic mechanism, shown in Scheme 6, that has been further refined by kinetic isotope effect (KIE) experiments.[52,53] Substrate binds to Cu(II), replacing bound solvent. The metal coordination facilitates the deprotonation of the substrate hydroxyl group. The proton is transferred to Tyr495, which dissociates from copper. The temperature and pH dependence of the visible absorption and circular dichroism spectra indicate that galactose oxidase exists as an equilibrium of the Tyr495-Cu(II) form (Tyr_{ON}) and the protonated Tyr495 state, where the phenolate is no longer a copper ligand (Tyr_{OFF}). For some substrates under some conditions, a significant solvent KIE has been observed, indicating that proton transfer may become rate-limiting. Electron transfer from substrate to Cu(II) occurs next, resulting in the formation of a Cu(I)-substrate alkoxyl radical. Ionization of the substrate alcohol lowers its redox potential, facilitating oxidation of the alcohol. Subsequent C–H bond cleavage via H atom transfer to the Tyr272 radical occurs next, producing fully oxidized substrate aldehyde and the fully reduced state of the enzyme, Cu(I)-Tyr_{red}. A large substrate KIE has been measured for C–H bond cleavage, indicating that hydrogen tunneling contributes to H atom transfer.

The second half-reaction of galactose oxidase turnover involves reduction of O_2 to form peroxide, H_2O_2. Although much less is known about this mechanistic step, it is thought that O_2 binds to Cu(I). Both substrate-derived protons are transferred to the peroxide product, as determined from the large substrate (alcohol) KIE on O_2 reduction; evidently hydrogen transfer is fully rate limiting for O_2 reduction. Additional work is necessary to develop a more detailed mechanism of O_2 reduction.

The biogenesis of the unique Tyr272-Cys228 cofactor of galactose oxidase requires only copper and O_2, and does not involve any accessory proteins or enzymes.[60] Another self-processing event, cleavage of the 17 N-terminal residues of the prosequence, is also copper/O_2-dependent. The order of these autocatalytic reactions has not been definitively determined and it is not clear if prosequence cleavage is linked to thio-ether bond formation in vivo.[60,61] The cross-linked cofactor of galactose oxidase is formed when the enzyme is expressed in *Pichia pastoris* without its prosequence.[61]

The crystal structure of progalactose oxidase has been determined.[62] Although it is generally quite similar to that of the mature enzyme, several loops show significant changes (see Figure 16(c) and 16(d)). The prosequence is not near the active site, suggesting that it does not function in copper transport into the active site. Rather, it has been proposed that the prosequence positions the active-site residues so that thio-ether bond formation is favored. The positions of the copper ligands His496, His581, and Tyr495 are nearly identical in both the pro- and mature forms of the enzyme. In contrast, both Tyr272 and Cys228 are rotated significantly. Additionally, Cys228 shows additional electron density at the sulfur atom, which is postulated to be the sulfenic acid (-SOH) oxidized form of Cys. It is likely that this form is a result of X-ray damage. The loop containing Trp290 is also significantly shifted from its final position. This opens up the active site and exposes Cys228 and Tyr272 to solvent.

Based on biochemical and structural studies, several mechanisms of biogenesis have been proposed. As shown in Scheme 7(a), one mechanism involves activation of the phenol group of Tyr272 (or the thiol of Cys228) by coordination to Cu(II) and is similar to the mechanism

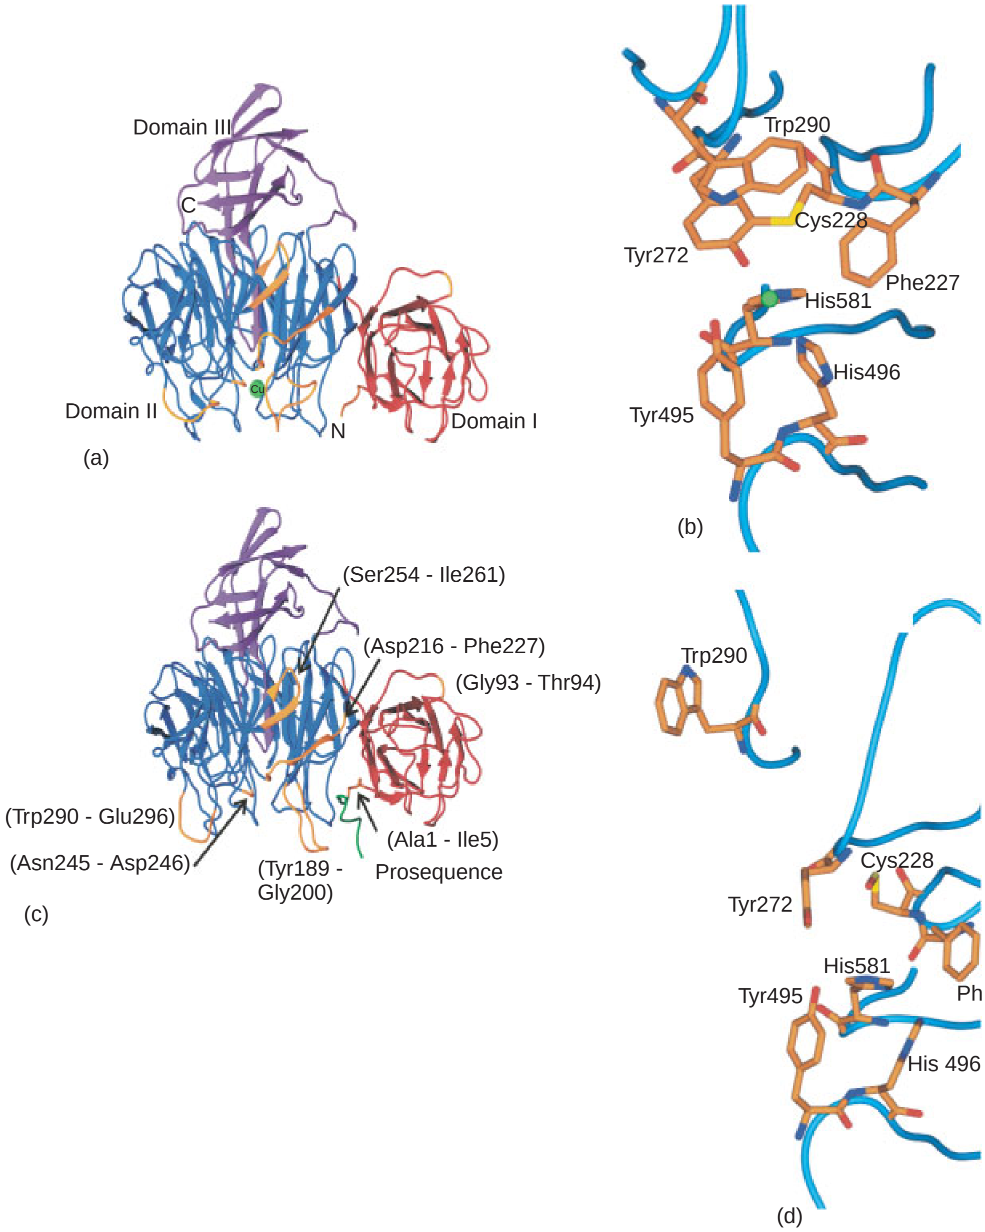

Figure 16 Comparison of the overall structures (a,c) and copper-binding/active-site regions (b,d) of processed, active galactose oxidase (a,b) with its precursor proform (c,d). (Reproduced from Ref. 62. © 2001 National Academy of Sciences, USA)

proposed for the biogenesis of the quinone cofactor of amine oxidase.[62] A second proposed mechanism shown in Scheme 7(b) is based on recent kinetic studies of the Cu(I) form of the unprocessed protein. Whittaker *et al*. show that, in vitro, Cu(I)-activated thio-ether bond formation is significantly faster than Cu(II)-mediated cross-linking and is associated with an active-site group ionizing with a $pK_a = 7.3$.[61] In this mechanism, O_2 binding to Cu(I) ultimately produces a Cys228 thiolate radical, which attacks Tyr272 to form the thio-ether bond. Additional studies are needed to elucidate the details of cofactor biogenesis at the molecular level, and to determine if Cu(I)- or Cu(II)-based biogenesis is more likely to occur under physiological conditions.

7 AMINE OXIDASE AND LYSYL OXIDASE

Copper-containing amine oxidases [E.C. 1.4.3.6] are one of the most widely distributed classes of Type 2 copper enzymes.[63] They have been highly purified from bacteria,

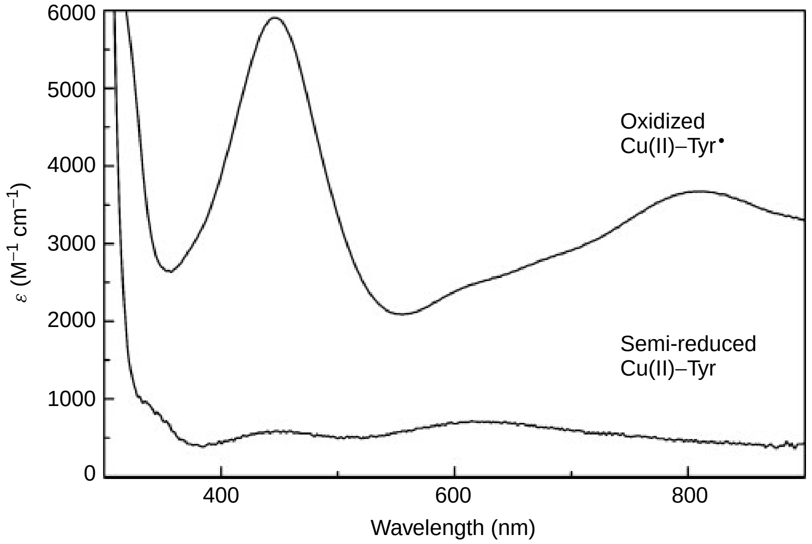

Figure 17 Visible absorption spectra of oxidized, active galactose oxidase and the semireduced, inactive form

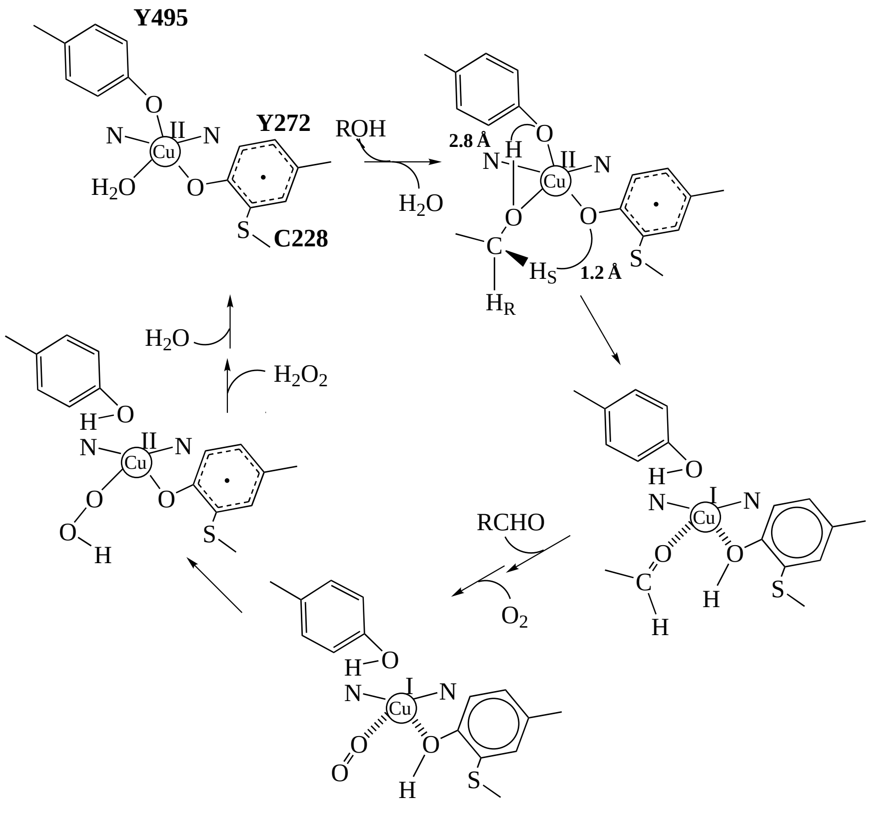
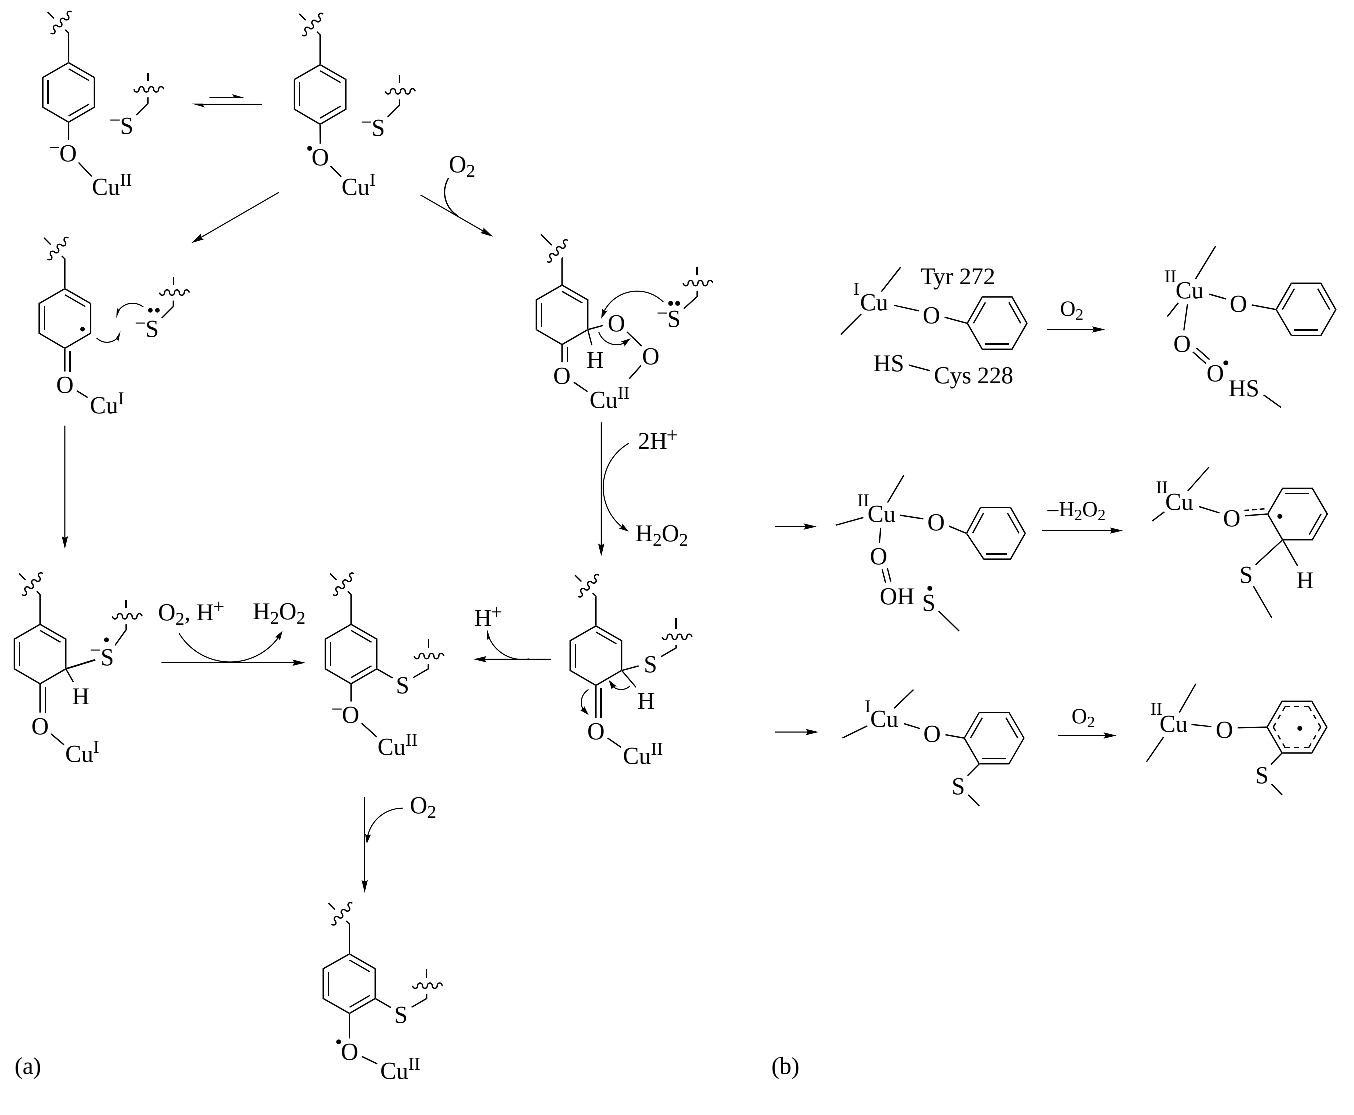


Scheme 6 Catalytic mechanism of galactose oxidase. (Reprinted with permission from Ref. 52. © 2003 American Chemical Society)

yeasts, plants, and mammals. Generally these enzymes are dimers composed of two identical subunits with a total $M_r \sim 130-150$ kD. Amine oxidases catalyze the oxidative deamination of primary amines in a ping pong mechanism (equations 8 and 9).

$$RCH_2NH_2 + E_{ox} \longrightarrow RCHO + E_{red} \quad (8)$$

$$E_{red} + O_2 + H_2O \longrightarrow E_{ox} + H_2O_2 + NH_3 \quad (9)$$



Scheme 7 Two possible mechanisms of thio-ether bond formation based on either (a) Cu(II) and a tyrosyl radical or (b) Cu(I) and a thiyl radical ((a) S.J. Firbank, M.S. Rogers, C.M. Wilmot, D.M. Dooley, M.A. Halcrow, P.F. Knowles, M.J. McPherson, and S.E. Phillips. *Proc. Natl. Acad. Sci. USA*, 2001, **98**, 12932. © 2001 National Academy of Sciences, USA and (b) Ref. 61. Reproduced by permission of The American Society for Biochemistry & Molecular Biology)

Substrate specificities depend on the enzyme source but nearly all biogenic primary amines are included, that is, histamine, tyramine, tryptamine, dopamine, serotonin, norepinephrine, mescaline, 1,5-diaminopentane, 1,4-diaminobutane, spermine, and spermidine. The physiological functions include nutrient metabolism in prokaryotes, regulation of physiological amine concentrations, and mediation of cell-cell interactions through adhesion and apoptosis. Another type of amine oxidase, known as lysyl oxidase, has been discovered in connective tissue.[63] Lysyl oxidases are responsible for the cross-linking of connective tissue in aorta, lung, and cartilage; their primary substrates are peptidyl lysines of elastin and collagen. The severe pathology of dietary copper deficiency and lathyrism is associated with extremely low levels or inhibition of lysyl oxidase. The molecular properties of lysyl oxidase are strikingly different from the soluble amine oxidases. Lysyl oxidase has $M_r = 30-32$ kD and is relatively insoluble in aqueous solution owing to severe aggregation. Lysyl oxidase is initially synthesized as a ~46 kD precursor polypeptide, which is subsequently cleaved to yield the native ~32 kD enzyme.

Both amine and lysyl oxidases possess a single Type 2 copper center and a redox-active cofactor per subunit. As shown in Figure 18, amine oxidases contain 2,4,5-trihydroxyphenylalanine quinone (TPQ) and lysyl oxidase contains lysyl tyrosine quinone (LTQ), in which a lysine side chain has been cross-linked to TPQ. These cofactors are produced from the oxidation of a specific active-site tyrosine residue via novel self-processing events that require only copper and O_2 (*see* ***Metal-mediated Protein Modification***).

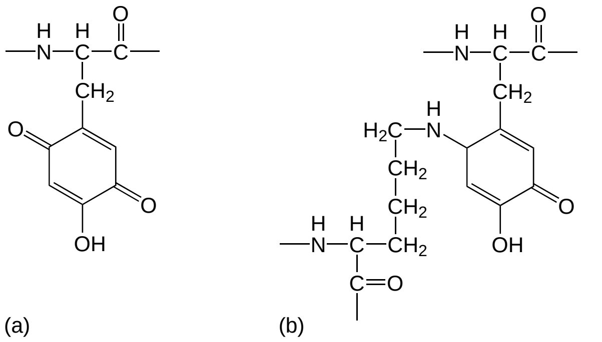


Figure 18 Tyrosine-derived quinone cofactors. (a) TPQ, 2,4,5-trihydroxyphenylalanine quinone; (b) LTQ, lysyl tyrosyl quinone

Although the two enzymes in this class are mechanistically similar, much more information is available on the structure and catalytic cycle of amine oxidase than lysyl oxidase. Therefore, only amine oxidases will be discussed in detail here; readers are directed to several excellent reviews for additional information on lysyl oxidase.[64,65]

The structures of five amine oxidases have been solved by X-ray crystallography: two are bacterial (*Escherichia coli*[66–68] and *Arthrobacter globiformis*[69]); two are from yeast (*Hansenula polymorpha*[70] and *P. pastoris*[71]); and one is from pea seedling.[72] Collectively these enzymes exhibit considerable structural homology. The structure of oxidized, resting-state *Arthrobacter globiformis* amine oxidase (AGAO) is shown in Figure 19(a). The actives sites are located within the large β-sandwich core domains, which surround a large, solvent-filled cavity (Figure 19(b)). Two β-hairpin arms extend from the central domain of one subunit across the surface of the other subunit; residues at the end of one arm form part of the entrance to the active-site channel. In most structures, this channel is long and narrow, as shown in Figures 19(b) and 20. An exception to this is the enzyme from *P. pastoris*, in which the substrate channel resembles a broad funnel that is able to accommodate the larger lysyl peptide substrates oxidized by this enzyme.[71] The shape of the substrate channel, along with variations in the numbers and types of residues in the hairpin arms, account for the wide ranges of substrate specificities noted for amine oxidases, which have highly conserved active-site structures (Figures 19(c) and 19(d)). A second metal site believed to bind calcium is present in numerous amine oxidases, although its function remains unknown.[72,73]

The active-site copper ion is coordinated in a distorted square pyramidal geometry by three conserved histidine residues (His431, His433, and His592 in AGAO) and two water molecules, one axial and the other equatorial, confirming the predictions of earlier spectroscopic experiments.[63] TPQ is in close proximity to the copper ion. Several conformations of TPQ have been noted in the available structures. Figure 19(c) shows the active, 'TPQ off' orientation where O-2 is hydrogen bonded to the axial water ligand and O-4 is hydrogen bonded to a conserved tyrosine residue (Tyr296). This orientation of

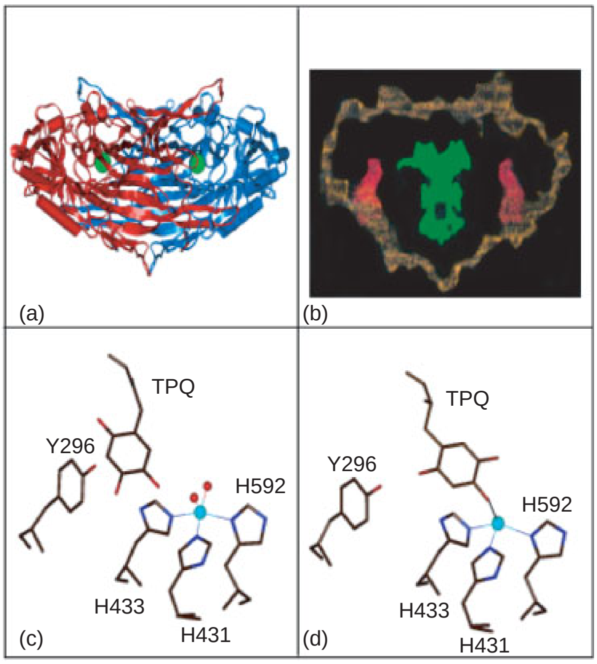

Figure 19 Structure of amine oxidase from *A. globiformis.* (a) ribbon diagram showing subunits in blue and red, copper as green spheres; (b) solvent map showing the substrate channels in red and the inland 'lake' in green; (c) close-up of the copper center showing the active TPQ_{off} conformation; (d) close-up of the copper center showing the inactive TPQ_{on} conformation. (Reprinted with permission from Ref. 69. © 1997 American Chemical Society)

TPQ places the nucleophilic C-5 in close proximity to the conserved active-site base (Asp298) and the substrate access channel. In the 'TPQ on' orientation (Figure 19(d)), TPQ is rotated and ligated to copper via O-4. Although the latter form is not immediately suited for reaction with substrate, the available data suggest that it is in facile equilibrium with the properly oriented form. Moreover, the availability of various TPQ conformations or orientations that have similar energies may be required for its biogenesis from tyrosine (vide infra).

The crystal structures of substrate-reduced amine oxidases have been solved,[67] along with site-directed mutants,[69,74,75] metal-substituted forms,[76,77] enzyme complexes with inhibitors,[67,75] the O_2 mimic nitric oxide (NO) and peroxide.[66] These have been correlated with a wealth of biochemical and spectroscopic data[78] that form the basis for the catalytic mechanism proposed in Scheme 8. A Schiff base complex species (b) is formed between substrate amine and TPQ C-5. Base-catalyzed proton abstraction from substrate α-methylene group, via the conserved active-site aspartate residue, yields the reduced cofactor in a product Schiff-base complex, species (c). Hydrolysis releases product aldehyde, leaving the cofactor in the reduced aminoquinol form, species (d).

The mechanism of O_2 reduction remains a central question; how does the enzyme activate dioxygen for a two-electron

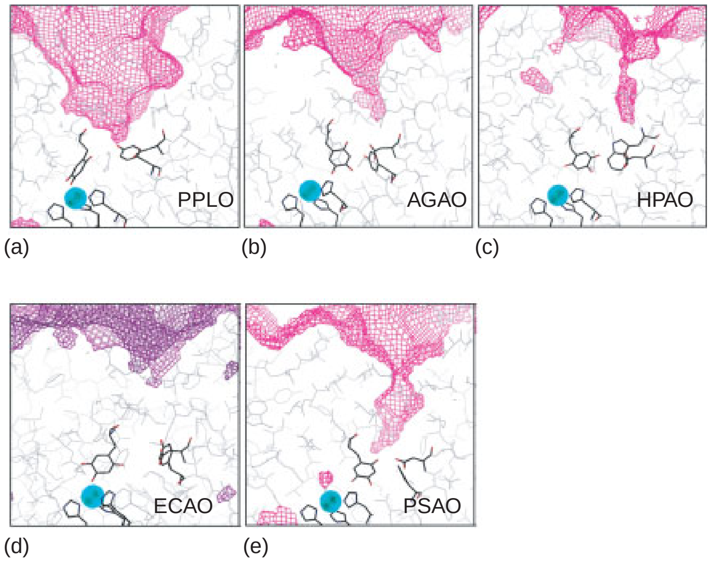

Figure 20 Views of the active-site channels in the known CuAO structures. (a) *P. pastoris*, (b) *A. globiformis*, (c) *H. polymorpha*, (d) *E. coli*, and (e) pea seedling. The surface of each funnel is shown as a blue mesh. Scheme 8 Mechanism of amine oxidase. (Ref.73. Reproduced by permission of Springer Verlag)

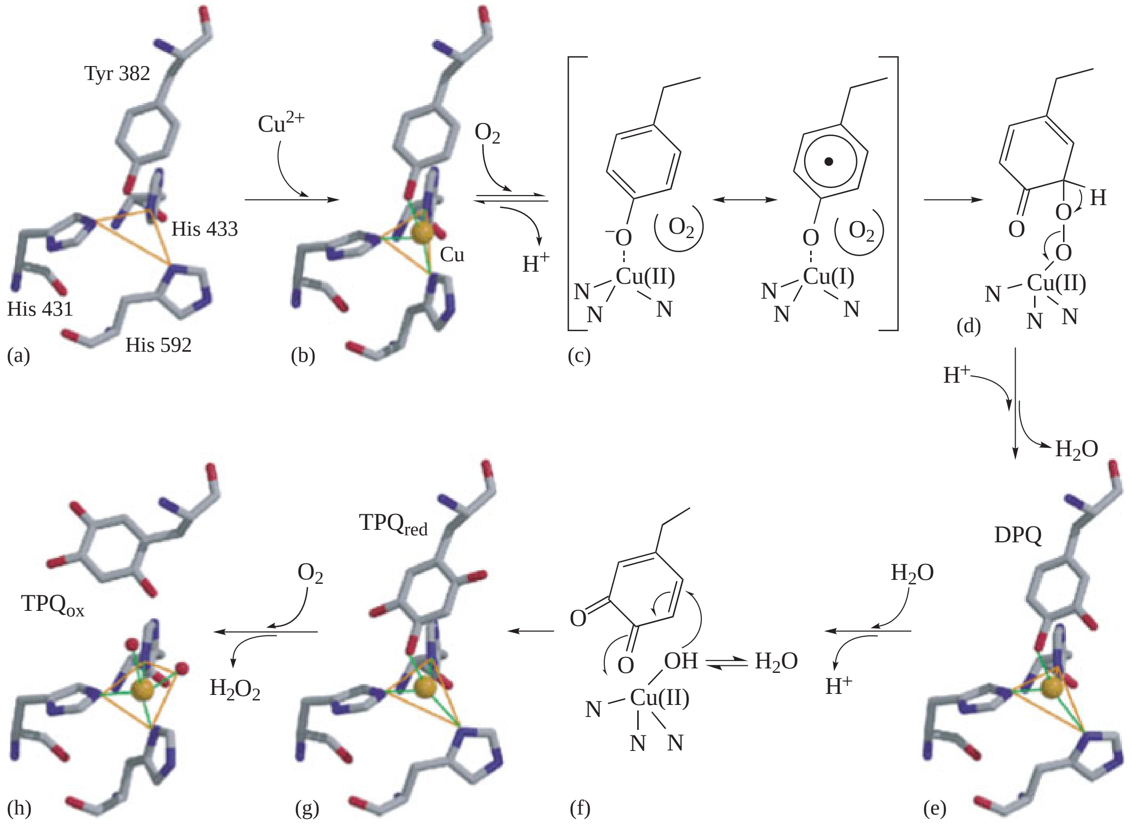
reduction to hydrogen peroxide? The anaerobic substrate-reduced enzyme has been shown by EPR to be an equilibrium mixture of Cu(II)−aminoquinol and Cu(I)−semiquinone radical species (d) and (e), and the Cu(I)−semiquinone species would be expected to react readily with O_2.[63] Formation of the Cu(I)−semiquinone has been shown to be kinetically competent in bacterial and plant enzymes. However, an obligatory role for a Cu(I)−semiquinone intermediate in the oxidative half-reaction of copper amine oxidases is not established, and other viable mechanistic alternatives have been presented. Recent solvent isotope effect, ^{18}O isotope effect, and solvent viscosity effect work using bovine serum amine oxidase indicates that the first electron transfer to O_2, and not oxygen binding, is the rate-determining step for the oxidative half-reaction.[78] Assuming that Cu(I) reduction of O_2 is expected to be relatively fast, Klinman proposes that O_2 is prebound and the rate-limiting, first electron transfer (to produce superoxide) occurs at a site other than the Cu(I) center. A hydrophobic pocket in the *H. polymorpha* active site was identified and suggested to be the site of O_2 binding and initial reduction.[79] The second electron transfer, resulting in the reduction of superoxide to peroxide, could either occur in the hydrophobic pocket or after superoxide binds to Cu(II). More recent work of Mills and Klinman using the cobalt-substituted *H. polymorpha* enzyme lends support to a non-redox role for copper in TPQ reoxidation.[80]

The structure of the anaerobic substrate-reduced enzyme from *E. coli* complexed with the O_2 mimic nitric oxide shows that NO binds between the TPQ-aminoquinol and copper and is not in the hydrophobic pocket thought to bind O_2 in *H. polymorpha*.[66] Additionally, a copper-oxygen species has been directly trapped by equilibrium turnover methods.[66] Here, the Cu–O distance of 2.8 and 3.0 Å and the Cu–O–O bond angle of 88° are consistent with the geometry expected for copper-bound peroxide. The peroxide replaces the axial water ligand to copper and occupies a similar position as NO does in the anaerobically reduced sample. The results also support solution studies that suggest both protons needed to form H_2O_2 are derived from TPQ.[78] These structures show a close interaction of the copper ion, TPQ cofactor, and O_2 or its mimic, NO. These intimate contacts strongly suggest all three entities work as a cohesive catalytic unit in amine oxidases.

One of the most fascinating questions concerning these enzymes is the mechanism of oxidation of the active-site tyrosine residue to form TPQ. This is a posttranslational, self-processing, six-electron oxidation that requires only the apo protein, Cu(II), and $2O_2$ per TPQ.[81] The structures



Scheme 9 Proposed mechanism of TPQ formation from tyrosine. Species drawn in stick figures have been structurally characterized. (Reproduced from Ref. 82)

of unprocessed AGAO with and without Cu(II) have been determined.[69,81] The copper is ligated by the three His and by the hydroxyl group of the TPQ-precursor tyrosine (2.5 Å) in a trigonal bipyramidal geometry; the site is preformed to accept the metal. The formation of a transient LMCT band (*see* ***Ligand Field Theory & Spectra***) between tyrosinate and Cu(II) has been observed in the biogenesis of TPQ in *H. polymorpha* amine oxidase.[78] These observations lead to the hypothesis that tyrosine coordination to Cu(II) activates the phenol ring for oxidation by O_2. Few intermediates have been observed in solution because the rate-limiting step occurs early in the mechanism and involves the reaction of the first molecule of O_2. Yet several intermediates have been freeze-trapped in crystals; these are incorporated into a plausible biogenesis mechanism that is illustrated in Scheme 9.[82] Species (c) is drawn to suggest ring activation via coordination; no evidence for radical intermediates in the tyrosine oxidation reaction has been obtained at this time. Note the need for conformational flexibility of the cofactor ring as it rotates nearly 180° ((e) → (f)). The addition of H_2O to the ring, illustrated as (e) → (f) → (g) → (h), has also been demonstrated in solution.[83]

Elucidating all the fascinating details of this reaction will require further mechanistic, structural, and model studies. Finally, the discovery of self-processing redox enzymes[84] (see Section 6; *see* ***Metal-mediated Protein Modification***) may be relevant to understanding aspects of the evolution of enzymes. Metal-ion mediated redox chemistry with oxygen can modify several amino acids, especially tyrosine, tryptophan, cysteine, and histidine. This may have provided a path to generate new redox cofactors prior to the advent of the complex biosynthetic pathways.

1 INTRODUCTION

Denitrification was identified as an important biochemical process over 100 years ago.[1] It is now recognized as a critical component of the global nitrogen cycle,[2] illustrated in Figure 1, and is the critical pathway for balancing the cycle, returning fixed nitrogen to the atmosphere.[3] The elucidation of denitrification at the molecular level is therefore essential to a comprehensive understanding of nitrogen metabolism. As stated concisely by Zumft,[4] 'Denitrification is a bacterial respiratory process that couples electron-transport phosphorylation to the stepwise, sequential reduction of nitrogenous oxides.' Strictly speaking, denitrification is characterized by growth on nitrate (NO_3^-) or nitrite (NO_2^-) with the concomitant evolution of NO, N_2O, or N_2 (*see* ***Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry***; ***Nitrogen: Inorganic Chemistry***). The central roles of nitrate and nitrite in the global nitrogen cycle are apparent in Figure 1. Note that both nitrate and nitrite are common to the denitrification *and* assimilation pathways, suggesting that enzymes controlling the metabolic fates of these compounds will be key points for regulation.[1] The ecology of nitrogen fixation, assimilation, and denitrification substantially impacts agricultural productivity and water quality.[1] Denitrification by soil bacteria leads to major losses of fertilizer nitrogen.[1,5] Yet, a benefit of denitrification may be its use to remove nitrates and nitrites from water supplies and industrial gas emissions.[6–8] Partial denitrification releases N_2O to the atmosphere, contributing to ozone depletion and global warming.[5] Denitrification can be viewed as composed of three somewhat independent components: nitrate respiration, nitrite respiration, and nitrous oxide respiration. Table 1 summarizes the reactions associated with denitrification. Complete denitrification is represented by (e) in Table 1, but the various partial reactions are also observed, as noted above.

Metalloenzymes have prominent roles in all of the redox reactions of denitrification (Figure 2, *see* ***Molybdenum: MPT-containing Enzymes***; ***Multi-Heme Cytochromes & Enzymes***; ***Iron: Inorganic & Coordination Chemistry***; ***Iron Proteins with Dinuclear Active Sites*** for information on the other types of metalloproteins).[9–11] Indeed, as an energy-conserving metabolic pathway, denitrification presents an extremely broad range of interesting issues in metallobiochemistry. This chapter focuses on the structures, mechanisms, and assembly of copper-containing nitrite reductases and nitrous oxide reductases. Nitrite reductases characterized to date are either copper enzymes or belong to the cytochrome cd_1 class.[1,2,4,9–11] Nitrous oxide reductases are generally multicopper enzymes, although the enzyme from *Wolinella succinogenes* is reported to contain a heme *c* center in addition to copper.[12] Nitrite reductases and nitrous oxide reductases have long been recognized as possessing unusual, even unique, spectroscopic properties. Both these enzymes are central to the denitrification pathway of soil and marine bacteria. Nitrite reductases contain a classic blue (Type 1, *see* ***Copper Proteins: Oxidases***) copper center and also contain a Type 2 copper site (*see* ***Copper Proteins with Type 2 Sites***). Nitrous oxide reductases have been shown to contain two unusual types of copper center, one of which is identical to the Cu_A center of cytochrome *c* oxidase (*see* ***Cyanide Complexes of the Transition Metals***). Elucidating and elaborating structure/function relationships for nitrite reductases and nitrous oxide reductases have been greatly aided by the availability of multiple crystal structures for these enzymes. In addition, fairly detailed descriptions of the electronic structures of the copper sites have been developed from extensive spectroscopic and computational studies.

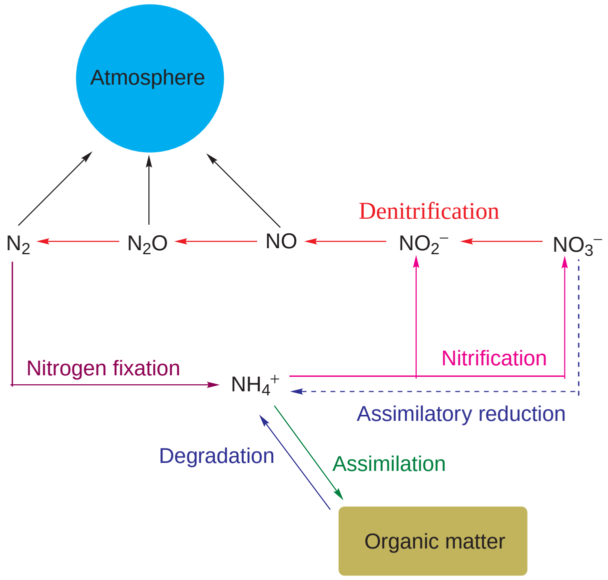

Figure 1 The global nitrogen cycle

Table 1 Redox conversions of nitrogenous oxides during denitrification

Type of reaction	Number of electrons	Formal valence change	E'_0 (mV)[a]	$\Delta G'_0$ (kJ mol^{-1})[b]
(a) Nitrate respiration				
$NO_3^- + [H_2] \longrightarrow NO_2^- + H_2O$	2	+5/+3	+420	−161.1
(b) Nitrite respiration				
$2NO_2^- + 2H^+ + 2[H_2] \longrightarrow N_2O(g) + 3H_2O$	4	+3/+1	+777	−459.2
(c) Nitrous oxide respiration				
$N_2O(g) + [H_2] \longrightarrow N_2(g) + H_2O$	2	+1/0	+1352	−339.5
(d) Nitrate respiration combined with nitrite respiration				
$NO_3^- + 2H^+ + 4[H_2] \longrightarrow N_2O(g) + 5H_2O$	8	+5/+1	+599	−781.9
(e) Nitrate respiration combined with nitrite and nitrous oxide respiration				
$2NO_3^- + 2H^+ + 5[H_2] \longrightarrow N_2(g) + 6H_2O$	10	+5/0	+749	−1121.2
(f) Nitrite respiration combined with nitrous oxide respiration				
$2NO_2^- + 2H^+ + 3[H_2] \longrightarrow N_2(g) + 4H_2O$	6	+3/0	+970	−799.9
(g) Nitric oxide formation and reduction				
$NO_2^- + 0.5[H_2] + H^+ \longrightarrow NO(g) + H_2O$	1	+3/+2	+374	−76.2
$2NO(g) + [H_2] \longrightarrow N_2O(g) + H_2O$	2	+2/+1	+1177	−306.3

[a]These values are for pH 7.0. E'_0 refers to the nitrogenous pair. [b]$\Delta G'_0$ values calculated versus the pair $H_2/2H^+$.

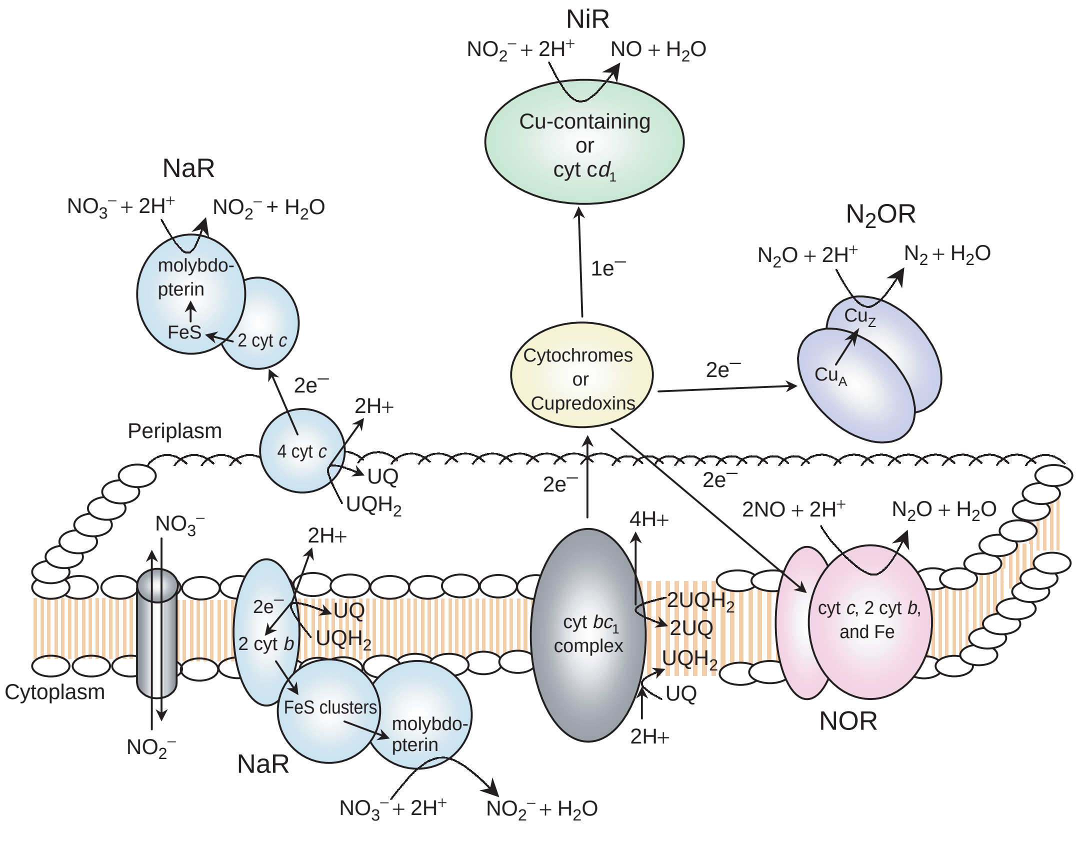

Figure 2 The dissimilatory denitrification pathway. NO_3^- is reduced to NO_2^- by a membrane-bound or periplasmic nitrate reductase(NaR). NO_2^- is reduced to NO by either a cytochrome cd_1 or copper nitrite reductase (NiR). NO is reduced to N_2O by nitric oxide reductase (NOR). N_2O is reduced to N_2 by nitrous oxide reductase (N_2OR). Electron transport from ubiquinol (UQH_2) at NaR and the cyt bc_1 complex is coupled to generation of a proton gradient

2 NITRITE REDUCTASE

Copper-containing nitrite reductases [E.C. 1.7.2.1] have been highly purified from several organisms, including, *Alcaligenes xylosoxidans*, *Alcaligenes faecalis* S-6, *Pseudomonas aureofaciens*[1,2,4,9–11] and *Haloferax denitrificans*, the first example from an Archeon.[13] Crystal structures have been determined for multiple forms of the first three enzymes.[14–21] Although there are significant variations in some of their reported properties, copper nitrite reductases appear to be trimers of identical subunits and to contain one Type 1 copper per subunit. Interestingly, some nitrite reductases are green in color, in marked contrast to the distinctive blue color of the classic Type 1 copper center. Figure 3 illustrates the electronic spectral differences between the Type 1 center of 'green' nitrite reductases and the canonical features of plastocyanin. The distinctive 480-nm band of the 'green' nitrite reductase results from the pseudo σ Cys(S) $\rightarrow$ Cu^{II} ligand-to-metal charge-transfer band gaining intensity from a distortion in the nitrite reductase site relative to the plastocyanin site.[22] This distortion is a result of the shorter Cu–S(Met) bond, which increases the ligand field strength (*see* ***Ligand Field Theory & Spectra***) and changes the orientation of the $d_{x^2-y^2}$ orbital such that the pseudo σ interaction with the S(Cys) is enhanced. A similar conclusion, based on analysis of resonance Raman spectra, was reached by Sanders-Loehr and coworkers.[23] The structurally characterized enzymes also contain a Type 2 copper site, which serves as the substrate binding site and is required for catalytic activity.[15–17,19,20,24–26] *Achromobacter cycloclastes* nitrite reductase was the first nitrite reductase to be structurally characterized (at 2.3 Å resolution).[14] A schematic view of the structure is shown in Figure 4; the protein crystallizes as a trimer (α_3) with the three subunits arranged in a head-to-tail arrangement around the crystallographic threefold axis. This structural motif is also observed in the other structures.[14–21] Each monomeric unit is composed of two domains each with a Greek key type of β-sheet topology. A Type 1 copper site is located in the amino-terminal domain. A second copper site is located at the interface between subunits in the trimer and is ligated by two histidine imidazoles from one molecule and a histidine imidazole of another molecule (Figure 4). Thus this copper site helps to stabilize the trimeric structure, in addition to the numerous amino acid contacts in the interfacial regions. The coordinated Cys in the Type 1 site and a His residue in the second site are adjacent, such that the two copper ions are separated by about 12.5 Å, a structural arrangement that is very similar to that seen in ascorbate oxidase and other multicopper oxidases (*see* ***Copper Proteins with Dinuclear Active Sites***). An especially interesting result from the crystallographic analysis is the structure of the Type 2 copper site (Figure 5). This Cu^{II} is coordinated by three histidine imidazoles and a solvent-derived ligand,

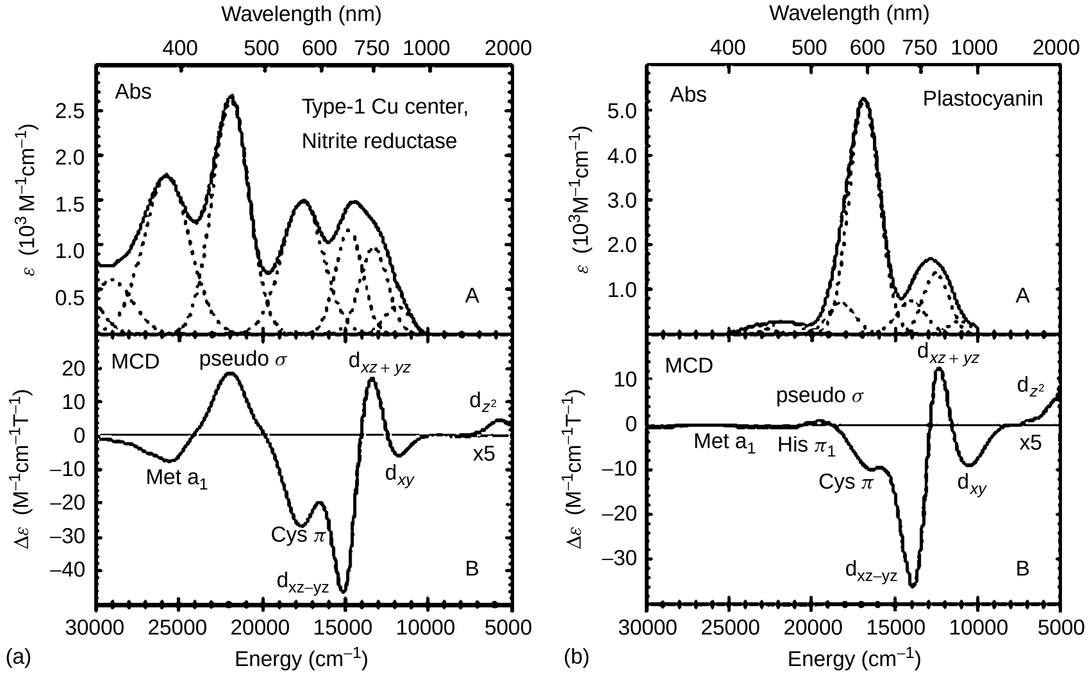

Figure 3 Electronic absorption (A) and magnetic circular dichroism (B) spectra of the Type 1 Cu site of *Achromobacter cycloclastes* nitrite reductase (a) and spinach plastocyanin (b). Absorption data were obtained at 120 K for nitrite reductase and at 25 K for plastocyanin. MCD spectra were obtained at 4.2 K. Gaussian resolution of bands in the absorption spectra is based on a simultaneous linear least-squares fit of Abs, MCD, and CD data for each. MCD data from 5000 to 8000 cm^{-1} have been multiplied by a factor of 5. (Reprinted with permission from Ref. 22. © 1996 American Chemical Society)

which is certainly a Type 2 ligand-donor set, but the geometry is distorted towards tetrahedral. Nevertheless, the Type 2 EPR signals associated with *Achromobacter* and other nitrite reductases are consistent with a $d_{x^2-y^2}$ ground state. Note that a fourth histidine is near but not coordinated to the 'Type 2' copper; this residue appears to influence nitrite binding to Cu^{II} via a hydrogen-bonding network in the active site (Figure 5).[24] Both crystallographic and spectroscopic results established that nitrite binds to the Type 2 copper,[15,17,19,27–29] displacing the solvent-derived ligand. Multiple structures of nitrite complexes of nitrite reductases have revealed bidentate O(2) coordination of nitrite, or in a few cases, monodentate O-coordination.[24] In no case has N-ligated nitrite been observed, but it has been pointed out that Cu^{II} complexes of nitrite are generally O-ligated, whereas Cu^{I} may prefer N-coordination with nitrite.[28] (*see* ***Copper: Hemocyanin/Tyrosinase Models*** for a discussion of copper coordination chemistry). Bound nitrite forms a hydrogen bond with an active site aspartic acid residue, which is also connected to the fourth histidine (see above) through H-bonds with a solvent molecule. The H-bond between coordinated nitrite and the aspartic acid residue is believed to be critical for catalysis.[24–27]

Nitrite reductases catalyze both of the reactions below; the physiological electron donors are either *c*-type cytochromes or small blue-copper proteins (equations 1 and 2).[10,11,28] The Type 1 center acts as an electron-accepting site, which then transfers the electron to the Type 2 copper where substrate binding and reduction occur.

$$NO_2^- + e^- + 2H^+ \longrightarrow NO + H_2O \quad (1)$$

$$2NO_2^- + 4e^- + 6H^+ \longrightarrow N_2O + 3H_2O \quad (2)$$

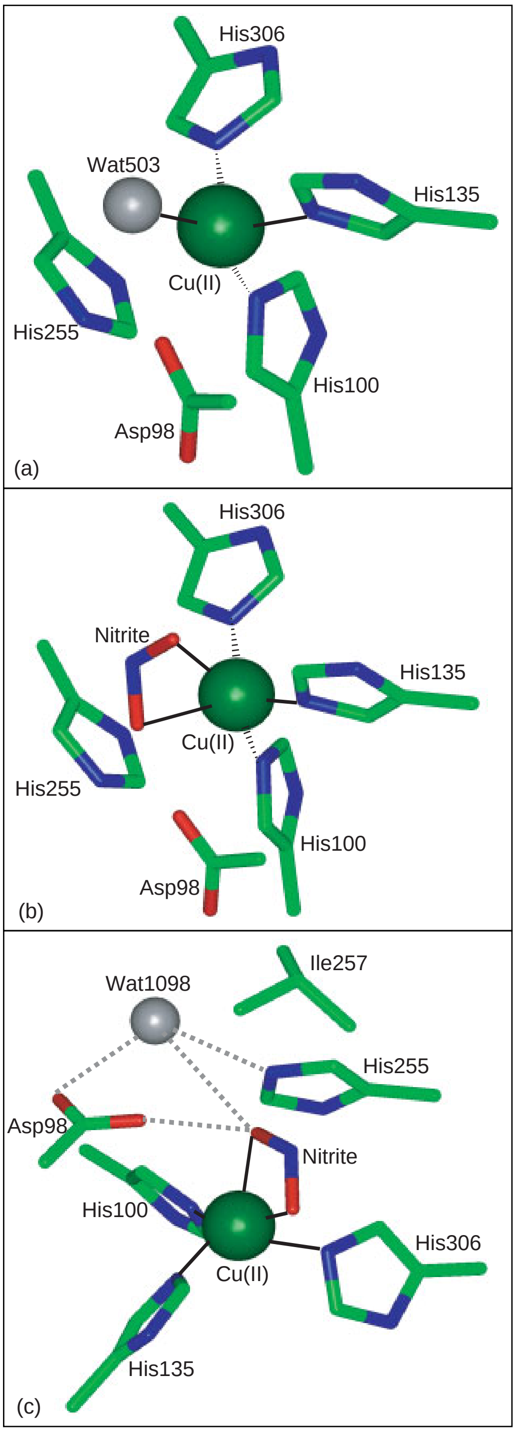

Figure 5 X-ray crystal structures of the Type 2 copper active site of nitrite reductase from *Alcaligenes faecalis* (a) oxidized and (b) nitrite-soaked. Panel (c) is a rotated view of (b) and shows the hydrogen-bonding network. Coordinates are from PDB entries 1AS7 and 1AS6[17]

The capability of nitrite reductases to catalyze both reactions initially raised the obvious question of which reaction occurred in vivo and whether NO was an obligatory

intermediate in the denitrification pathway. It is now generally agreed that nitrite reduction in most organisms proceeds stepwise with NO as an intermediate.[28–30] Mechanistic studies are consistent with the blue-copper center serving an electron-transfer function, as expected. An excellent electron-transfer pathway exists between the cysteine ligand of the Type 1 site and the His ligand of the Type 2 site (see above and ***Long-range Electron Transfer in Biology*** and ***Copper Proteins with Dinuclear Active Sites***). Proposed mechanisms for nitrite reduction, based on the structural results as well as kinetics studies of the enzymes, are shown in Figure 6. These mechanistic proposals are based on results from steady-state

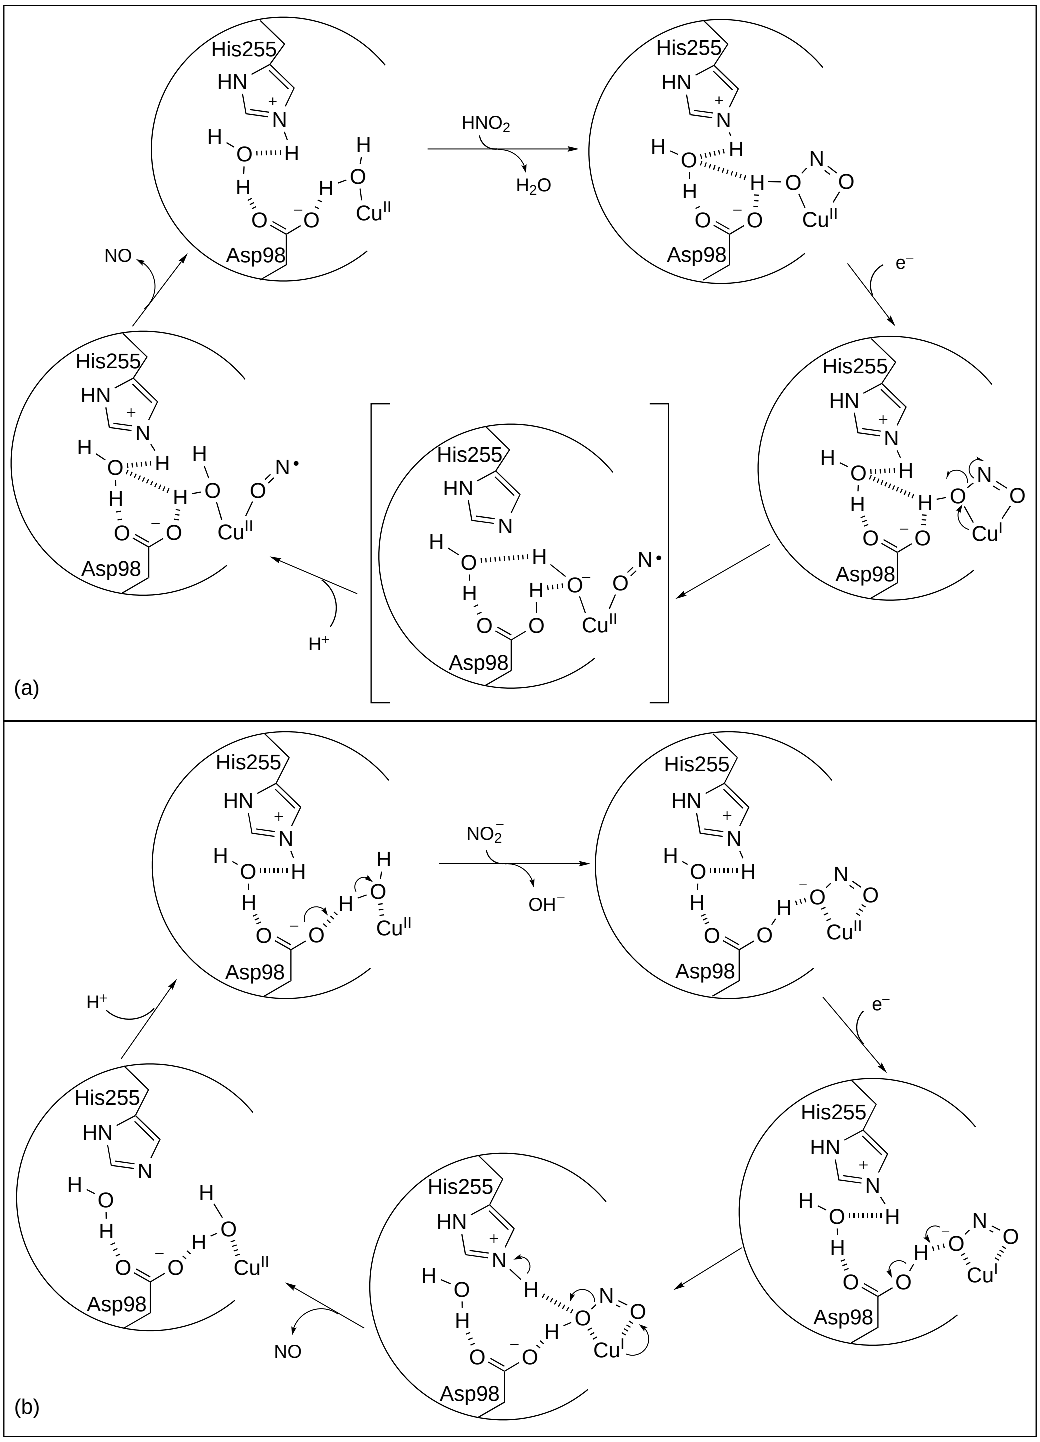

Figure 6 Proposed mechanisms for copper-containing nitrite reductase (a) via an O-bonded nitrosyl[25] or (b) a bound HONO intermediate[30]

and stopped-flow kinetics, pH effects, and the characteristics of enzyme variants produced by site-directed mutagenesis. Note that one mechanism (a) invokes an O-bonded nitrosyl, whereas b postulates a bound HONO intermediate. It should be noted however that the existing data do not completely rule out a Cu^{I}–NO^{+} species as an intermediate, although no direct evidence for such an intermediate is available. A Cu^{I} nitrosyl intermediate would be analogous to the ferrous–nitrosyl intermediate established for the cytochrome cd_1 nitrite reductases and is well precedented in model copper chemistry.[28] Indirect evidence for a Cu^{I}–NO^{+} species as an intermediate in nitrite reduction has been presented.[31,32] Further experiments are clearly required to establish the identity of the key intermediates in turnover.

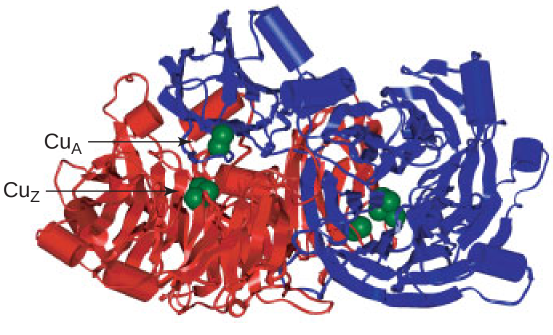

Figure 7 X-ray crystal structure of N_2O reductase from *Paracoccus denitrificans* at 1.6 Å resolution. Coordinates are from PDB entry 1FWX[50]

3 NITROUS OXIDE REDUCTASE

Nitrous oxide reductase [E.C. 1.7.99.6] catalyzes the two-electron reduction of N_2O to N_2 (equation 3).

$$N_2O + 2e^- + 2H^+ \longrightarrow N_2 + H_2O \qquad (3)$$

This is a remarkable reaction because the transition metal chemistry of N_2O is sparse, especially with copper. Most N_2O reductases are soluble, periplasmic homodimers; however, there are examples of membrane-associated enzymes.[33,34] The best characterized N_2O reductases are from *Paracoccus denitrificans*, *Pseudomonas nautica*, and *Pseudomonas stutzeri*, and most of the information presented here is derived from experiments on these enzymes. Where comparable data are available, N_2O reductases from various organisms appear to be fairly similar, with the exception of the enzyme from *Wolinella succinogenes*,[12] as noted above. The crystal structures of N_2O reductase from *P. nautica*,[35] and more recently from *P. denitrificans*,[36] show two distinct copper clusters per subunit: a bis-thiolate bridged dinuclear electron-transfer site (Cu_A), which is analogous to the Cu_A site in cytochrome *c* oxidase (*see* ***Cyanide Complexes of the Transition Metals***),[37–43] and a novel four-copper cluster ligated by seven histidines, the catalytic copper site (Cu_Z), where N_2O is thought to bind and be reduced.[44–46] Cu_Z was proposed to be a copper-histidine cluster on the basis of the presence of nine strictly conserved histidine residues,[47] and this was supported by a ^1H NMR study that identified two non-Cu_A associated resonances that were assigned as copper-histidine N–H protons.[48]

The crystal structure of the *P. denitrificans* N_2O reductase (Figures 7 and 8) established that each monomer consists of an N-terminal, seven-bladed β-propeller fold containing the Cu_Z center and a C-terminal cupredoxin fold containing the Cu_A center.[36] The dimer exhibits domain sharing, with the Cu_A site from one monomer interacting with the Cu_Z site from the other monomer. Several intersubunit contacts between Cu_A

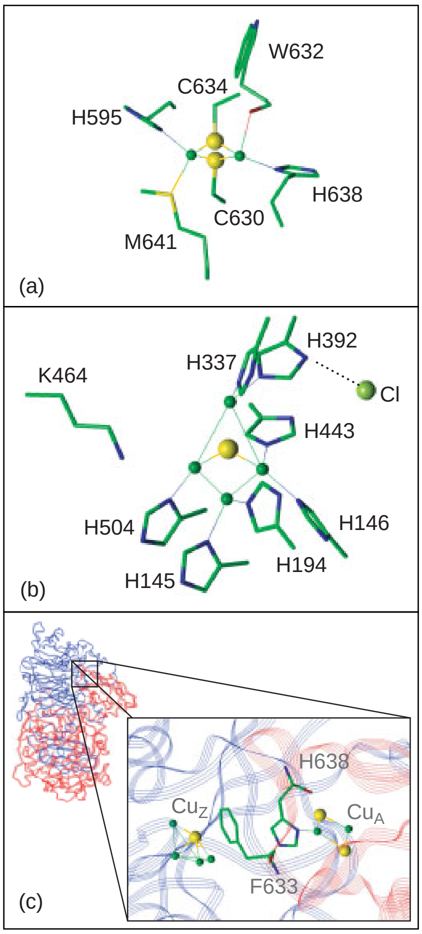

Figure 8 X-ray crystal structure of *Paracoccus denitrificans* N_2O reductase showing (a) the Cu_A site, (b) the Cu_Z site, and (c) the proposed electron-transfer path between the copper sites. Coordinates are from PDB entry 1FWX[50]

and Cu_Z ligands have been identified and are thought to provide a pathway for electron transfer. F633 is conserved and located at the dimer interface; it is postulated to be involved in the

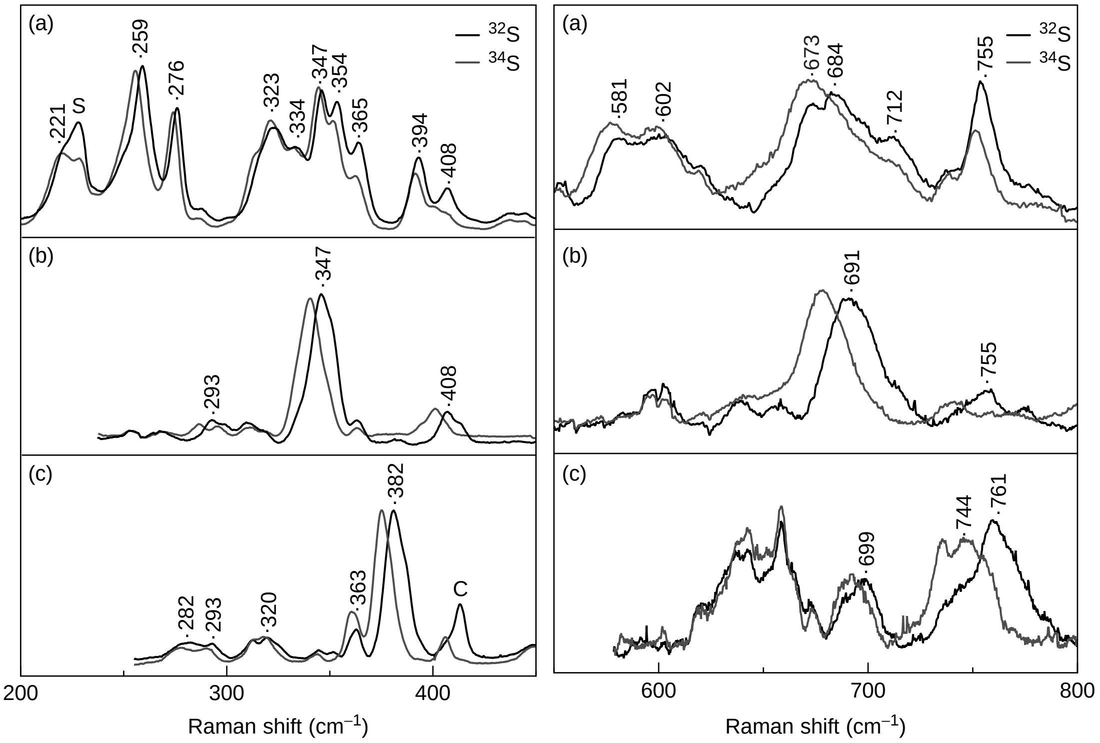

Figure 9 Sulfur isotope dependence of resonance Raman vibrational frequencies for (a) the [Cu(1.5)•Cu(1.5)] mixed-valence Cu_A site, obtained with 488-nm excitation; (b) the [2Cu(I)2Cu(II)] Cu_Z site in semireduced N_2O reductase, obtained with 568-nm excitation; and (c) the dithionite-reduced Cu_Z site, obtained with 647-nm excitation. S denotes 230-cm^{-1} ice mode from frozen solvent. C denotes a band believed to arise from an altered Cu_A site. (Reprinted with permission from M.L. Alvarez, J. Ai, W.G. Zumft, J. Sanders-Loehr, and D.M. Dooley, *J. Am. Chem. Soc.*, 2001, **123**, 476. © 2001 American Chemical Society)

intramolecular electron transfer.[35,36] Additionally, there is a Cl^- ion bound near the Cu_Z center (Figure 8(b)) and two Ca^{2+} ions lie near the dimer interface. Sulfide analysis of native and mutant forms of N_2O reductase, as well as the observation of sulfur isotope shifts in the resonance Raman of N_2O reductase (Figure 9), revealed the presence of inorganic sulfide as the bridging ligand in the Cu_Z center.[49] The recent crystal structure of N_2O reductase from *P. denitrificans*,[36,50] spectroscopic data, and chemical analysis has confirmed the structure of Cu_Z as a μ_4-sulfide bridged tetranuclear Cu center (Figures 8 and 10).[35,49,51] Variable-temperature, variable-field MCD, Q-band EPR, X-ray absorption spectroscopy (XAS), and density functional theory calculations (DFT) showed that the Cu_Z center in the dithionite-reduced enzyme from *P. nautica* is in an $S = 1/2$ state with 3Cu(I)/1Cu(II).[51,52] The DFT calculations predict a delocalized wave function with ~40% of the spin density found on Cu1 (the oxidized Cu). The μ_4-bridging sulfur forms significant σ-bonding interactions with Cu1 and Cu2, allowing the latter to hold 14% of the spin density and contributing to significant delocalization of the unpaired electron.[51] Two variants of the Cu_Z center identified as Cu_Z and Cu_Z* have been characterized from *Paracoccus pantotrophus*. While the variants have distinct spectral properties, they appear to share the same basic Cu_4S structure.[53] Spectroscopic

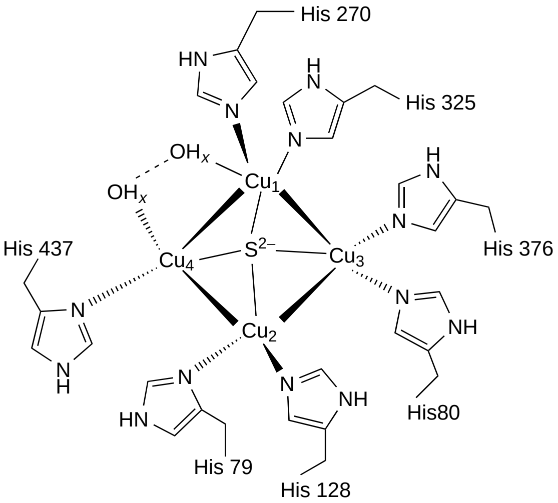

Figure 10 Model of the Cu_Z site in N_2O reductase. (Reprinted with permission from M.L. Alvarez, J. Ai, W.G. Zumft, J. Sanders-Loehr, and D.M. Dooley, *J. Am. Chem. Soc.*, 2001, **123**, 476. © 2001 American Chemical Society)

studies in conjunction with molecular orbital calculations have produced a detailed description of the electronic structure

of the [Cu(1.5)•Cu(1.5)] mixed-valence Cu_A site.[54–57] The structure of the Cu_A site is exquisitely designed for its electron-transfer role.[47,54,58–65] Pronounced covalency and electronic delocalization are characteristic of the Cu_2S_2 unit and may influence or dictate both the redox potential and the electron-transfer pathway.[56,57] Detailed analysis of the ground-state wave function of Cu_A by XAS has provided important implications for electron transfer in model systems.[66]

It is reported that approximately 50 genes are required for bacterial denitrification.[67] Their arrangement and location are organism specific, although typically the structural genes for the four key reductases are organized in clusters containing the necessary genes for regulation, cofactor assembly, and protein maturation.[10,68] (*see* ***Metallocenter Biosynthesis & Assembly*** and ***Metallochaperones & Metal Ion Homeostasis*** for general information on these topics.) The organization of the *nos* (N_2O reductase) cluster is illustrated in Figure 11, along with a schematic representation of mature protein localization. The *nos* cluster is composed of four transcriptional units, *nosR, nosZ, nosDFYL*, and *nosX*. Full sequence data for the *nosRZDFYL* clusters of *P. denitrificans*,[69] *Pseudomonas stutzeri*,[70] *Achromobacter cycloclastes*,[71] *Sinorhizobium meliloti*,[72] and *Bradyrhizobium japonicum*[73] are available. *nosR* is located upstream of the N_2O reductase structural gene, *nosZ*, and codes for a regulatory protein with two C-terminal Cys clusters similar to [4Fe-4S] binding motifs of bacterial ferredoxins (*see* ***Iron–Sulfur Proteins***). Another potential metal binding site in NosR, consisting of two CXXXCP motifs, has been identified.[71,74] *nosDFYL* contains genes for proper copper insertion or metal-cluster assembly.[70] *nosX* is located in the *nos* cluster in *S. meliloti*, *P. denitrificans*, *B. japonicum*, and *A. cycloclastes*, but is absent in *P. stutzeri* (but may be located elsewhere). Preliminary data indicate that *nosX* is required for denitrification, but its function is uncertain.[75] NosX may be involved in transcriptional regulation[75] or in the formation of the Cu_A center of N_2O reductase.[76] Transcription of the operon *nosDFYL* (Figure 11) is obligatory for the production of enzymatically active N_2O reductase[70,77] and is likely to contain the genes necessary for Cu_Z biosynthesis.[70] Preliminary characteristics of NosD, F, Y, and L have been deduced from their translated sequences and provide useful clues into their functions. NosD may be a chaperone that keeps apo N_2O reductase in a conformation amenable to copper insertions,[70] or might directly assist in copper cluster assembly. Analysis of NosD sequences has revealed the presence of two CASH (carbohydrate binding protein and sugar hydrolase) domains.[78] Additionally, the C-terminal portion of Nos D (residues 210–440) is 50% similar to NosX. NosF has sequence homology to the family of nucleotide-binding proteins of the ABC transporters and contains an ATP/GTP-binding motif.[79] A maltose binding protein, NosF fusion protein, was shown to have ATPase activity, suggesting that Cu_Z assembly involves an energy-requiring step.[80] NosY appears to be an integral membrane protein of unknown function,[71] perhaps involved in transport. NosL is a Cu(I) protein that may function as a metallochaperone (*see* ***Metallochaperones & Metal Ion Homeostasis***), providing a source of copper under limiting conditions and/or conferring metal specificity to the bioassembly process.[81] NosL has been expressed and characterized and has been shown to specifically bind Cu(I) in a 1:1 stoichiometry (Figure 12).[81] *nosD,F,Y,L* have similarities to ABC transporter families. The nucleotide-binding protein in these systems is found in the cytoplasm like NosF, with a transmembrane protein like NosY, and 1–2 periplasmic components like NosD/L. Results from transposon mutagenesis experiments in *Pseudomonas stutzeri* and reconstitution experiments in the nondenitrifier *Pseudomonas putida* indicated NosD, NosF, and NosY were required to produce functional N_2O reductase,[70,77,82] whereas NosL was not.[80] Copper chaperones are known to be involved in the insertion of copper into several proteins, and this has been suggested to be a general phenomenon

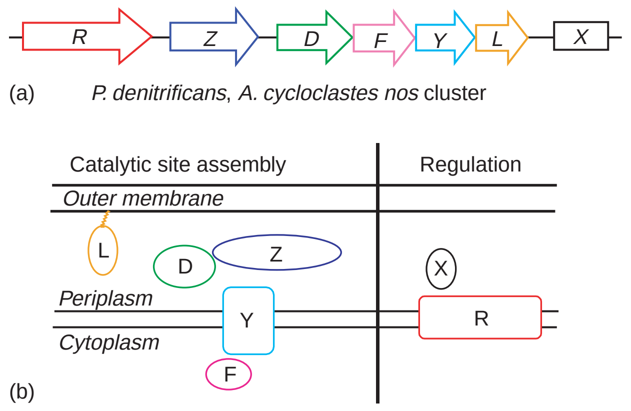

Figure 11 (a) The organization of the *nos* cluster from *Achromobacter cycloclastes* and *Paracoccus denitrificans*. (b) The predicted locations of Nos proteins

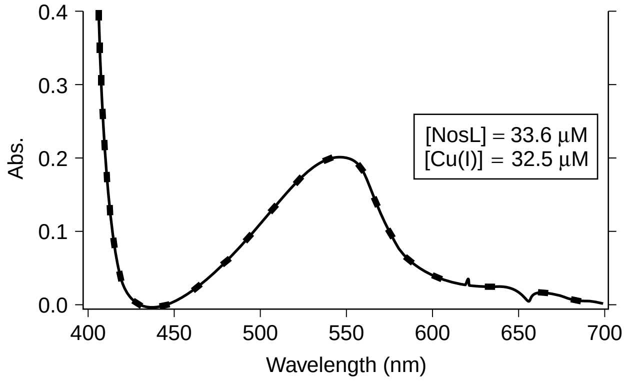

Figure 12 Reaction of NosL, anaerobically stored, with the Cu(I)-selective reagent 2,2′-biquinoline, which forms a purple complex with Cu(I) that absorbs at 546 nm; (dashed line) protein as isolated, (solid line) protein reduced with ascorbate. (Ref. 81. Reproduced by permission of Springer Verlag)

for cytoplasmic or mitochondrial proteins,[83] but may not be absolutely required for periplasmic proteins. In this context it has been suggested that the *nosDFY* ABC transporter system facilitates sulfur transfer from the cytoplasm to the Cu_Z center, with copper provided by NosL.[77] The discovery that several metalloproteins require other proteins for metal-site assembly or proper protein folding, or both, has opened an interesting and important area of research in metallobiochemistry.[81]

Chromotropic acid: 4,5-dihydroxynaphthalene-2,7-disulfonic acid
GME: gmelinite
Tiron: 4,5-dihydoxybenzene-1,3-disulfonic acid

1 INTRODUCTION

Beryllium is a lightweight, nonmagnetic, X-ray transparent, robust metal with a high melting point (1285 °C), and a stiffness six times that of steel.[1] Two forms of beryllium dominate in nature: bertrandite, $Be_4(OH)_2Si_2O_7$, and beryl, $Al_2Be_3Si_6O_{18}$ (Figure 1). Beryl is best known for its gemstone forms, emerald, and aquamarine. Beryl is converted to beryllium oxide or beryllium hydroxide by heating with sodium fluorosilicate, then extracting with water (the Copaux process), or by decomposing beryl with sulfuric acid.[2] Beryllium metal is usually prepared by generating the appropriate beryllium halide (*vide infra*), followed by electrolysis of beryllium chloride, or magnesium reduction of beryllium fluoride. Beryllium metal is used in airplanes and satellites for its combined lightness and strength, and as a window in many X-ray applications (*see* ***Diffraction Methods in Inorganic Chemistry***). The largest use of beryllium is in alloys with other metals that can produce unique properties, such as copper–beryllium, which increases in strength 6-fold with just 2% beryllium and is used in a variety of applications including nonsparking tools (*see* ***Alloys***). Beryllium oxide is a good electronic insulator with excellent thermal conductivity and is used for demanding electronic applications including supercomputers and cell phones.

Beryllium is toxic, both as a carcinogen, and as the agent that initiates chronic beryllium disease (CBD) (*see* ***Metal-related Diseases of Genetic Origin***). CBD, a granulomatous lung disease, is an uncontrolled cell-mediated immune response from inhaling beryllium in 6 to 20% of exposed individuals. The onset of CBD can be delayed for 10 to 40 years after exposure, and no strong correlation is known between dose of the beryllium and the development of CBD, although it is clear that very low levels of beryllium exposure can lead to the development of CBD. The nature and effects of CBD have been well studied,[3] but the molecular level mechanism of how beryllium triggers CBD is not well understood.[4,5] The areas of biological and environmental effects of beryllium have been the main focus of study, and far less effort has been devoted to the speciation and interactions of beryllium under physiological conditions. Despite the high toxicity of beryllium, it is still widely used for its unique properties. The use of beryllium in industry and government has increased over time and shows no sign of decline, making it imperative to understand the speciation of beryllium and its interactions with biological systems.

2 BERYLLIUM HYDROXO SPECIATION

Beryllium speciation in water, in the absence of ligands other than H_2O and OH has been well characterized (*see* ***Water & O-donor Ligands***).[6] One interesting result is the tendency of beryllium to form clusters in solution. Above pH 5.5, beryllium begins to precipitate as polymeric beryllium hydroxide $[Be(OH)_2]_n$. It is known that the hydrolysis of the aquo cation $[Be(H_2O)_4]^{2+}$ between pH 3 and pH 6 gives both monomeric and polynuclear species. The compounds $[Be_3(OH)_3]^{3+}$ and $[Be_2(OH)]^{3+}$ have been indicated as dominant species, and their corresponding formation constants have been precisely determined (Figure 2).[6,7] Additional species for beryllium hydroxo complexes are formed at intermediate Be^{2+} to OH^- ratios; in most studies, the best fit to the data was obtained with the addition of the $[Be_5(OH)_6]^{4+}$ and $[Be_6(OH)_8]^{4+}$ species (Figure 2). Using this data, a speciation diagram (Figure 3) displays the concentration of species present in solution at a given pH. The formation of different hydrolysis species is dependent on the concentration of the beryllium solution. As the concentration of the beryllium is decreased, the polynuclear species decrease in concentration, and at 10^{-6} M Be^{2+}, only Be^{2+} and $Be(OH)_2$(s) are present in solution.

Beryllium is amphoteric and the $Be(OH)_2$(s) at pH > 12 begins to dissolve, forming $Be(OH)_3{}^-$ and $Be(OH)_4{}^{2-}$ species. The ^9Be NMR gives a narrow peak at 2 ppm, which is most likely due to the $Be(OH)_4{}^{2-}$ species.

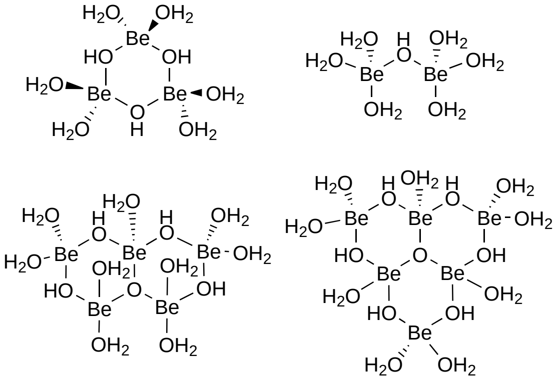

Figure 2 Proposed structures of beryllium hydroxo complexes under acidic conditions

3 INORGANIC LIGANDS WITH BERYLLIUM

Most inorganic ligands do not form stable complexes with beryllium ions under aqueous conditions because of beryllium's high affinity for oxygen donor ligands such as water. The fluoride ion exhibits the highest affinity for the Be^{2+} ion in aqueous conditions, and can contend with water for the Be^{2+} ion.[6] Fluoride can form all four substitution products with water, $[Be(H_2O)_{4-n}F_n]$ ($n = 1-4$). The fluoride ion competes with water < pH 8 at which point $Be(OH)_2(s)$ precipitates. Equilibrium constants from literature were used to form the speciation diagram in Figure 4.[6] The diagram illustrates that the $Be(H_2O)_2F_2$ and $Be(H_2O)F_3$ are the dominate complexes of beryllium at pH ranging from 0.5 to 8, although changing the concentration or varying the Be^{2+}/F^- ratio does result in the formation of the different species.

The speciation of beryllium fluoride has been monitored by NMR.[6,7] The ^{9}Be NMR of a mixture of the four species gives a spectrum that is complicated due to the overlap of the multiplet resonances. Beryllium NMR has a narrow range in chemical shifts and line broadening caused by the quadrupolar beryllium nuclei ($S = 3/2$). NMR techniques such as selective cross-polarization are used to distinguish the species from each other,[8] but the ^{19}F nuclei allows for a better distinction of the species in solution. The ^{19}F spectrum of the beryllium species exhibits a 1:1:1:1 quartet splitting due to ^{9}Be having an S-value of 3/2 (Figure 5). The three species $[BeF(H_2O)_3]^+$, $[BeF_2(H_2O)_2]$, and $[BeF_3(H_2O)]^-$ are easily distinguished as separate signals. The quartet in the ^{19}F NMR indicates the fluorides are connected to one beryllium atom, and no bridging fluorides are observed in solution. In

$[BeF_4]^{2-}$	−87.71 – −87.41	33.6	−0.34 – −0.28

$$(NH_4)_2BeF_4 \xrightarrow{>270^\circ} BeF_2 + 2NH_4F \quad (2)$$

$$BeO + Cl_2 + C \xrightleftharpoons{600-800^\circ} BeCl_2 + CO \quad (3)$$

$$Be + 2NH_4I \longrightarrow BeI_2 + H_2 \quad (4)$$

$$Be + 2KNH_2 \longrightarrow Be(NH_2)_2 + 2K \quad (5)$$

Beryllium halides are not easily prepared in the presence of water.[2] The dehydration of $BeX_2 \bullet 4H_2O$ (X = F, Cl, Br, and I) often leads to hydrolysis products; thus other methods are utilized. Beryllium fluoride is produced by thermally decomposing $(NH_4)_2BeF_4$ (equations 1 and 2). One of the common methods for the synthesis of $BeCl_2$, is heating BeO and Cl_2 gas in the presence of activated carbon at high temperatures (equation 3). Beryllium bromide can be synthesized in a similar manner as $BeCl_2$ (equation 3), using higher temperatures (1100–1200°).[2] The iodide form, BeI_2, can be prepared by heating beryllium oxide with aluminum iodide in a sealed tube. BeI_2 can also be prepared by dissolving beryllium metal in a solution of ammonium iodide in liquid ammonia (equation 4). Other inorganic beryllium compounds can be formed in liquid ammonia such as $Be(NH_2)_2$ (equation 5). Most inorganic beryllium compounds are very hydroscopic.

Little solution work has been performed with beryllium phosphate complexes. Solutions of beryllium phosphate precipitates above pH 2.5. Even chelating ligands, such as citric acid and salicylic acid, cannot solubilize beryllium in the presence of phosphate. The only reported beryllium phosphate structures known are zeolite-type structures (*see* ***Zeolites***), which are formed under elevated temperature and pressure. In recent years, a number of zeolite-type framework structures have been made.[9–11] One, beryllophosphate, forms a gmelinite framework ($BePO_4$-GME) depicted in Figure 6. The beryllophosphates are usually templated with an amine. $BePO_4$-GME used triethylene tetramine as the template. A few beryllium-containing phosphorus type ligands

such as phosphonate have been made and structurally characterized.[12,13]

4 ORGANIC LIGANDS WITH BERYLLIUM

There has been a significant amount of research on the interactions of organic ligands with beryllium due to the toxicity of beryllium and the role beryllium plays in CBD.[14,15] Most of the research has focused on mononuclear species at low pH, which is mainly due to the precipitation of $Be(OH)_2$ above pH ~5.8, and the formation of polynuclear species. Only a few ligands are able to compete with the formation of $Be(OH)_2$ ($K_{sp} = 1 \times 10^{-20}$).

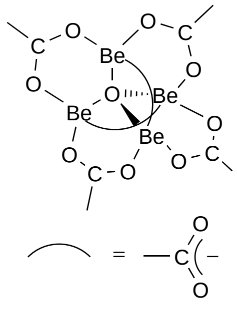

Figure 7 Beryllium acetate structure $[Be_4O(O_2CMe)_6]$ showing the Be_4O core

There are few monodentate ligands that interact with beryllium at higher pH in aqueous conditions; acetates show some affinity for beryllium and have been the most studied. Similar to the hydroxide speciation, there is a tendency for the formation of polynuclear species such as $Be_4(OAc)_6$, where the six acetates act as bridging ligands for the four beryllium atoms to form a tetrahedral Be_4O core (Figure 7).

Aliphatic bidentate carboxylate ligands have increased binding, but are still unable to compete with hydroxide precipitation at pH >6. The stable complexes of beryllium usually form at a 1:1 or 2:1 L:Be species ratio such as $Be(H_2O)_3L$, $BeL_2{}^{2-}$, or $[Be_3(OH)_3(L)_3]^{3-}$. The stability constants for some bidentate ligands are listed in Table 2. Bidentate and multidentate aliphatic hydroxycarboxylic acids are relatively poor ligands for beryllium, with binding constants ranging from 1×10^3 to 1×10^5. Coordination of these ligands is typically weak due to the weak acidity of the hydroxide, and the larger bite size caused by the sp^3 carbon alpha to the hydroxide. Citric acid (CA) on the other hand is an excellent ligand for beryllium. Citric acid solubilizes beryllium at molar concentration across the entire pH range.[16] The speciation of beryllium complexes of citric acid at high beryllium concentrations is determined by using NMR, and it shows that the dominant beryllium complex has a CA:Be ratio of 1:2. The binding features a central Be-O-Be unit with the oxygen coming from the central RO^- of CA, and one carboxylate bound on each side of the two berylliums (Figure 8). Ligands similar to citric acid (Citramalic acid, malic acid, and 3-hydroxy-3-methylglutaric acid), which provide a bridging RO^- and two carboxylates capable of forming 5 and 6 member rings upon binding to Be, also form stable complexes up to pH 9.[16] The addition of a hydroxide group on one of the methylene carbons, as in tartaric acid, dramatically disrupts the Be-O-Be motif, resulting in the precipitation at pH > 5.8.

Table 2 Stability constants for aliphatic bidentate complexes of beryllium

Ligand	K_1	β_2
Oxalate	4.08, 3.26	5.91, 5.32
Malonate	5.73, 5.35	9.28, 8.85
Succinate	4.69, 2.74	6.43, 4.36
Maleate	4.33	6.46
Folate	4.65, 5.15	8.35, 9.05

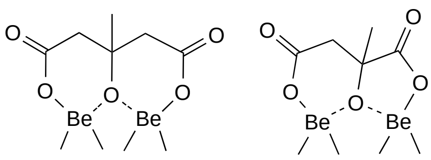

Figure 8 Citric acid binding pockets for beryllium

Aromatic hyrdroxycarboxylic acids and dihydroxy ligands form very stable complexes with beryllium. Salicylic acid type ligands, namely 5-sulfosalicyclate, have been broadly studied over the years for use as a chelation agent for beryllium poisoning.[6] Two main species are formed with these bidentate ligands, BeL and $[BeL_2]^{2-}$ (Figure 9). Catechols and other dihydoxy ligands form complexes similar to the salicylates. Stability constants for some of the higher binding beryllium ligands are listed in Table 3. Chromotropic acid forms the most stable bidentate complex with beryllium reported in literature. 2-hydroxyisophthalic acid and 2,3-dihydroxybenzoic acid form the highest stable complexes utilizing a similar motif of citric acid.[17]

Beryllium prefers to form 5-membered and 6-membered chelated rings with ligands. Seven-membered rings can be formed, but produce weaker complexes. Beryllium tends to favor the 6-membered ring, although 5-membered chelate rings with ligands such as tiron are also very stable. Where the ligand binds two berylliums, the ideal structures contain one six-membered and one five-membered rings, such as in the case of citric acid derivatives.[16,17] Functional groups also play a large part in determining whether a ligand forms a stable complex with beryllium. Hydroxides, carboxylates, or a combination of the two tend to form the majority of the stable complexes in the literature. Chromotropic acid, with a high stability constant, contains two phenolic oxygens, and forms a 6-membered ring with beryllium.[18]

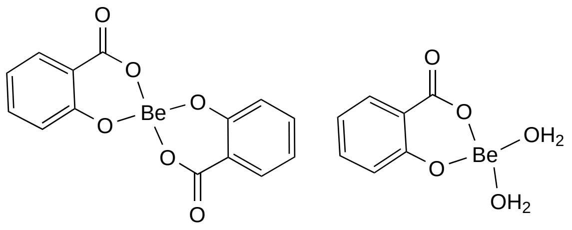

Figure 9 Structures of BeL_2 and $BeL(H_2O)_2$

Table 3 Stability constants for aromatic bidentate complexes of beryllium

Ligand	K_1	β_2
Chromotropic acid	16.2 16.34	28.2 28.19
Tiron	12.2 13.5	21.5 26.0
Catechol	13.7 13.52	25.72 23.35
5-Sulfosalicylic acid	11.2 11.74	19.7 20.66
5-nitrosalicylic acid	10.1 9.64	18.1 17.17

Beryllium is a quadrupolar nucleus ($S = 3/2$), but NMR can be a useful characterization technique. Aqueous beryllium sulfate ($Be(H_2O)_4{}^{2+}$) is used as the standard reference peak at 0 ppm. Although the frequency is affected by the concentration of the solution, at higher concentration, an upfield shift in frequency is observed. Beryllium-9 NMR is used to help determine the number of ligands and waters bound to a beryllium atom, and can also determine the size of the chelating ring formed with beryllium. As water is exchanged by anionic ligands on the beryllium, the beryllium resonance shifts downfield. The ring size also causes a shift in resonance frequency. Beryllium, in a 5-membered ring, is shifted downfield, and as ring size increases, the resonance frequency shifts upfield. The shift in frequency is more notable from a 5-membered ring to a 6-membered ring, than a 6-membered ring to a 7-membered ring chelate.

1 INTRODUCTION

1.1 Oxidation States and Their Consequences

The concept of an atom's oxidation state (*see Oxidation Number*) can provide fundamental information about the structure and reactivity of the compound in which the atom is found. In fact, it can be argued that oxidation states provided the basis for Medeleev's initial organization of the periodic table. For the main group elements, the relative stability of lower oxidation states within a given group increases as the atomic number increases. This trend in the periodic table (*see* ***Periodic Table: Trends in the Properties of the Elements***) is generally attributable to the presence of an inert s pair (*see Inert Pair Effect*) caused by relativistic effects (*see Relativistic Effects*).

Whereas discrete low oxidation state compounds of the transition metals are common in organometallic chemistry, the most typical series of examples being the transition metal carbonyl compounds (*see Carbonyl Compound*), there are at present significantly fewer classes of compounds containing main group elements in low oxidation states. An element in a low oxidation state formally has more valence electrons than it would in higher oxidation states. For the transition metals, these valence electrons are generally found in VSEPR-inactive d orbitals. In contrast, for the main group elements, the electrons are in VSEPR-active valence s and p orbitals. Thus a further consequence of having a lower oxidation state is that the main group element will tend to be coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*). Overall, the combination of low-coordination number, incompletely filled orbitals and available electrons makes compounds containing elements in low oxidation states significantly more reactive than their higher oxidation state relatives and the modes of reactivity are often distinct. For example, a low oxidation state can make a group 13 element that typically acts as an acceptor act as a donor instead. In addition to the fundamental chemical insights such compounds provide, the unique structural and chemical properties of low oxidation state main group compounds has resulted in their use as catalysts and as precursors for the formation of new and useful materials.

1.2 Scope

The types of molecules considered in this work are those that have structural or chemical features that are manifestly different than are those of their more common oxidation state counterparts. Because of the breadth of this subject, selected examples are presented to illustrate typical behavior. The properties of the types of compounds containing the elements in more typical oxidation states may be found in the *Inorganic* and *Organometallic* sections describing each element or group and will not be discussed in this article. Similarly, minerals, metal phosphides, metal carbides, and compounds where the oxidation state of the element is low based on formal electron counting techniques (as in some catenated *Catenation* group 14 compounds), but that do not result in unusual chemistry, are not included.

The chemistry of the elements in the second period is generally different from that of their heavier analogues and is only mentioned in certain illustrative cases. The very electropositive elements of the s-block lose their valence electrons readily and do not tend to form stable compounds containing the elements in low oxidation states. For group 1, the lowest typical oxidation state is the elemental form. Similarly, for group 2, while the possibility of the +1 oxidation state exists, the low electronegativity of the elements in conjunction with lattice energy considerations render the lower oxidation state unfavorable. Conversely, the more electronegative elements from groups 16–18 are typically found in the lowest available oxidation state (having an ns^2np^6 electron configuration) and the typical chemistry of such compounds is covered in the appropriate entries on each of the elements of those groups.

Apart from some important reactive intermediates, the compounds considered in this article are 'stable' in that

they may be made, characterized, used and perhaps stored under conditions that are conveniently accessible in a modern inorganic laboratory. This caveat requires that the compounds have lifetimes of at least 30 minutes in an inert gas or vacuum atmosphere at temperatures greater than −198 °C (preferably at least −78 °C). In this light, the vast amount of spectroscopic and matrix-isolation (*see Matrix Isolation*) work that has been performed on numerous diatomic and other small molecules is not discussed explicitly – in most cases, information on such species may be found in the appropriate *Inorganic* chemistry section of the particular element or group.

2 GROUP 13 ELEMENTS

In discrete molecules, the elements of group 13 are most typically found in the +3 oxidation state. There are major exceptions to this rule, such as the polyhedral boranes (*see* ***Boron Hydrides***) and carboranes (*see* ***Boron: Polyhedral Carboranes*** and ***Boron: Metallacarbaboranes***), which formally contain B^{I} and are outlined elsewhere in this Encyclopedia, and the compounds of thallium (Tl), which typically contain Tl^{I} for the reasons described above.[1] Thus, in this section, compounds containing group 13 elements in the atypical +1 and +2 oxidation states are presented.

2.1 Oxidation State +1

2.1.1 Synthesis

Compounds containing group 13 elements in the +1 oxidation state are synthesized using a number of different methods, usually through the reduction of a group 13 element in a higher oxidation state.[2,3] As illustrated in Scheme 1, the reduction of M^{III} dihalides with reducing agents such as alkali metals, alkaline earth metals, and other agents produces M^{I} compounds. In the case of In, oxidation of the metal has also been shown to produce In^{I} compounds.[4,5] Likewise, it should be noted that in some cases metallic group 13 elements can be oxidized to form RM^{I} and naked M^{I} ligands in the coordination sphere of transition metals.[6] In theory, the products of most of the preceding preparations are compounds of the form RM^{I}, which have a lone pair and two vacant *n*p orbitals and one substituent in their valence shell, as depicted in Figure 1. Such compounds are typically indicated by the suffixes '−diyl' or '−ylene', for example, RB may be called a 'borylene' or a 'boranediyl'.

Alkyl, aryl, silyl and amido substituents are all amenable to the in situ reduction protocol and similar RM^{I} compounds may also be made from univalent halides.[2,3] The structures of the compounds produced in such reactions are dependent on the nature of the substituent; for most substituents, oligomeric polyhedral clusters are obtained. The use of sterically demanding substituents tends to result in the formation of smaller clusters and oligomers, examples of which are shown in Figure 2 and can even result in monomeric compounds such as (**1**).[7] Similarly, the presence of electron-donating substituents, such as amido groups, can influence the geometry and stability of the oligomer adopted, as exemplified by $(BNMe_2)_6$ (**2**), which adopts a cyclic structure instead of a more typical octahedral arrangement.[8]

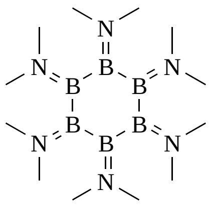
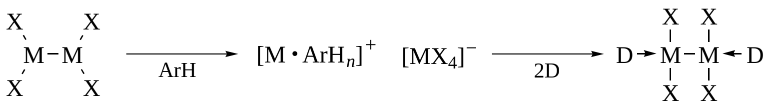
(**1**)



(**2**)

Univalent group 13 compounds also form spontaneously from certain M^{II} precursors. Dissolution of $X_2M{-}MX_2$ (M = Ga, In, Tl) in aromatic solvents results in a disproportionation to produce mixed valence salts of the form $[M\cdot arene_n][MX_4]$.[9] This process is reversed upon addition of other donors (D), as depicted in Scheme 2.

A more direct method used to prepare M^{I} compounds is through metathesis reactions with reagents that already contain



Scheme 2

$$M_{(g)} + HX_{(g)} \xrightarrow[-1/2\ H_2]{} MX \xrightarrow[\text{base}]{} [MX \cdot \text{base}]_n$$

Scheme 3

univalent group 13 elements. Whereas M^IX salts are common for In and Tl, the corresponding salts of the lighter elements have only been prepared since the late 1980s by Schnöckel and coworkers.[2,3,10] All of the univalent halides M^IX (M = Al, Ga) are prepared by the high-temperature gas-phase reaction of the appropriate metal atoms with HX, as illustrated in Scheme 3, using a specially designed apparatus (*see* ***Metallic Materials Deposition: Metal-organic Precursors***). The univalent metal halides may be stored at low temperature as metastable solutions in donor solvents; some examples M^IX have been crystallized and these exist as donor-stabilized oligomers in the solid state.

Until recently, the only unusual M^IX reagent that could be prepared using conventional synthetic procedures was the compound know as 'GaI'.[11] As shown in equation (1), this material is prepared by the sonication (*see Sonication*) of Ga metal and 0.5 equivalents of I_2 in toluene at 50 °C; however, the exact composition has not been determined.[12] Similar preparations using different stoichiometries of I_2 have resulted in other subvalent reagents such as 'Ga_2I_3', 'Ga_3I_5', and so on.

$$Ga + \tfrac{1}{2}I_2 \longrightarrow \text{``GaI''} \qquad (1)$$

Some of the most extensively explored univalent group 13 compounds are the various cyclopentadienyl 'half-sandwich' complexes of the general formula Cp′M, where Cp′ is any cyclopentadienyl ligand and M is Al, Ga, In, and Tl.[13,14] For Al and Ga, these compounds are typically prepared by the reduction of suitable dihalogenated M^{III} precursors, as outlined in Scheme 4, and they may also be prepared from available univalent halide precursors. For Cp′ ligands bearing relatively small substituents, Cp′M compounds tend to form polyhedral $(Cp'M)_n$ clusters in the solid state and dissociate into monomers in both solution and the gas phase; a depiction

$$Cp'MX_2 \xrightarrow{[\text{red}]} Cp'M \xleftarrow[-M'X]{} MX + M'Cp'$$
$$M' = \text{Li, Na}$$

Scheme 4

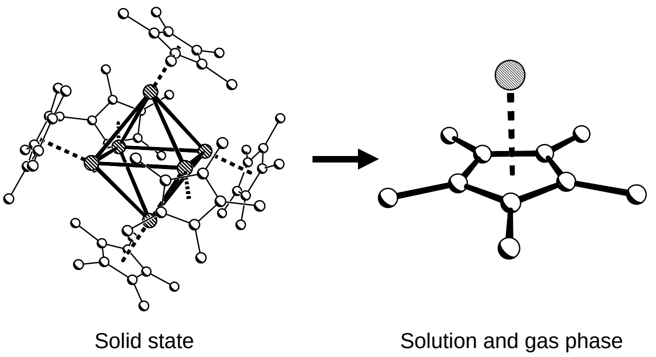


Figure 3 Oligomeric and monomeric structures of Cp*M (M = Ga, In)

of representative oligomeric and monomeric structures is presented in Figure 3. The relative stability of the monomeric form is attributable to the ability of the η^5-Cp′ ligand to donate electron density into both of the formally empty *n*p orbitals on the M^I atom (providing for a valence octet of electrons around M) in addition to the steric demands of the ligand.[15]

It has been demonstrated that the presence of even a single Cp′ substituent can, in some cases, alter the thermodynamic preference of certain systems to favor lower oxidation state products.[16] Because of its relative stability, Cp*In provides an alternative route to univalent indium pseudohalides by way of the protonolysis of Cp*H using nonoxidizing protic acids, such as HOTf or HBF_4, as illustrated in equation (2); such reactions may be applicable to the lighter congeners.[17]

$$Cp^*\text{–In} + \text{HAn} \xrightarrow[-Cp^*H]{} In^+\ An^- \qquad (2)$$
$$An = OTf, BF_4$$

A number of compounds bearing ligands that are isolobal (*see Isolobal Analogy*) with Cp′, such tris(pyrazolyl)borate, $(^tBuC)_4P^-$, or $(^tBuC)_3P_2{}^-$ and even fullerides, have also been investigated and have chemistry similar to that of the cyclopentadienyl analogues. Similarly, some other chelating ligands have been used to isolate stable, monomeric M^I compounds. Of particular note are the neutral β-diketeniminate (nacnac) complexes (**3**)[18,19] and the anionic diazabutadiene complexes (**4**)[20,21] shown below. These monomeric compounds formally have six electrons in their valence shells and are potentially group 13 analogues of carbenes (*see* ***Main Group Carbenes***).[22]

(**4**)

2.1.2 *Reactivity*

The reactivity of univalent group 13 compounds has generally been studied for compounds that dissociate, to a significant extent, into monomers in solution.[23] The electronic structure of monomeric RM^I compounds has a group 13 metal with one lone pair of electrons opposite the R ligand and two formally vacant np orbitals, as shown in Figure 1. The presence of the lone pair of electrons allows RM^I compounds to be used as donor ligands and such compounds have been used to synthesize a large number of transition metal complexes. In general, the complexes are prepared by the reaction of the RM^I donor with a transition metal complex bearing at least one readily lost ligand, as illustrated in Scheme 5, and complexes containing more than one RM^I ligand can be made in this way. The RM^I donors can act either as terminal ligands or as bridging ligands in polynuclear complexes. The molecular structure of one such transition metal complex is depicted in Figure 4.

Although no monomeric boranediyl species have yet been prepared, such ligands have been prepared in the coordination sphere of transition metals through the reaction of RBX_2 with alkali metallates such as $K_2Fe(CO)_4$.[24] Such an approach has also been used to prepare transition metal complexes for other RM^I ligands that do not dissociate into monomers in solution. Many of the transition metal complexes of univalent group 13 ligands have proved to be useful precursors for the MOCVD (*see Metal–Organic Chemical Vapor Deposition* and *Organometallic Chemical Vapor Deposition*) preparation of intermetallic (*see Intermetallics*) films and materials.[25]

The bonding between the transition metal and the group 13 element has been studied extensively by computational methods.[26] Because RM^I compounds have a valence electronic structure consisting of a filled orbital of σ symmetry and two unfilled orbitals of π symmetry, they are analogous to carbonyl ligands in that they can act as sigma donors and pi acceptors (*see π-Acid Ligand*). Such an electronic structure

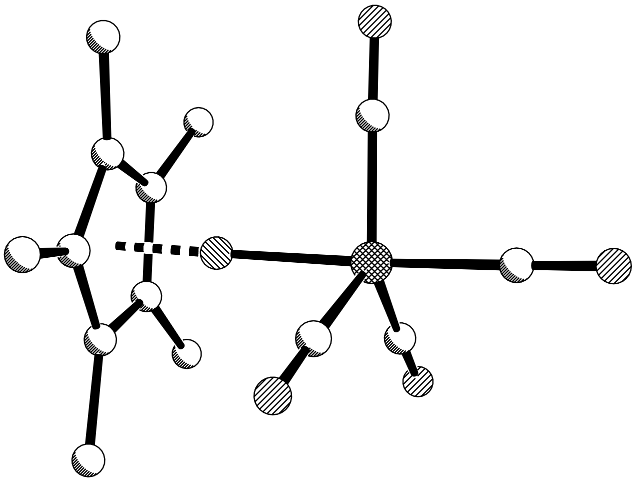

Figure 4 Molecular structure of a terminal $RM-TML_n$ complex: $Cp^*B-Fe(CO)_4$

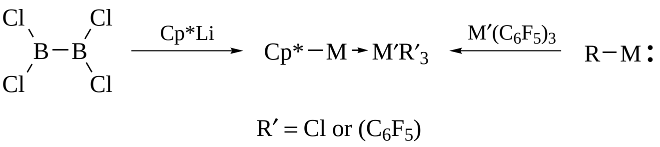
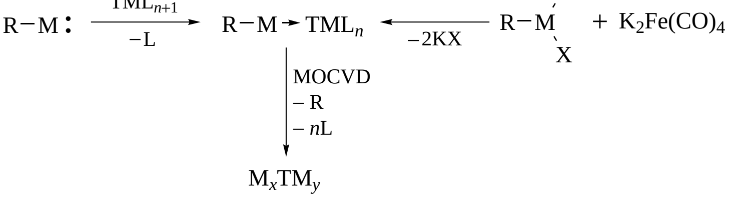
allows for numerous possible descriptions of the nature of the bond between the group 13 element and the transition metal; bonding models ranging from mostly ionic to multiple bonded covalent have been proposed.[26,27] The actual amount of transition metal to ligand back-bonding (*see Back Bonding*) is influenced by the nature of the R group on the RM^I ligand and π-acceptor ability of any other ligands on the transition metal.

Donor–acceptor complexes of univalent group 13 ligands have also been prepared with a variety of main group acceptors.[16,28–31] Such complexes are generally synthesized through the reaction of monomeric RM^I compounds with the desired Lewis acid as illustrated in Scheme 6. In particular, the reaction of a series Cp*M compounds (M = Al, Ga, In) with the strong Lewis acids $M'(C_6F_5)_3$ (M' = B, Al, Ga, In) is illustrative. Stable donor–acceptor complexes are obtained



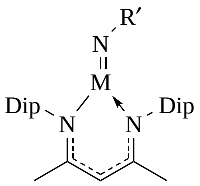
Scheme 6



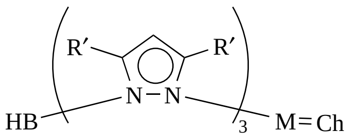
Scheme 5

in many cases and the structural features of complexes suggest that Cp*M donors are comparable in strength to triphenylphosphine. In contrast, the reaction of Cp*Al with $In(C_6F_5)_3$ results in the formation of $Cp^*Al(C_6F_5)_2$ and $[In(C_6F_5)]_n$ because of the relative stabilities of the M^I and M^{III} oxidation states for Al and In.

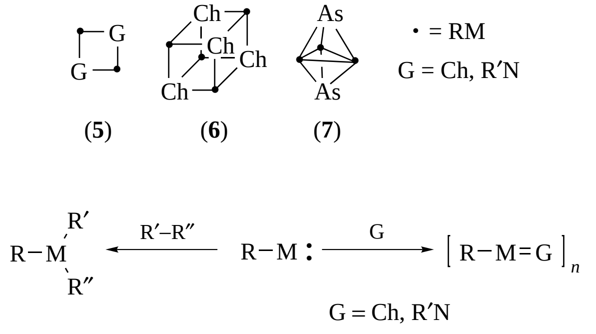
As summarized in Schemes 7 and 8, oxidation of the group 13 element in RM^I compounds is another common mode of reactivity. The reaction of RM^I with reagents such as $R'_3P{=}O$, $Me_3N{-}O$, S_8, Se, Te, or $R'N_3$ produces oligomeric M^{III} compounds of the general form $[RMCh]_n$ or $[RMNR']_n$ presumably via transient double-bonded compounds of the type RM=Ch or RM=NR′. The size of the oligomers obtained appears to be dependent on the size of the substituent(s) present. Small substituents tend to produce dimers (**5**), tetramers (heterocubanes), (**6**) and other clusters.[32] Similar clusters containing ligand-free group 15 elements, such as (**7**), can be obtained through the reaction of RM^I compounds with some of the low oxidation state group 15 compounds described in Section 4. Sterically demanding substituents can allow for the isolation of the double-bonded monomers, such as in the cases of (nacnac)M=NR′ (**8**)[33] or for TpM=Ch (**9**).[34] Similarly, various RM^I compounds insert into reactive bonds in transition metal, main group, or organic compounds to produce M^{III} species. This process is analogous to the oxidative addition process observed for some organometallic species and such reactivity has resulted in the use of RIn^I salts as catalysts for various C–C bond-forming reactions.[4]



(**8**)



(**9**)



Scheme 7

The oxidation of the reactive M^IR compounds through cycloaddition with organic multiple-bonded reagents, such as alkynes, dienes, and heterodynes, produces heterocyclic compounds that contain M^{III} (Scheme 8). In the case of Al^ICl, the initial cycloaddition products often oligomerize to form larger heterocycles and clusters compounds.

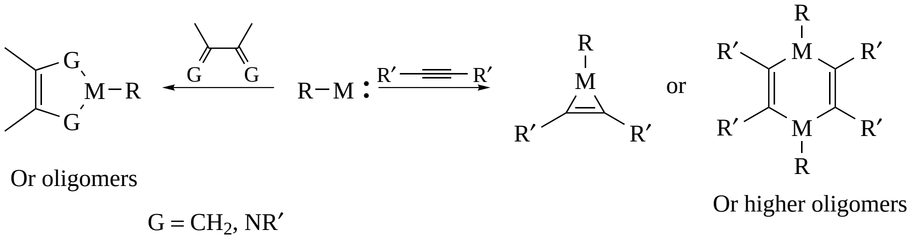
Reduction or disproportionation of univalent group 13 compounds generally results in the formation of multiple-bonded species, clusters, and metals (equation 3).[35–37] Such reactivity has been exploited for the production of indium nanoparticles (y = 0) by the solvothermal decomposition of CpIn.[38] Similarly, the thermal decomposition of many RM^I compounds (M = Al, Ga, In) results in the elimination of a portion of the substituents and produces metal-rich group 13 clusters of various sizes; the clusters obtained are thought to be intermediates on the pathway to the formation of bulk metal.[39]

$$\text{R–M:} \xrightarrow[-(x-y)\text{R}]{\Delta} M_xR_y \text{ clusters} \qquad y < x \tag{3}$$

2.2 Oxidation State +2

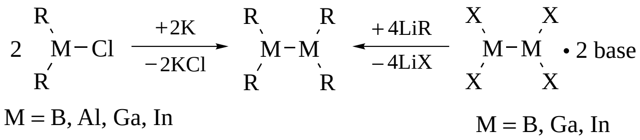
2.2.1 *Synthesis*

As outlined in Scheme 9, compounds containing group 13 elements in the +2 oxidation state are generally synthesized either by the alkali metal reduction of suitable halogenated precursor R_2MX or by metathesis reactions with available $X_2M{-}MX_2$ compounds that contain M^{II}.[40] The ligands that have been introduced using this method include aryl, alkoxy, and diketonates, but the most extensively examined series of compounds bear either the bis(trimethylsilyl)methyl (‘disyl’),



Scheme 8

tris(trimethylsilyl)methyl (‘trisyl’) or other bulky silyl ligands. The general name for compounds of the type $R_2M–MR_2$ is ‘dimetallane’; thus a compound containing an Al–Al bond is termed a ‘dialane’.



Scheme 9

2.2.2 *Reactivity*

Compounds containing M–M bonds can be further reduced, typically through the action of alkali metals and some alkyllithium reagents, to produce either multiple-bonded radical anions or M^{I} compounds; examples of such reduction products compounds are depicted in Figure 5.[41]

Some of the most extensively explored classes of reactivity of M^{II} compounds are oxidation of the group 13 elements either by insertion of a molecule into the M–M bond, cleavage of the M–M bond, or addition of a molecule to the M–M bond. Selected examples of such reactions are depicted in Schemes 10 and 11.[41]

The reaction of $R_2M–MR_2$ compounds with carboxylic acids provides different M^{III} products depending on the group 13 element, as summarized in Scheme 12. For Al, the reaction results in the cleavage of the Al–Al bond and the formation of a carboxylate-bridged and hydrogen-bridged dinuclear aluminum compound. For indium, the reaction also results in the cleavage of the In–In bond and yields In^{III} products and indium metal. For gallium, the Ga–Ga bond remains intact and two of the R ligands are cleaved instead.[42]

The transition metal ligand chemistry of M^{II} compounds has largely been restricted to the diboranes $R_2B–BR_2$, which

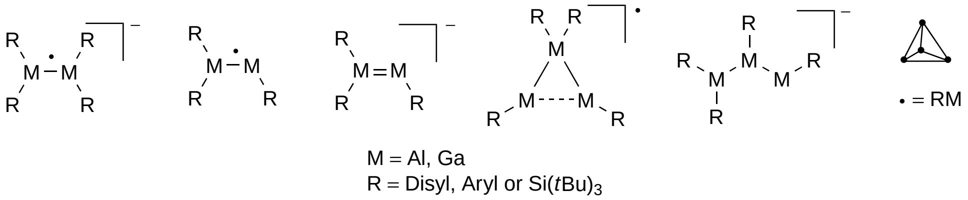


Figure 5 Some products obtained from the reduction of $R_2M–MR_2$ compounds

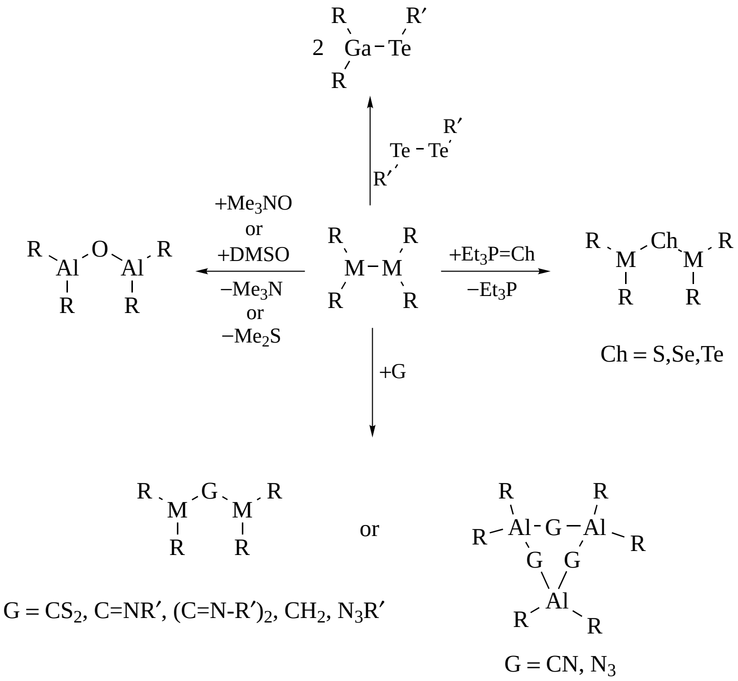
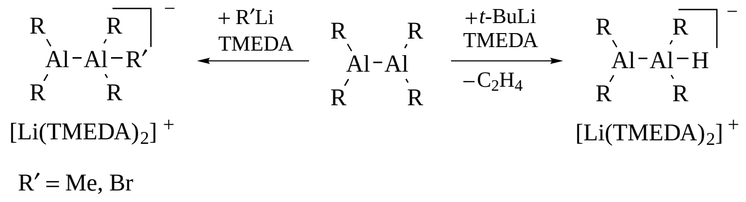
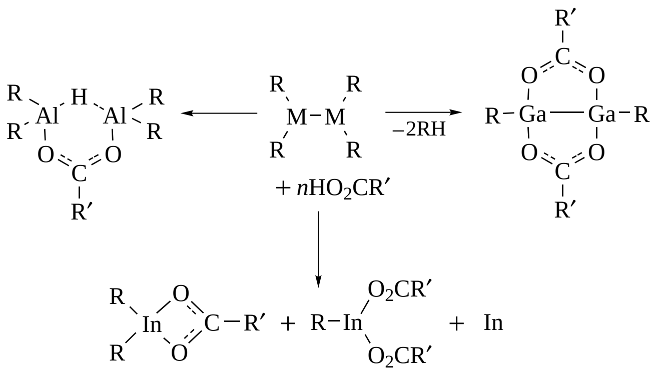


Scheme 10

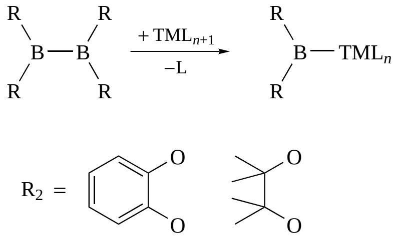


Scheme 11



Scheme 12

produce boryl ligands through the cleavage of the B–B bond (equation 4).[43] The boryl groups can act as either terminal or bridging ligands and the transition metal complexes have been investigated extensively as reagents for hydroboration reactions.[44]



(4)

3 GROUP 14 ELEMENTS

The typical oxidation state for the lighter group 14 elements is +4 and because of periodic trends, the +2 oxidation state is common for the heavier elements such as Sn and Pb. There are numerous cluster compounds, known as Zintl compounds (*see* ***Zintl Compounds***), that contain group 14 elements in formally low oxidation states and that are described elsewhere in this Encyclopedia. Likewise, the group 14 carbene analogues (*see* ***Main Group Carbenes***) and multiply bonded compounds (*see* ***Main Group: Multiple Bonding***) that contain formally univalent or divalent group 14 elements are presented in the appropriate entries. Similarly, compounds containing E–E bonds are not discussed; thus only group 14 elements with oxidation states of less than +2 are considered in this section.

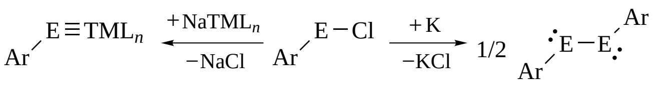
The only E^{I} halide yet reported is $[GeBr]_n$, which was made by the gas-phase reaction of Ge atoms and HBr.[45] While the structure of the bromide compound has yet to be determined, it has been used to make Ge_xR_y clusters ($y < x$) through the metathesis reaction with silyl-lithium or sodium reagents as shown in Scheme 13.[46,47] The formal oxidation state of the Ge atoms in the metal-rich clusters is less than one.

A few compounds containing R–E fragments have been made by the reduction of chlorinated E^{II} precursors bearing very bulky aromatic or silyl substituents. In the absence of other reagents, the univalent group 14 fragments dimerize to form multiple-bonded compounds. If the reaction is performed using a transition metallate reducing agent, the resulting transition metal complex contains a terminal multiple-bonded Ar–E ligand. These reactions are summarized in Scheme 14.[48,49]

Apart from the numerous Zintl ions, compounds containing zero-oxidation state group 14 atoms are rare because of the energetically favorable deposition of the element. Compounds (**10**)[50] and (**11**)[51] have been described as containing stabilized E atoms. Both of the compounds contain neutral ligands, bipy, and DAB, which are readily reduced to the corresponding

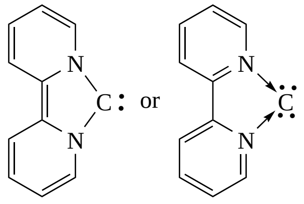
$$Ge_{(g)} + HBr_{(g)} \xrightarrow[-1/2\ H_2]{} 1/n\ [GeBr]_n \xrightarrow[-LiBr\ \text{or}\ -NaBr]{+LiR\ \text{or}\ +NaR} Ge_xR_y\ \text{clusters}$$

Scheme 13

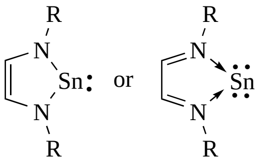


TML_n = CpTM(CO)$_2$
TM = Cr, Mo, W

Scheme 14

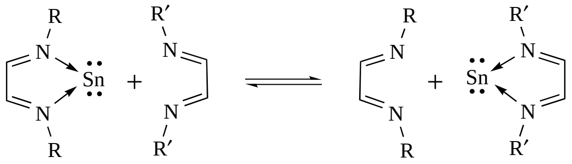


(**10**)



(**11**)

dianions, which also allows for the element to be described as being in the +2 oxidation state. The zero-valent description of the tin complex is supported by the observation of tin exchange from one DAB ligand to another neutral DAB ligand as shown in equation (5).[51]



(5)

4 GROUP 15 ELEMENTS

In compounds, the elements of group 15 (pnictogens, Pn) are typically found in either the +3 or +5 oxidation state. Low oxidation state compounds are known for group 15 elements in the +2, +1, 0, −1, and −3 oxidation states; examples of compounds exhibiting common structural types are shown in Figure 6.

4.1 Oxidation State +2

The most common examples of pnictogens in the +2 oxidation state are the class of compounds of the general form $R_2Pn–PnR_2$ called 'dipnictines'; a molecule of the type $R_2As–AsR_2$ is called a 'diarsine'. Such compounds are typically prepared from the reduction of halopnictines by alkali metals, alkaline earth metals, or other reducing agents (equation 6). Alternatively, elimination of hydrogen from secondary pnictines and acid or salt elimination reactions have also been employed to synthesize dipnictines (equations 7 and 8). There are numerous examples of such compounds containing each of the group 15 elements (*see* ***Phosphorus: Organophosphorus Chemistry***; ***Arsenic: Organoarsenic Chemistry***; ***Antimony: Organometallic Chemistry***, and ***Bismuth: Organometallic Chemistry***), with the nitrogen analogs (hydrazines) being ubiquitous.

$$R_2PnX \xrightarrow[-NaX]{Na} R_2Pn–PnR_2 \qquad (6)$$

$$R_2PnH \xrightarrow[-H_2]{\Delta} R_2Pn–PnR_2 \qquad (7)$$

$$R_2PnX + R_2PnH \xrightarrow[-HX]{} R_2Pn–PnR_2 \qquad (8)$$

Although dipnictines formally contain +2 oxidation state pnictogens, most of their chemistry is similar to their +3 oxidation state PnR_3 analogs. In exceptional cases, unique behavior is observed. For example, when the R-groups are of sufficient steric bulk, the Pn–Pn bond in dipnictines can cleave homolytically to produce two PnR_2 radicals (equation 9) in either solution or the gas phase. The gas-phase structure of one such radical is depicted in Figure 7.[52] In addition, the metathesis reaction of diphosphines or diarsines with R′ChChR′, when R′ is sufficiently bulky, can also result in the generation of pnictinyl radicals (equation 10). Phosphinyl radicals can be generated by reduction under photolytic conditions in the presence of electron-rich olefins or by alkali metals (equation 11). In addition, both phosphinyl and arsinyl radicals have been obtained by the addition of excess aryllithium to the corresponding diarylchloropnictine (equation 12).[53]

$$R_2Pn–PnR_2 \xrightarrow{\Delta} :\dot{P}nR_2 \qquad (9)$$

$$RP{=}PR \xrightarrow[R' = t-Bu,\ n\text{-}Pr;\ Ch = O,S]{R'ChChR'} :\dot{P}n(R)(ChR') \qquad (10)$$

$$R_2PnX \xrightarrow[\text{or Na}]{h\nu + \text{olefin}} :\dot{P}nR_2 \qquad (11)$$

$$PnMes^*Cl_2 \xrightarrow[-LiCl]{\text{ex LiMes}^*} :\dot{P}nMes^*_2 \qquad (12)$$

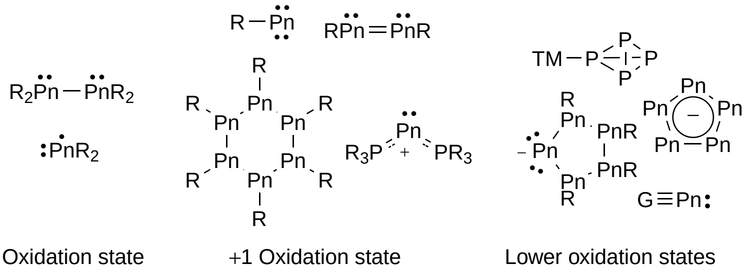


Figure 6 Common structural types of compounds containing low oxidation state group 15 elements

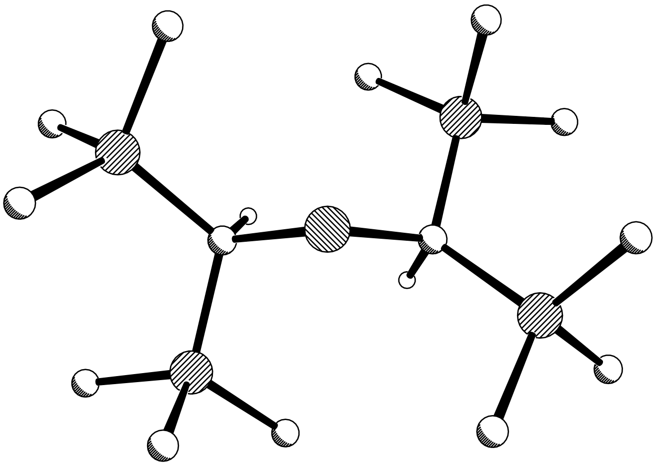

Figure 7 Gas-phase structure of a $Pn(CH(SiMe_3)_2)_2$ radical

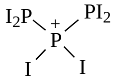
Cationic compounds that formally contain P^{II} are accessible through the reduction of phosphorus trihalides. $P_2X_5^+$ can be synthesized by treating two equivalents of PX_3 (X = Br, I) with a silver salt (equation 13).[54] Similarly, the addition of PI_3 and P_2I_4 to a silver salt produces salts containing the cation $P_3I_6^+$ (equation 14).[55] Organophosphorus analogs of such salts can be synthesized by addition of phosphines to Lewis acidic phosphenium cations R_2P^+ to produce $[R_2P–PR_3]^+$; however, such compounds exhibit chemistry typical of P^{III} and are thus not generally considered in the context of containing phosphorus in a lower oxidation state.[56]

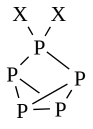
$$PX_3 \xrightarrow[-AgX]{Ag[Al(OR)_4]} X_2P–\overset{+}{P}X_3 \qquad (13)$$

$$PI_3 + P_2I_4 \xrightarrow[-AgI]{Ag[Al(OR)_4]} \qquad (14)$$



An alternate route to +2 oxidation state pnictogens is through the oxidation of the elemental form, which leads to compounds such as Pn_2I_4 (Pn = P, As) (*see* ***Phosphorus: Inorganic Chemistry*** and ***Arsenic: Inorganic Chemistry***). Cationic P^{II} compounds can also be generated using this method, as exemplified by the addition of a silver salt to an equimolar mixture of P_4 and PX_3 (X = Br, I) to give $P_5I_2^+$ (equation 15).[54]

$$PX_3 + P_4 \xrightarrow[-AgX]{Ag[Al(OR)_4]} \qquad (15)$$



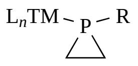
4.2 Oxidation State +1

The largest class of +1 oxidation state group 15 compounds are the 'pnictinidenes', R–Pn (e.g. a compound of the type R–P would be called a 'phosphinidene'), and their cyclic oligomers, which are known for all of the heavier pnictogens. Putative monomeric pnictinidenes are composed of a pnictogen atom with a single substituent and four nonbonding electrons. They may have either a singlet ground state with two lone pairs and an empty p orbital or a triplet ground state with one lone pair and two singly occupied p orbitals. Such highly reactive species are not able to be isolated under standard conditions and are generally used as intermediates that are generated in situ or as stabilized compounds such as those described below. Putative pnictinidenes are typically generated by either reduction of a dihalopnictine or photolytic release of either ethane from pnictiranes or CO from phosphaketenes. The nitrogen analogues, known as nitrenes, can form when azides are photolyzed (equation 16); however, the lack of appropriate starting materials prevents the use of such a method for the preparation of higher congeners.[57] Pnictinidenes are highly reactive and must be either trapped or stabilized (through cycloaddition with olefins, coordination to transition metal fragments, or donation from a Lewis base), otherwise they dimerize into multiply bonded dipnictines, RPn=PnR (*see* ***Main Group: Multiple Bonding***), oligomerize into rings (Scheme 15), or become oxidized.

Terminal phosphinidene-metal complexes, $L_nTM{=}PR$, readily add to double bonds (equation 17). Both metal-stabilized and phosphine-stabilized phosphinidenes, $R'P{=}PR_3$, can act as phospha-Wittig reagents, which undergo metathesis reactions with carbonyl-containing compounds to generate carbon–phosphorus double bonds (equations 18 and 19).[58] Pnictinidenes and their complexes have been extensively reviewed in terms of both their syntheses and reactivities.[59–62]

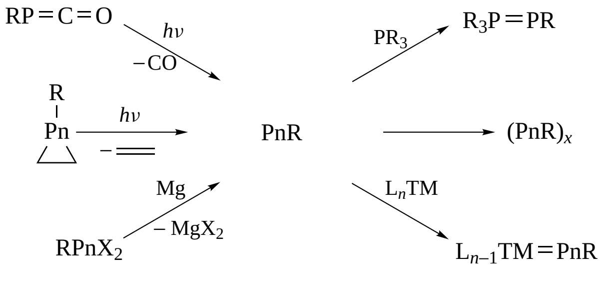
$$R–N_3 \xrightarrow[-N_2]{h\nu} R–N \qquad (16)$$

$$L_nTM{=}PR \xrightarrow{=\!=} \qquad (17)$$



$$L_nTM{=}PR \xrightarrow{O{=}CR_2} R_2C{=}PR \qquad (18)$$

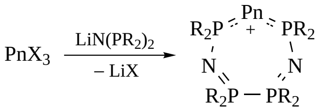
$$R_3P{=}PR \xrightarrow{O{=}CR_2} R_2C{=}PR \qquad (19)$$



Scheme 15

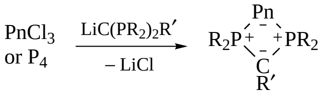
Cyclic pnictinidenes, $(PnR)_n$, can coordinate to transition metal centers as monodentate or polydentate ligands. Alternatively, the homocycles can undergo ring opening and coordinate as chelating ligands or, in some cases, the compounds can liberate pnictinidene units that coordinate to metal centers. The actual mode of reactivity is dependent on the R-substituent and on the nature of the pnictogen atom.[63–66]

Stabilized pnictogen atoms in the +1 oxidation state are typically found in cations of the general formula $[R_3P–Pn–PR_3]^+$ (Pn = P, As). Cyclic and acyclic examples of such compounds have been synthesized by the reduction of PnX_3 in the presence of stabilizing phosphines (Scheme 16).[67–69] External reducing agents are not necessary in the case of PnI_3 (Pn = P, As), which disproportionates spontaneously in the presence of the phosphine ligands to form Pn^I salts.[70] The molecular structure of one such cation is depicted in Figure 8. Another route to related low oxidation state compounds is the reaction of lithium diphosphinoamides with pnictogen trihalides, which typically results in seven- or eight-membered ring compounds (equation 20).



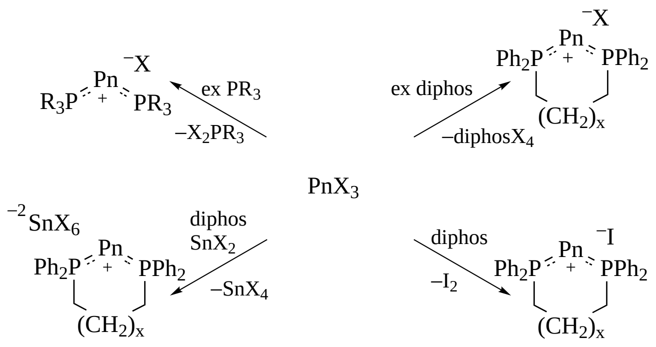
(20)

A group of related zwitterionic (*see Zwitterion*) compounds is formed by the addition of lithium phosphinomethanides to either $PnCl_3$ or P_4, which result in four- or six-membered rings (equation 21).[71] It should be noted that the attempted reduction of Sb and Bi trihalides to form +1 oxidation state compounds typically results in the production of Sb^0 or Bi^0, which precipitates from solution.[72]



(21)

Several of the phosphine-stabilized P^I and As^I cations are air stable; the electronic structure of such compounds, as summarized by the various canonical forms shown in Figure 9, provides insight into the surprising stability. Pn → ligand back-bonding allows for the delocalization of electron density on Pn to the ligands, and reduces the reactivity of the cations.



diphos = $Ph_2P(CH_2)_xPPh_2$

Scheme 16

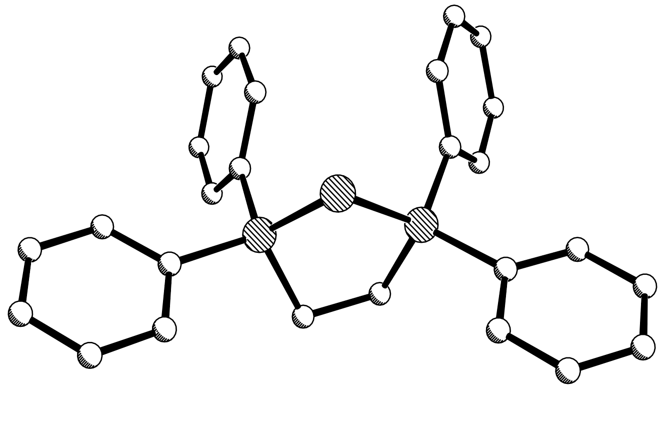


Figure 8 Molecular structure of a cation containing P^I, $[(dppe)P]^+$

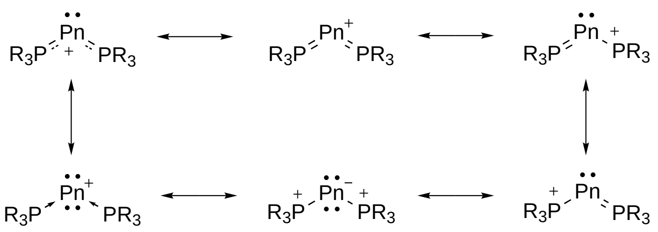

Figure 9 Canonical structures of stabilized P^I and As^I cations

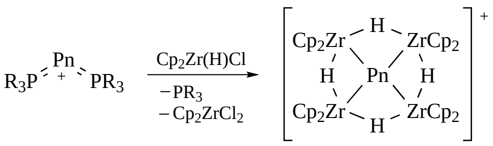
Cationic P^I compounds exhibit several modes of reactivity, including: coordination to Lewis acids; oxidation by acids, water, and alkyl chlorides; and substitution of the stabilizing phosphine ligands by stronger donors (Scheme 17).[73–75] Some of these P^I and As^I cations have also been shown to be useful sources of P^I and As^I ions that provide zirconium complexes (**12**) containing unique square-planar Pn environments (equation 22).[76]

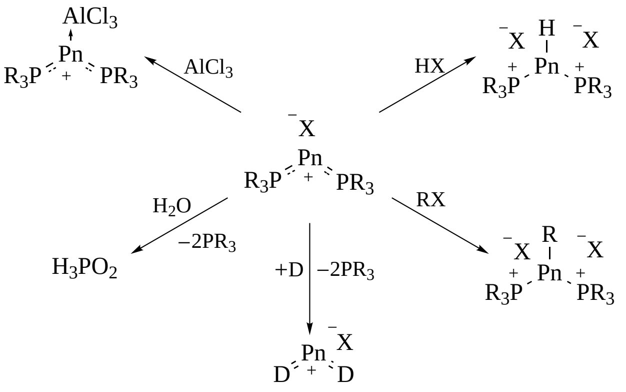


(22)

(**12**)

4.3 Lower Oxidation States

There are a limited number of examples of white phosphorus, composed of P^0 atoms (equation 23), acting as a ligand to transition metals.[77–79] Lower oxidation state compounds of the pnictogens typically consist of oligomers



Scheme 17

of substituent-free pnictogen atoms. Phosphorus, arsenic, and antimony all form planar Pn_x, anionic rings that are analogous to Cp′, while bismuth can form a planar, dianionic four-membered ring.[80] These compounds can act either as terminal or bridging ligands for transition metal compounds. Other −1 oxidation state compounds include alkali metal salts of Pn clusters and various Zintl ions (*see* ***Zintl Compounds***), which are known for all the heavier pnictogens.

(23)

The lowest oxidation state, −3, having a ns^2np^6 electron configuration, is found in transition metal complexes of ligand-free Pn anions. When a single Pn^{-3} ion is attached to a metal, they are collectively referred to as 'pnictido' ligands and form terminal metal–pnictogen triple bonds, which are known for all group 15 elements except bismuth.[81]

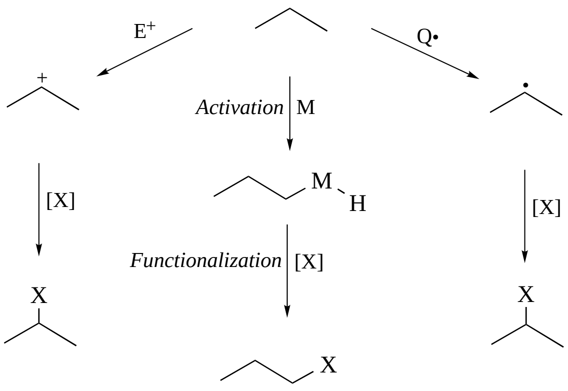
1 INTRODUCTION

'CH Activation' is sometimes used rather too loosely to cover a wide variety of situations in which CH bonds are broken. As Sames has most recently pointed out,[1] the term was first adopted to make a distinction between organic reactions in which CH bonds are broken by classical mechanistic pathways, and the class of reactions involving transition metals that avoid these pathways and their consequences in terms of reaction selectivity. For example, radicals such as RO• and •OH readily abstract an H atom from alkanes, RH, to give the alkyl radical R•. Also in this class, are some of the metal catalyzed oxidations, such as the Gif reaction and Fenton chemistry (*see* ***Oxidation Catalysis by Transition Metal Complexes***). Since this reaction tends to occur at the weakest CH bond, the most highly substituted R• tends to be formed, for example, *i*Pr• and not *n*Pr• from propane. Likewise, electrophilic reagents such as superacids (*see Superacid*), readily abstract a H^- ion from an alkane. The selectivity is even more strongly in favor of the more substituted carbonium ion product such as $i\text{Pr}^+$ and not $n\text{Pr}^+$ from propane. The result is that in any subsequent functionalization, the branched product is obtained, for example, *i*PrX and not *n*PrX (Scheme 1).

In a broad class of reactions of CH bonds with low-valent transition metals, however, the metal inserts into a CH bond of the alkane to give an alkylmetal hydride in which there is often a preference for formation of the least substituted alkyl. In any subsequent functionalization, the linear (or least branched) product is obtained, for example, *n*PrX and not *i*PrX. Since the branched product can be obtained



Scheme 1

by classical organic procedures, CH activation is potentially important in providing a route to the linear compounds that are often more useful in many applications. Unfortunately, CH activation has not so far been made efficient enough for it to become commercially important. With the rise of methane as a feedstock for the twenty-first century, the need for alkane activation will become more acute. Methane is hard to transport and use, while its oxidation product, methanol (or a methanol derivative such as $MeOCH_2OMe$) would make a convenient fuel and carbon source.

The case of methane to methanol brings up a second important selectivity problem in the field: how to stop at the methanol oxidation level. Methanol is much more sensitive to oxidation than methane, so any classical oxidation procedure is likely to overoxidize the methanol to CH_2O, CO, and CO_2. The CH activation route has the advantage that the CH bond of methanol is not exceptionally reactive relative to that of methane, so the overoxidation problem, while not completely eliminated, is nevertheless reduced to manageable proportions.

The case of methane also raises the issue of enzymatic oxidation. This proceeds selectively to methanol with the methane monooxygenases (MMO, *see Monooxygenase*; ***Iron: Models of Proteins with Dinuclear Active Sites***; ***Iron Proteins with Dinuclear Active Sites***) but the selectivity is not a function of the chemistry employed, which appears to be H atom abstraction by a high-valent oxoiron cluster, but of the 'chemical engineering' of the site. The monooxygenase pathway automatically delivers only 2e of oxidation after which the hydrophobic site expels methanol before the site is reactivated for the next oxidation to occur. This step occurs by the provision of 2e of reducing power that serves to reduce one O atom of the O_2 substrate to water, leaving the remaining oxygen atom available for transfer to the substrate – hence the term monooxygenase.

Early work with transition metals, following Fenton-type chemistry (*see Fenton Chemistry*), employed the transition metal as a catalyst for the decomposition of a primary oxidant to yield radicals such as RO• and •OH that readily abstract an H atom from alkanes, RH, to give R•. These radicals

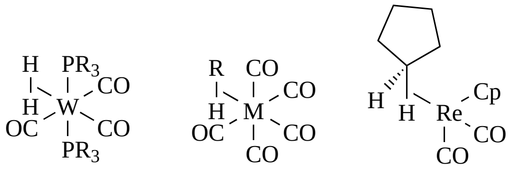
can be functionalized, for example, by reaction with O_2 to give RO_2•, which in turn decompose under the conditions used to give a mixture of alcohol and ketone. This puts the chemistry within the realm of classical organic reactions, at least from a mechanistic perspective. Some high-valent oxometal intermediates may be able to oxidize alkanes without production of radicals but this area is controversial and we do no more than indicate a recent book.[2] Other early reactions, such as those of arenes with Hg^{2+}, led to electrophilic aromatic substitution, another well-recognized reaction of classical organic chemistry.

We restrict our attention to the reactions of CH bonds with low-valent transition metals that avoid radical or electrophilic selectivity patterns and are therefore considered CH activation in the sense considered at the outset of the review. A number of non-alkane CH activation reactions are included where they derive from concepts developed in alkane work and where they have proved particularly useful.

2 ALKANE COMPLEXES

Many CH activation pathways are thought to go via an intermediate in which the alkane is bound to the metal as a sigma complex. Sigma complexes[3,4] involve binding of a sigma bond to a metal without cleavage, of which the paradigmatic example is the Kubas[5] H_2 complex, $[W(H_2)(CO)_3(PCy_3)_2]$ (Scheme 2, *see* ***Hydride Complexes of the Transition Metals***). In such a case, the pair of electrons in the H–H bond acts as a 2e donor to the metal. Another important class of such complexes, agostic species, have a hemilabile ligand in which there is at least one normal metal–ligand bond and at least one C–H···M sigma bonded group, as first established by Trofimenko[6] and Cotton.[7] The alkyl CH bond is a poor ligand but as part of a chelate, it can readily form a sigma complex. Alkanes themselves can also form sigma complexes without the need for assistance from chelation, but these are rarely isolable. The first solid evidence for such species in the condensed phase came from $M(CO)_6$ photolysis in an alkane matrix where formation of $[M(CO)_5(\text{alkane})]$ (Scheme 2) was identified by Perutz and Turner in 1975.[8] Alkane complexes were proposed as intermediates to explain the scrambling and inverse kinetic isotope effects seen in a variety of reductive eliminations of alkylmetal hydride complexes.[9–12] A variety of studies has shown that alkane complexes are involved in the alkane reactions to be mentioned in later sections. $CpRe(CO)_2$(*n*-heptane) was detected by FTIR at room temperature in heptane,[13] and $CpRe(CO)_2$(cyclopentane) (Scheme 2) was detected by NMR.[14] Crystal structures have been obtained for a heptane complex of an iron porphyrin[15] and for a cyclohexane uranium complex.[16]

The key properties of a C–H sigma complex relevant to CH activation are: 1) the very large degree of acidification of the



Scheme 2

CH proton; 2) the ability of the adduct to undergo oxidative addition; and 3) the preference, probably of steric origin, for binding at the least-hindered CH bond. The first allows facile deprotonation or H/D exchange in an alkane complex. The second leads to alkylmetal hydrides that can evolve to give alkene or a functionalized product. The third may be a factor in the selectivity (primary > secondary > tertiary) shown by many of the systems described in this article, a selectivity that contrasts with that seen for conventional radical and electrophilic CH reactions (tertiary > secondary > primary).

3 SHILOV CHEMISTRY AND ALKANE OXIDATION CATALYSIS

In the late 1960s, Garnett and Hodges described the exchange of hydrogen for deuterium in polycyclic aromatic hydrocarbons and heterocycles, homogeneously catalyzed by platinum(II) salts in a deuterated aqueous acetic acid medium.[17–20] They noted that in alkylaromatics, the exchange also occurred in several carbons out along the alkyl chain. Noticing this point, Shilov[21] and coworkers took the critical step of extending the system to alkanes themselves. They noted slow but definite exchange at modest temperatures. More remarkable than the isotope exchange itself was the selectivity: activation of primary CH bonds in the terminal positions of long chain alkanes was preferred, in contrast with the preferential attack at secondary and tertiary positions by classical radical and electrophilic reagents.

$$CH_4 \xrightarrow{\text{DOAc, } PtCl_4^{2-}} CH_{(4-x)}D_x \qquad (1)$$

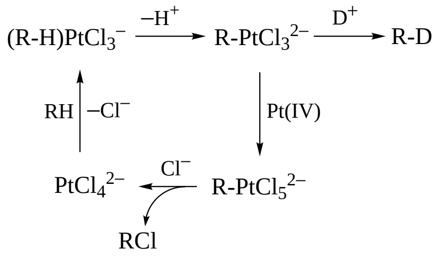
Moving to a system having $[Pt(IV)Cl_6]^{2-}$ as primary oxidant and platinum(II) as catalyst, Shilov and coworkers saw alkane oxidation to ROH and RCl with the same nonstandard selectivity pattern they saw for the isotope exchange: terminal attack was preferred. The Pt(IV) was clearly intercepting the same intermediate alkyl that led to RD in the deuteriation experiments. In the case of methane as substrate, clinching evidence was obtained for a methylplatinum intermediate.[22,23] Through the 1970s, this work was met with reserve in the West and the field remained at a low level of activity at that time. The 1980s saw a growing number of CH activation systems, to be described in a later section, that led to a great increase

in attention to the topic and a growing awareness of the true significance of the Shilov work. The state of Shilov chemistry and the field as a whole at this stage can be judged from Shilov's 1984 book[23] and the present author's 1985 review.[24]

$$\mathrm{PrH} \xrightarrow{\mathrm{PtCl_6^{2-},\ PtCl_4^{2-}}} n\mathrm{PrCl} \qquad (2)$$

From 1993, Bercaw and Labinger[25] examined the system in detail and employed a series of mechanistic probes that confirmed all the main points made by Shilov and helped refine the mechanistic picture. The current view of the mechanism is shown in Scheme. 3. An alkane complex either leads to oxidative addition of the alkane (i.e. metal insertion into the CH bond) and loss of a proton, or the alkane complex loses a proton directly. In the isotope exchange, the resulting alkyl is cleaved by D^+ to give RD. The selectivity for the terminal CH bond is either decided by the tendency for oxidative addition to occur at the terminal CH or by the tendency of alkane complexes to prefer binding and deprotonation at the terminal CH. In either case, the steric effect of the metal certainly contributes to this preference. The relatively low electronegativity of the metal may also have a role in analogy to the anti-Markownikov addition of a BH bond to an alkene in hydroboration, where a terminal C–B bond is preferred. In the alkane functionalization, the next step is oxidation of the Pt(II) alkyl by Pt(IV) to give a Pt(IV) alkyl; this occurs by electron transfer and not by alkyl transfer. The Pt(IV) now becomes a good leaving group, and Cl^- or OH^- can nucleophilically attack the R–Pt(IV) species with departure of Pt(II) to regenerate the catalyst. The origin of the unusual selectivity (methane $\sim$ MeOH) is not completely clear; it may be decided by the greater facility with which the sterically small methane, with its relatively basic CH bonds, is able to bind to Pt(II) or, more likely, it may be that CH_4 has more basic CH bonds that are better able to bind to the electrophilic Pt.

In an important development, Periana[26] made Shilov-like chemistry more practically useful with a series of methane conversion catalysts. The first such system involved Hg(II) salts in H_2SO_4 at 180°, the latter being both a solvent and a mild reoxidant (equation 3). Methane was converted to the methanol ester, methyl bisulfate, $MeOSO_3H$, in which the $-OSO_3H$ provides a powerful deactivating group to prevent overoxidation of the methanol. The reaction is efficient: at a methane conversion of 50%, 85% selectivity to methyl bisulfate (ca.43% yield) was achieved with the major side product being carbon dioxide. The molar productivity is 10^{-7} mole mL^{-1} s^{-1} with a Hg(II) turnover frequency of 10^{-3} s^{-1}. $MeHg^+$ was detected as an intermediate by NMR spectroscopy, and a Shilov-like mechanism was proposed.



Scheme 3

$$\mathrm{CH_4} \xrightarrow{\mathrm{H_2SO_4,\ Hg(II)}} \mathrm{CH_3OSO_3H} \qquad (3)$$

The next development[27] was a Pt(II) catalyzed process in H_2SO_4 at 180°, where the metal was stabilized with a 2,2′-bipyrimidine ligand or alternatively with two ammonias. The latter was more active but deactivated faster, while the diazene was more robust but less active.

The most spectacular system of this type, Periana[28] reported catalytic, oxidative condensation of CH_4 to CH_3COOH in one step. This direct, selective, oxidative condensation of two methane molecules to acetic acid took place at 180° in liquid sulfuric acid with Pd(II) salts as catalyst. C-13 isotopic labeling showed that both carbons of acetic acid originate from the methane. The results are consistent with the reaction occurring by tandem catalysis, involving methane C–H activation to generate Pd–CH_3 species, followed by efficient oxidative carbonylation with methanol, generated in situ from methane, to produce acetic acid. Sen[29] has reported an intriguing series of catalytic systems for conversion of methane and other alkanes that are probably similar in character.

Shilov-type chemistry has been extended to complex organic synthesis by Sames,[30] who finds that amino acids such as valine can be functionalized at their terminal –CH_3 groups by conversion to –CH_2OH (equation 4). The preferred catalyst is the usual Pt(II) but the oxidant is not Pt(IV) but the much more convenient Cu(II). An aqueous medium is used and functional group protection is not needed, but 130° is required for catalytic turnover.

$$\mathrm{Me_2CHCH(COOH)NH_2} + [\mathrm{O}] = \mathrm{(HOCH_2)MeCHCH(COOH)NH_2} \qquad (4)$$

4 OXIDATIVE ADDITION AND RELATED ALKANE CONVERSION CATALYSIS

Early efforts were directed at reversing the well-known transition metal catalyzed hydrogenation of alkenes to alkanes. In 1979, the stoichiometric dehydrogenation of alkanes was reported,[31] for example, of cyclopentane with $[IrH_2(Me_2CO)(PPh_3)_2]^+$ to $[CpIrH(PPh_3)_2]^+$, using tBuCH=CH_2 as mild oxidant, or 'hydrogen acceptor' (equation 5). Oxidative addition was proposed as the pathway.

$$[\mathrm{IrH_2(Me_2CO)(PPh_3)_2}]^+ \xrightarrow{\mathrm{C_5H_{10}},\ t\mathrm{BuCHCH_2}} [\mathrm{CpIrH(PPh_3)_2}]^+ \qquad (5)$$

The key oxidative addition was directly observed in 1982, with the photogeneration of Cp*Ir(PMe_3) from the dihydride, followed by reaction with the alkane solvent, RH, to give a variety of Cp*Ir(R)(H)(PMe_3) species (equation 6).[32] The surprise was the high selectivity for attack at a terminal CH bond, contrary to typical organic reactivity, but analogous to Shilov chemistry. Strong CH bonds, as are present in the terminal CH bonds of linear alkanes or in cyclopropane or in benzene were cleaved in preference to weaker bonds, such as the internal CH bonds of linear alkanes, implying that the Ir–R bond strength tracked the H–C bond strength. Analogous iridium carbonyls and rhodium phosphine complexes gave similar chemistry.[33–35]

$$\mathrm{Cp^*Ir(PMe_3)H_2} \xrightarrow[-\mathrm{H_2}]{h\nu} \mathrm{Cp^*Ir(PMe_3)} \xrightarrow{\mathrm{PrH}} \mathrm{Cp^*Ir(PMe_3)}(n-\mathrm{Pr})\mathrm{H} \quad (6)$$

Thermal reaction proved possible by starting from Cp*Ir(R)(H)(PMe_3) by thermally eliminating RH in the presence of methane to give the very thermodynamically and kinetically stable Cp*Ir(Me)(H)(PMe_3).[36] It had previously been thought that alkane activation of this sort was an unpromising prospect because *cis*-alkyl hydrides tended always to be unstable and eliminate RH. The key point in the Bergman system was the nonlability of the Cp*Ir(Me)(H)(PMe_3) complex. Reductive elimination, it was soon recognized, only becomes easy when a five-coordinate 16-electron intermediate is produced by ligand loss.

Reactions related to equation (6) are probably the most intensively studied in the whole field of organometallic chemistry. Ultrafast kinetics have given evidence for the formation of intermediates such as alkane and rare gas complexes in this system.[37]

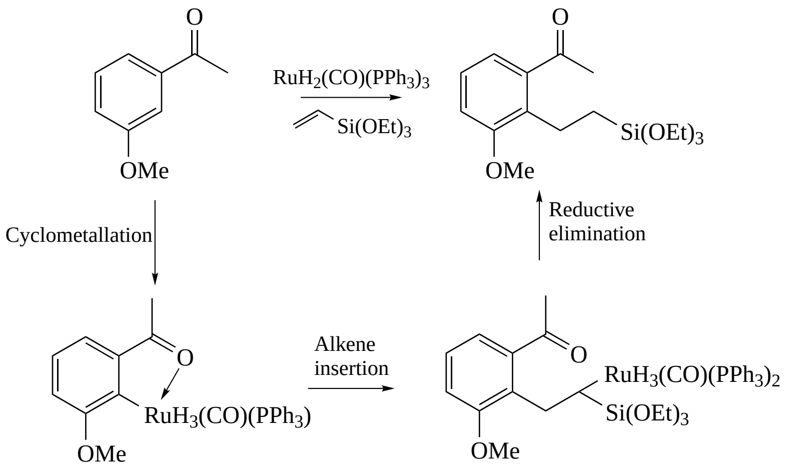
A number of catalytic reactions have also been found that depend on oxidative addition as the first step. Felkin[38] described the selective catalytic conversion of a variety of cycloalkanes into cycloalkenes by using a soluble rhenium polyhydride system, $ReH_7(PR_3)_2$, and tBuCH=CH_2 as hydrogen acceptor. The selective conversion of n-pentane into pent-1-ene also proved possible.[39] Other increasingly efficient alkane dehydrogenation (equation 7) catalysts were soon found,[40–42] although none has so far proved commercially useful. Alternatives to the use of tBuCH=CH_2 were developed: the reaction can either be run photochemically or the H_2 removed by reflux.

$$\mathrm{RCH_2CH_3} + t\mathrm{BuCH{=}CH_2} \xrightarrow{\text{cata.}} \mathrm{RCH{=}CH_2} + t\mathrm{BuCH_2CH_3} \quad (7)$$

Catalytic carbonylation of alkanes, RH, proved possible via CH activation catalyzed by RhCl(CO)(PMe_3)$_2$ under irradiation.[43] In this reaction, the alkyl hydride intermediate undergoes CO insertion, followed by reductive elimination of the aldehyde, RCHO.

Perhaps the most interesting development of these types of reactions, the formation of a single product from terminal borylation of linear alkanes by a transition metal catalyzed reaction, comes from Hartwig.[44] Cp*Rh(η^4-C_6Me_6) catalyzes the high-yield formation of linear alkylboranes from commercially available borane reagents under thermal conditions. Iridium catalysts are also effective.[45]

The Murai reaction (Scheme 4), the replacement of an ortho-CH on an aromatic ketone by an alkyl group derived from a substrate olefin, is catalyzed by a variety of Ru complexes. This C–C bond formation occurs via chelate directed C–H bond activation (cyclometalation) in the first step, followed by alkene insertion into RuH and reductive elimination of the alkylated ketone.[46] In a recent example of the use of a related cyclometalation in complex organic synthesis, Sames[47] reports catalytic arylation (Suzuki reaction) and alkenylation (Heck reaction) of alkyl segments of a synthetic intermediate mediated by Pd(II).



Scheme 4

Cyclometalation,[48] one of the earliest reactions involving CH oxidative addition, has been reviewed recently. Apart from the Murai reaction, cyclometalation has also been incorporated into a number of other catalytic reactions of interest in organic synthesis.[49,50]

5 SIGMA BOND METATHESIS PATHWAYS

Sigma complexes are particularly relevant to sigma bond metathesis pathways of alkane activation. Alkane binding induces a depletion of electron density on the CH bond that acidifies the CH proton. In the right situation, this can lead to exchange of the R group from the RH substrate with an M–R′ alkyl already present on the metal. The important early example of this process was Watson's[51] methane exchange, verified with C-13 methane (C^*H_4). The significance of this pathway is that the oxidation state of the metal does not change, so the route is available to metals that are redox-inactive like d^0 ions and the lanthanides. Indeed, the metalation of CH bonds with alkyllithiums, albeit only possible for substrates somewhat more activated than simple alkanes, is an example of the same general type of reaction. Marks[52] showed similar reactions with actinides.

Even the late metals can show this reaction, although in such cases it is hard to completely eliminate the possibility of oxidative addition/reductive elimination as an alternative redox pathway to the same products. Bergman[53] proposed a sigma bond metathesis pathway for the reaction of alkanes including methane with the dichloromethane complex, $[Cp^*IrR(PMe_3)(ClCH_2Cl)]^+$.

In a related type of reaction, an alkane RH is activated by addition across a metal-heteroatom bond, as in the Zr=N system of Wolczanski.[54] This could be considered a metathesis-like process where the RH proton is taken up by the basic heteroatom.

6 SURFACE-BOUND ORGANOMETALLICS

Marks[55] has reviewed this area. Basset[56] has bound organometallic species to a silica surface and seen interesting alkane reactions that go via initial CH bond activation; this step probably proceeds by a sigma bond metathesis pathway since the metals involved are d^0. Subsequent reactions include CC bond cleavage and carbon skeletal rearrangements.

7 CARBENES AND CH ACTIVATION

Diazo precursors to organic carbenes can be induced to insert into relatively unactivated CH bonds by transition metal catalysis, typically involving dirhodium(II) tetracarboxylates.[57] The Rh carbene complex that is proposed as an intermediate attacks the CH bond of a substrate, often with chelate control of the site of attack. Asymmetric ligands can provide good (enantiomeric excess) e.e.s in asymmetric synthesis. A recent example[58] is the asymmetric synthesis of (+)-indatraline using rhodium-catalyzed C–H activation. In all such cases, the CH bonds are activated by chelate control or by adjacent functionality, so the selectivity problem is simplified.

Carbene complexes have been synthesized by various CH activation routes. For example, amines and ethers can undergo double geminal CH activation to yield a Fischer-type (heteroatom substituted) carbene[59] and an imidazolium salt can yield *N*-heterocyclic carbenes directly in the same way.[60] In the latter case, abnormal binding via C-4 can occur as well as the usual C-2 binding.

8 OTHER APPROACHES

A whole range of reactions are known that do not fall within the categories above. The very long-established mercury photosensitized alkane reactions are radical in character,[61,62] but Schwarz[63,64] in particular has looked at other gas-phase reactions by metal ions. The vast metal oxo area is covered elsewhere (*see* ***Oxidation Catalysis by Transition Metal Complexes***) but two proposals that come from this work are worth mentioning because they may well relate to organometallic systems, too. The first is the two-state reactivity (TSR) model proposed[65,66] from theory for hydroxylation and epoxidation by cytochrome P-450. This postulates that when two different spin surfaces are accessible, both may contribute to reaction. TSR is used to reconcile the dilemma of the consensus 'rebound mechanism' of alkane hydroxylation, which came from experimental studies of ultrafast radical clocks. The dilemma is that radicals appear to be either present or absent depending on the experiment used to probe for them, so the standard rebound mechanism remained problematic. On TSR, this is simply understood on a two-state model, one low-spin (LS) the other high-spin (HS). In both states, CH bond activation proceeds in a manner akin to the rebound mechanism, but the LS mechanism is effectively concerted, whereas the HS is stepwise with the appearance of radical intermediates. In another proposal, Mayer[67] has shown how coupled proton/electron transfer can efficiently remove a hydrogen atom from a CH bond, a process that can readily occur in high-valent oxo species. The TSR proposal highlights the growing importance of computational chemistry in helping clarify difficult mechanistic problems in organometallic chemistry.

Finally, a number of useful recent books on[68] or including[69] the topic of CH activation have now appeared.

9 CONCLUSION AND FUTURE CHALLENGES

CH Activation and functionalization, once exotic, has now entered the mainstream. It is routinely used in synthesis even of complex organic molecules and is likely to greatly expand in future. In the inorganic realm, we still need a wider range of functionalization reactions to accompany the CH activation step. The latter provides a metal–alkyl bond, but these are often either inert or simply revert to alkane on attempted functionalization. Another problem is that functionalizing reagents tend not to be compatible with the alkane binding function of the catalyst – this is unsurprising since alkanes bind weakly and may be displaced by the functionalizing reagent. So far, it is hard to imagine how one could design a system capable of attacking not just a site along a linear alkyl chain of, say a carboxylic acid, but be tunable to attack at different specific sites as required. Such enzyme-like selectivity will no doubt need the introduction of molecular recognition at a very sophisticated level. In spite of the strong progress to date, much work therefore still remains.

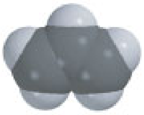
1 INTRODUCTION

The allyl ion, $C_3H_5^-$, is a commonly encountered ligand (*see Ligand*) in organometallic chemistry. Transition metal-allyl complexes (*see Allyl Complexes*) have been known for over fifty years, and many varieties of homoleptic (*see Homoleptic Compound*) allyl compounds were prepared in the 1960s. Nevertheless, with a few important exceptions (e.g. the bis(allyl) complexes of Ni, Pd, and Pt, which are useful in organic synthesis (*see* ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***)), most $(C_3H_5)_nM$ compounds are poorly studied. A major reason for this is that metal centers in homoleptic allyl complexes are often coordinately unsaturated (*see Coordinative Saturation & Unsaturation*), and low-energy pathways for decomposition are available. Consequently, many of them are unstable and difficult to handle; for example, $(C_3H_5)_3V$ explodes above −30 °C, and $(C_3H_5)_4Zr$ decomposes at 0 °C (even $(C_3H_5)_2Ni$ decomposes within a day at room temperature). The early work in the area of homoleptic allyl complexes is summarized in a classic review by Wilke;[1] more recent specialized reviews are available.[2,3]

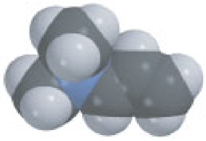
Sterically bulky cyclopentadienyl rings (*see Cyclopentadienyl*) (e.g. C_5Me_5, $C_5H_3(SiMe_3)_2$) are frequently used to synthesize compounds of greater diversity and stability than is possible with Cp alone, and a similar approach has recently been found effective with the allyl ligand. Some early research along these lines was conducted with methylated allyl ligands. For example, modest (30 °C) improvements in the thermal stability of iron complexes $(2\text{-Me-}C_3H_4)_2Fe(PR_3)_2$ were observed in solution when compared to the unsubstituted analogues $(C_3H_5)_2Fe(PR_3)_2$.[4] More recent research in the area has used larger substituents on the allyl groups, such as trimethylsilyl and dimethyl(*tert*-butyl)silyl, and compounds synthesized with these ligands not only are more stable than their unsubstituted analogues, but in many cases they also represent new classes of metal-allyl complexes.

2 SUBSTITUTED ALLYL LIGANDS

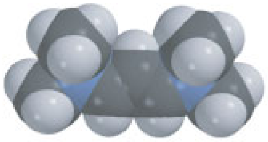
Although in principle a variety of substituents could be used to increase the steric bulk of the allyl ligand (e.g. *t*-Bu, Ph, $SiMe_2(t\text{-Bu})$), to date the most commonly used is the trimethylsilyl group. Fraenkel first reported the synthesis of $Li[(SiMe_3)_2C_3H_3]$ in 1990,[5] and allyl ligands with one to three trimethylsilyl substituents are now known. Space filling models of the parent allyl ligand (**1**), compared to the mono- (**2**), bi- (**3**), and tri-substituted (**4**) anions indicate how the steric profile of the anion is modified with successive substitution.



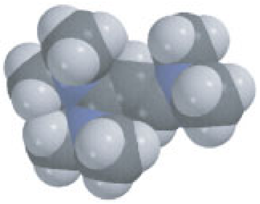
(**1**)



(**2**)

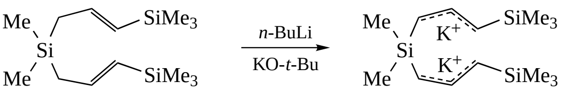


(**3**)



(**4**)

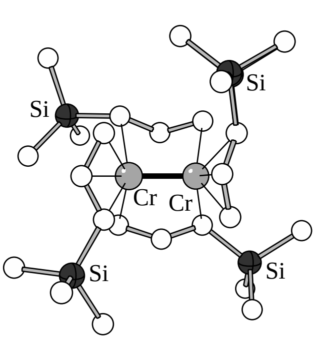
A silyl-bridged bis(allyl)ligand made from the bis(allyl) silane $Me_2Si(CH_2CHCHSiMe_3)_2$ can be converted into its dilithium or dipotassium salt (i.e. $K_2[3\text{-}(C_3H_3SiMe_3\text{-}1)_2SiMe_2]$) (equation 1); it has been used in the synthesis of *ansa*-bis(allyl) complexes.[6,7]



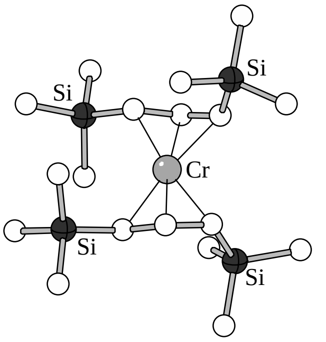
(1)

The terminal substituent in an allyl ligand can be found in a *syn* or *anti* position; the former conformation places

the substituent on the same side of the ligand as the central hydrogen atom; in the *anti* form, the opposite arrangement occurs. To date, π-bound monosubstituted allyl ligands are found in *syn* orientations, and unless constrained by an *ansa*-bridge, 1,3-disubstituted allyl ligands have *syn*, *syn* configurations in complexes of highly electropositive metals (s- and f-block). Both *syn*, *syn* and *syn*, *anti* arrangements occur in allyl complexes of the d-block transition elements.



(**5**)



(**6**)

3 SYNTHESIS AND STRUCTURES

3.1 d-Block Complexes

Halide metathesis reactions such as that in equation (2) are commonly used as a route to bulky allyl metal complexes.

$$MX_n + nK[(SiMe_3)_mC_3H_{5-m}] \xrightarrow{THF} [(SiMe_3)_mC_3H_{5-m}]_nM + nKX\downarrow \qquad (2)$$

The 1,3-bis(trimethylsilyl)allyl anion, frequently in the form of its potassium salt, has been used extensively, and it reacts with $CrCl_2$,[8] $FeCl_2$,[9] $CoCl_2$,[10] or $NiBr_2$(dme)[11] in THF to produce the corresponding [1,3-$(SiMe_3)_2C_3H_3]_2$M compounds in good yields.[12]

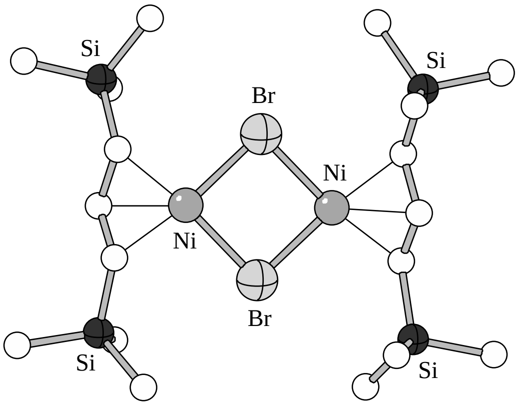
The first-row [1,3-$(SiMe_3)_2C_3H_3]_2$M compounds are soluble in ethers and both aromatic and aliphatic hydrocarbons. The chromium, iron, and cobalt complexes are highly air-sensitive, but are indefinitely stable under a nitrogen atmosphere. The nickel compound is stable in water for several hours and in air for several days, unlike $(C_3H_5)_2$Ni, which inflames on contact with air. The thermal stability conferred on the complexes by the trimethylsilyl substituents is such that all have melting points above 50 °C, and can be sublimed under vacuum without decomposition. The Cr, Fe, Co, and Ni complexes have magnetic susceptibilities corresponding to 4, 2, 1, and 0 unpaired electrons, respectively. Calculations on the model compound $(C_3H_5)_2$Cr have been used to rationalize the electronic structure (*see* ***Electronic Structure of Organometallic Compounds***) of [1,3-$(SiMe_3)_2C_3H_3]_2$Cr.[8] Evidently, the trimethylsilyl groups do not appreciably affect the ordering of the energy levels.

Some indication of the tunability of the molecular structures in response to the steric bulk of the allyl ligands is provided by the bis(allyl)chromium complexes. For example, the structure of dimeric {[1-$(SiMe_3)C_3H_4]_2Cr\}_2$ (**5**) is closely similar to that of the parent $[(C_3H_5)_2Cr]_2$ complex, including the length of the Cr–Cr bond (1.9784(7) Å and 1.97 Å, respectively).[8] With the bulkier [1,3-$(SiMe_3)_2C_3H_3$] anion, the monomeric 12-e^- complex is generated; the staggered ligands display *syn, anti* trimethylsilyl groups (**6**).

A staggered [π-$(SiMe_3)_2C_3H_3]_2$M arrangement with *syn, anti* trimethylsilyl groups is also found for the cobalt analogue, although the iron complex is found with eclipsed allyl ligands, and both staggered and eclipsed forms occur for the nickel compound. Direct comparison of the staggered nickel complex [1,3-$(SiMe_3)_2C_3H_3]_2$Ni with that of $(C_3H_5)_2$Ni[13] indicates that the core metal-allyl framework is essentially unaffected by the substituents (e.g. Ni–C bond lengths range from Ni–C = 1.970(3)–2.064(3) Å in the substituted complex, compared to 1.980(1)–2.031(1) Å in $(C_3H_5)_2$Ni).

The reaction of one equivalent of K[1,3-$(SiMe_3)_2C_3H_3$] with $NiBr_2$(dme) in toluene yields the mono(allyl)nickel species [1,3-$(SiMe_3)_2C_3H_3$]NiBr.[11] The same compound can be formed in THF from the reaction of $Ni(COD)_2$ with 1,3-$(SiMe_3)_2C_3H_3Br$ (equation 3). It forms a dimer in the solid state, with *syn, syn* allyl ligands and Ni–Br = 2.331(4) and 2.368(2) Å (**7**).

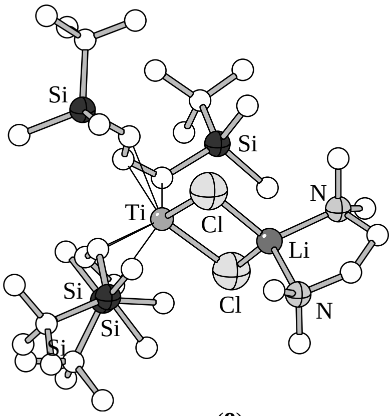
$$Ni(COD)_2 + 1,3\text{-}(SiMe_3)_3C_3H_3Br \xrightarrow{THF} \{[1,3\text{-}(SiMe_3)_2C_3H_3]NiBr\}_2 + 2COD \qquad (3)$$



(**7**)

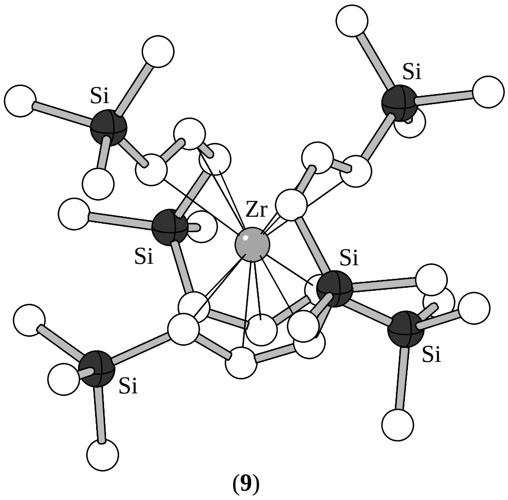
Reaction of $TiCl_4$ or $ZrCl_4$ with two equivalents of Li[1,3-$(Si(t\text{-}Bu)Me_2)_2C_3H_3$]•tmeda generates the trivalent complexes [1,3-$(Si(t\text{-}Bu)Me_2)_2C_3H_3]_2$(Ti,Zr)($\mu$-Cl)$_2$Li•tmeda, along with the coupled dimer of the allyl ligand, 1,3,4,6-tetrakis(tert-butyldimethylsilyl)-1,5-hexadiene.[14] In the solid-state structures of both compounds, the allyl ligands are slightly slipped to one side of the metal, suggesting a distortion toward a σ,π-(η^3) bonding arrangement. In the

titanium complex (**8**), for example, the difference between the Ti–$C_{terminal}$ distances is ca. 0.2 Å. Both the titanium and zirconium complexes can be oxidized to form neutral tetravalent species [1,3-(Si(t-Bu)Me_2)$_2C_3H_3$]$_2$(Ti,Zr)Cl_2, which display $\eta^3 \rightleftharpoons \eta^1$ allyl ligand fluxionality (*see Fluxional Molecule*) on the ^{1}H NMR timescale.



(**8**)

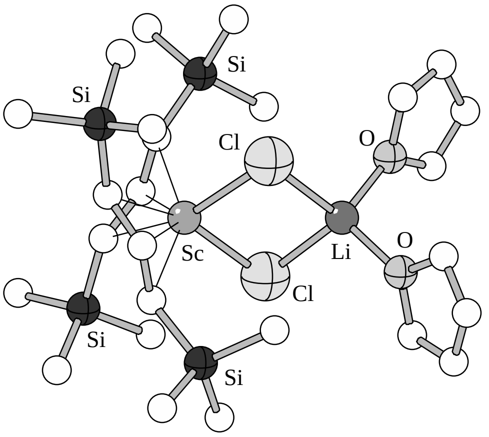
Hafnium tetrachloride reacts with [Li(tmeda)]$_2${3-(C_3H_3 $SiMe_3$-1)$_2SiMe_2$} to form the *ansa*-bis(allyl) complex [3-($C_3H_3SiMe_3$-1)$_2SiMe_2$]$_2$Hf, and zirconium tetrachloride reacts with the dipotassium derivative of the same allyl anion to produce [3-($C_3H_3SiMe_3$-1)$_2SiMe_2$]$_2$Zr (**9**).[6] The latter molecule lies on a crystallographic twofold axis, with the allyl ligands binding in a η^3-chelating manner; the Zr–C distances range from 2.46 to 2.59 Å.



(**9**)

3.2 Scandium, Yttrium, and f-Block Metal Complexes

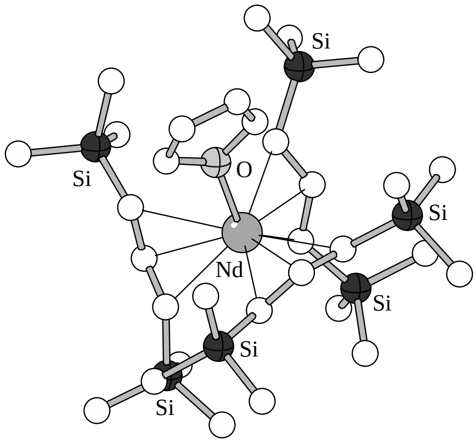
Reaction of $ScCl_3(thf)_3$ with two equivalents of Li[1,3-($SiMe_3$)$_2C_3H_3$] in THF gives the heterometallic bis(π-allyl) complex [1,3-($SiMe_3$)$_2C_3H_3$]$_2$Sc(μ-Cl)$_2$Li(thf)$_2$ (**10**).[15] The Sc–C distances range from 2.31–2.46 Å, and the Sc–Cl distances are nearly identical at 2.44 Å.



(**10**)

Yttrium trichloride is reported to react with two equivalents of K[1,3-($SiMe_3$)$_2C_3H_3$] in THF to produce the bis(allyl) complex [1,3-($SiMe_3$)$_2C_3H_3$]$_2$YCl. Reaction of three equivalents of K[1-($SiMe_3$)C_3H_4] with YCl_3 in THF yields the expected tris(allyl) complex [1-($SiMe_3$)C_3H_4]$_3$Y.[15]

Lanthanide(III) triflates (Ln(OTf)$_3$) react with three equivalents of the 1,3-bis(trimethylsilyl)allyl anion to produce neutral, solvated tris(allyl) species [1,3-($SiMe_3$)$_2C_3H_3$]$_3$Ln(thf) (Ln = Ce, Nd, Tb).[16] The neodymium complex has three η^3-coordinated allyl ligands, with an approximate threefold axis through the Nd–O bond (**11**); Nd–C distances range from 2.64 to 2.78 Å.



(**11**)

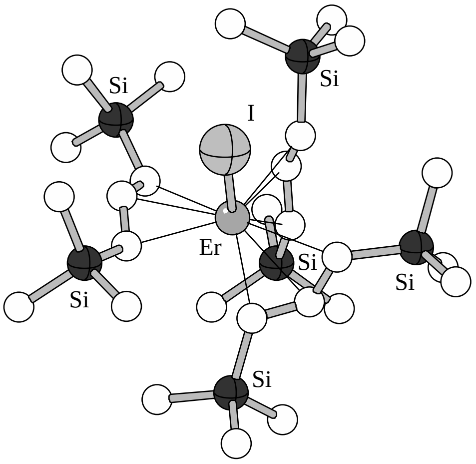
Consistent with the stability of the divalent oxidation states (*see Formal Oxidation State*) of ytterbium and europium, the triflates of Yb(III) and Eu(III) are reduced by the bis(trimethylsilyl)allyl anion, leading to Ln(II) species (equation 4).[12] The same compounds can be made in higher yield by starting with Yb(II) and Eu(II) triflates directly.

$$\begin{aligned} Ln(OTf)_3 + 3K[1,3\text{-}(SiMe_3)_2C_3H_3] &\longrightarrow [1,3\text{-}(SiMe_3)_2C_3H_3]_2Ln(thf)_2 \\ &+ \tfrac{1}{2}[1,3\text{-}(SiMe_3)_2C_3H_3]_2 + 3K[OTf]\downarrow \\ Ln &= Yb, Eu \end{aligned} \quad (4)$$

Reactions employing lanthanide triiodides do not always provide the anticipated products. For example, two equivalents of $K[1,3\text{-}(SiMe_3)_2C_3H_3]$ and $NdI_3(thf)_{3.5}$ produce a mixture of the mono(allyl) compound $[1,3\text{-}(SiMe_3)_2C_3H_3]NdI_2(thf)_{1.25}$[15] in addition to the expected bis(allyl) complex $[1,3\text{-}(SiMe_3)_2C_3H_3]_2NdI(thf)_2$.[17] The reaction of three equivalents of $K[1,3\text{-}(SiMe_3)_2C_3H_3]$ with LnI_3 (Ln = Ce, Pr, Nd, Gd, Tb, Dy, Er) in THF generates ion pairs of the general formula $\{K[thf]_4\}\{[1,3\text{-}(SiMe_3)_2C_3H_3]_3LnI\}$, as confirmed by X-ray structures of the Ce, Er, and Tb species (equation 5).[16]

$$LnI_3 + 3K[1,3\text{-}(SiMe_3)_2C_3H_3] \xrightarrow{\text{THF}} \{K[thf]_4\}\{[1,3\text{-}(SiMe_3)_2C_3H_3]_3LnI\} + 2KI\downarrow \quad (5)$$

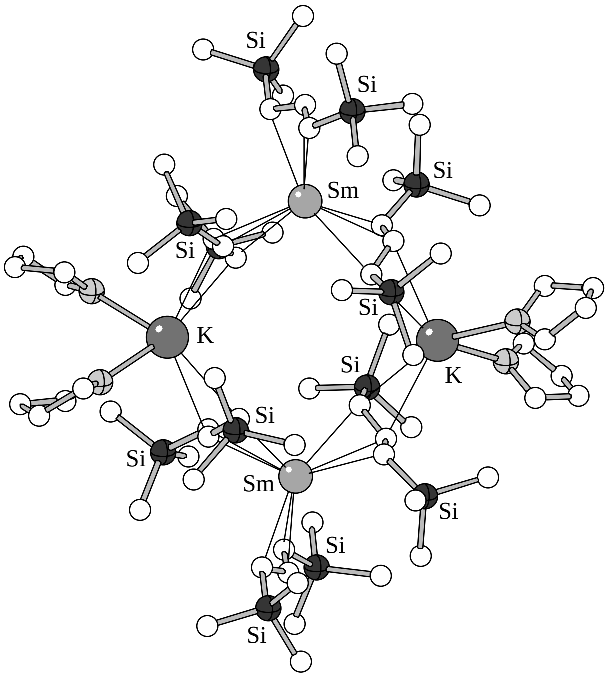
The erbium derivative (**12**) is typical for the class, with Er–I = 2.979(8) Å, and Er–C distances ranging from 2.61 to 2.64 Å.



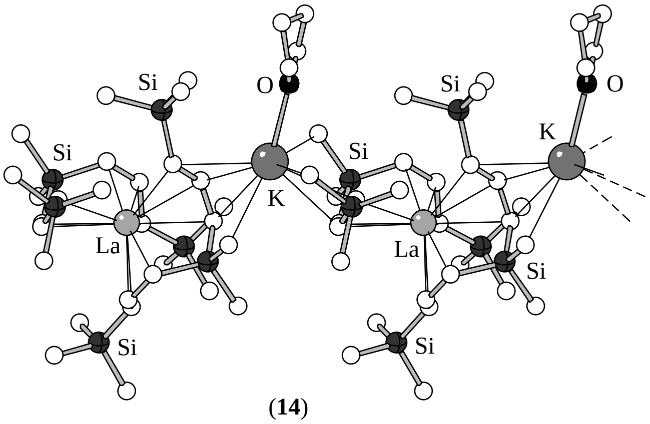
(**12**)

On reaction with two equivalents of the appropriately substituted allyl anions, the divalent $SmI_2(thf)_2$ forms the neutral bis(allyl)complexes $[1,3\text{-}(SiMe_3)_2C_3H_3]_2Sm(thf)_2$ and $[1,3\text{-}Ph_2C_3H_3]_2Sm(thf)_2$.[18] The use of three equivalents of the trimethylsilyl-substituted allyl with $SmI_2(thf)_2$ results in the tetrametallic salt $\{K(thf)_2Sm[1,3\text{-}(SiMe_3)_2C_3H_3]_3\}_2$, whose structure has been confirmed in the solid state (**13**).[17] The samarium and potassium ions are linked by four η^3-allyl ligands, and the potassium ions, which are in three separate coordination environments, display both π (*see π-Bond*) and agostic (*see Agostic Bonding*) interactions with the allyl ligands.

Various lanthanide halides ($ScCl_3$, YCl_3, $LaCl_3$, NdI_3) react with $K_2[3\text{-}(C_3H_3SiMe_3\text{-}1)_2SiMe_2]$ to form *ansa*-bis(allyl) complexes. The lanthanum derivative has been structurally authenticated as a coordination polymer (**14**), in which allyl anions interleave alternating lanthanum and potassium ions; the latter display K···MeSi contacts of 2.79(3) and 2.96(4) Å.[7]



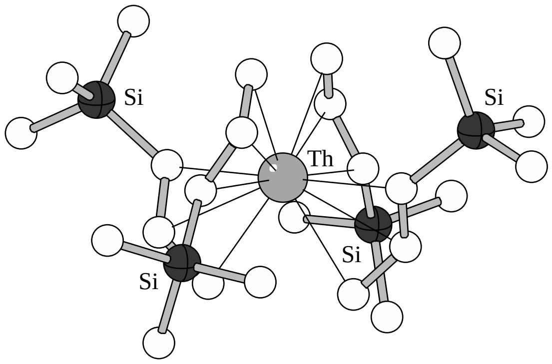
(**13**)



(**14**)

Curiously, when the divalent starting material $SmI_2(thf)_2$ reacts with a $Li_2[3\text{-}(C_3H_3SiMe_3\text{-}1)_2SiMe_2]$/KO-*t*-Bu mixture in light petroleum/Et_2O, the trivalent Sm(III) complex $[Li(OEt_2)_4][Sm\{(\eta^3\text{-}C_3H_3SiMe_3)_2SiMe_2\}_2]$ precipitates in low yield.[7] The anion is structurally similar to the zirconium analogue (**9**); Sm–C distances vary from 2.70–2.74 Å, and the trimethylsilyl substituents are in a *syn, anti* configuration.

$ThBr_4(thf)_4$ reacts with four equivalents of $K[1\text{-}(SiMe_3)C_3H_4]$ or $K[1,3\text{-}(SiMe_3)_2C_3H_3]$ in THF to form the homoleptic tetra(allyl)thorium complexes $[(SiMe_3)_nC_3H_{5-n}]_4Th$ (n = 1,2).[19] The compounds are stable up to 90 °C ($n = 1$) or 124 °C ($n = 2$) under an inert atmosphere, and $[1,3\text{-}(SiMe_3)_2C_3H_3]_4Th$ can tolerate brief (<5 min) exposure to air. The stability of these complexes contrasts strongly with $(C_3H_5)_4Th$, which decomposes at 0 °C.[1] Both molecules are fluxional (*see Fluxional Molecule*) on the ^{1}H NMR timescale,



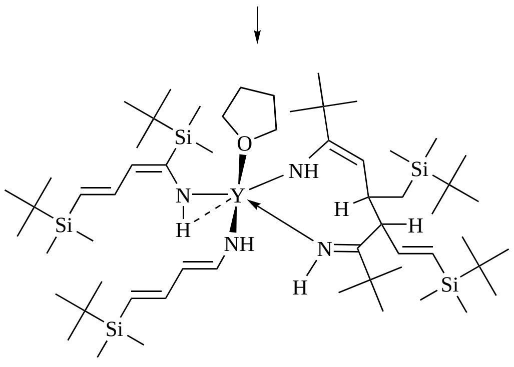
(**15**)

and $\eta^3 \rightleftharpoons \eta^1$ ligand rearrangements are involved in the interchange of their allylic protons. The thorium complexes contain four *syn* or *syn*, *syn* η^3-ligands; in the case of [1-$(SiMe_3)C_3H_4]_4$Th (**15**), they are in a configuration with approximate S_4 symmetry.[19]

4 REACTIONS AND APPLICATIONS

Owing to the relative newness of the area, extensive studies of the reactions of complexes with bulky allyl ligands have yet to be made. In some cases, however, it seems that the ligands can block reactions with large substrates. For example, none of the [1,3-$(SiMe_3)_2C_3H_3]_2$M (M = Cr, Fe, Co, Ni) compounds react with PPh_3, presumably because of steric interference; the smaller phosphine PMe_3, however, will react with the compounds. The tris(allyl) complex [1-($SiMe_2$-*t*-Bu)$C_3H_4]_3Y(thf)_{1.5}$ evidently provides enough access to *tert*-butylnitrile that it can insert multiple times into the metal-allyl bonds, yielding a *sec*-amido species (equation 6).[15]

[1-($SiMe_2$-*t*-Bu)$C_3H_4]_3Y(thf)_{1.5}$ + 4 *t*-BuCN



(6)

A variety of metal complexes with bulky allyl ligands function as polymerization catalysts; this may become a major area of application for these compounds. For example, [1,3-$C_3H_3(SiMe_3)_2]_2$LaCl(thf), [1,3-$C_3H_3(SiMe_3)_2]_2$YCl and [1,3-$C_3H_3(SiMe_3)_2]NdI_2(thf)_{1.25}$ have been examined with several activators, including methylaluminoxane (MAO), as catalysts for the polymerization of 1,3-butadiene.[15] When activated with MAO, [1,3-(Si(*t*-Bu)$Me_2)_2C_3H_3]_2$(Ti,Zr)(μ-Cl$)_2$Li•tmeda and [1,3-(Si(*t*-Bu)$Me_2)_2C_3H_3]_2(Ti,Zr)Cl_2$ are polymerization catalysts for ethylene (forming high density polyethylene) and propylene (forming an elastomeric polypropylene with the Ti complexes and a stereoregular polymer with the Zr species).[14]

The cyclic {K(thf$)_2$Sm[1,3-$(SiMe_3)_2C_3H_3]_3\}_2$ (**10**) is an effective single-component catalyst for the polymerization of methyl methacrylate and ε-caprolactone. [1,3-$(SiMe_3)_2C_3H_3]_3$Nd(thf) (**9**), [1,3-$(SiMe_3)_2C_3H_3]_2Yb(thf)_2$,[12] [Ln{($\eta^3$-$C_3H_3SiMe_3)_2SiMe_2\}_2\{\mu$-K(thf)}(thf$)]_\infty$ (Ln = Sc, Y, Nd) and [Li(OEt$_2)_4$][Sm{(η^3-$C_3H_3SiMe_3)_2SiMe_2\}_2$] polymerize methyl methacrylate without activation, and the yttrium compound displays turnover numbers (*see Turnover*) at 0 °C of over 86 000 per hour.[7]

1 INTRODUCTION

Subvalent main group compounds can be broadly defined as compounds in which the mean oxidation state (N_{ox}) of the central element is lower than the normal oxidation state for elements in that group. In practical terms, this applies to group 13 compounds in which $N_{ox} < 3$ and group 14 compounds in which $N_{ox} < 4$, and, extending the concept more broadly, to group 15 compounds in which $N_{ox} < 3$ and group 16 compounds in which $N_{ox} < 4$. However, the range of such compounds is distinguished not by their adherence to a narrow definition, but by the diversity and richness of their structures and chemistry. More importantly, subvalent compounds present challenges to established ideas of 'normal' valence, chemical bonding, reactivity, and stability, and research directed towards meeting these challenges has extended the boundaries of our fundamental understanding of these concepts.

A predominant characteristic of subvalent compounds is the presence of homonuclear element–element bonds. As a very simple example, trialkylaluminium, AlR_3, contains Al(III), the normal oxidation state for this element. The dialane R_2Al-AlR_2 contains an Al–Al single bond between two Al(II) centres, and as such can be considered to be a subvalent aluminium compound. Indeed, the first example of a molecular aluminium compound containing a 2c,2e (2-centre, 2-electron) Al–Al bond was reported only as recently as 1988.[1] For other main group elements, however, simple 2c,2e homonuclear element–element bonding is well established in the chemistry of silicon, germanium, tin, phosphorus, arsenic, antimony, sulfur, and selenium.[2]

The challenges to our understanding of chemical bonding have arisen in examining subvalent compounds in which the bonding does not conform to simple classifications. These categories of compound fall into several classes. The first of these comprise the simple molecular compounds, which potentially contain element–element multiple bonds, for example, heavy element analogs of alkenes and alkynes. These have been extremely significant and, at times, highly controversial over the last two decades. Secondly, a wide variety of main group cluster molecules are known that contain element–element bonds, and these can be subdivided in a number of ways on the basis of electron counting, structural features, or bonding models.[3] Possibly the best known such class of main group cluster compounds are the polyhedral boranes and carboranes (neutral or anionic) for which electron-deficient, multicenter bonding described by Wade's rules has been established.[4] More recently it has been recognised that the bonding in a number of heavier group 13, 14, and 15 element clusters known as Zintl ions can also be described using Wade's rules. These clusters can occur within molecular compounds, but the same electron counting tools and electron-deficient, multicenter bonding can be attributed to clusters occurring within the solid state, known as Zintl phases. A further and different kind of cluster are those in which 'naked' metal atoms (not supported by ligands) occur, the largest of which are the $Al_{77}\{N(SiMe_3)_2\}_{20}^{2-}$ and $Ga_{84}\{N(SiMe_3)_2\}_{20}^{4-}$ clusters reported in 1997 and 2001.[5,6] Each cluster contains concentric shells of metal atoms whose arrangement has a close relationship with the structure of the pure element.

The most significant advances in the chemistry of subvalent compounds in the last decade arise in the synthesis of stable molecular compounds. One driver for this has been the development of elegant methods of synthesis, for example, the preparation of toluene solutions of metastable alumimum(I) halides, which in turn can be used to prepare molecular subhalides, metalloid cluster compounds and low-valent organometallic complexes.[7] Secondly, the development of sterically demanding ligands that impart kinetic stabilisation to otherwise reactive molecules has enabled further advances, particularly bulky substituted aryl groups, terphenyls, and bulky alkyl or silyl groups such as supersilyl, Si*t*-Bu_3 and hypersilyl, $Si(SiMe_3)_3$. Finally, electronic stabilisation has led to the isolation of stable low-valent compounds, for example, the N-heterocyclic carbenes and their heavier congeners.[8]

The scope of main group subvalent compounds is broad and this article does not attempt to be comprehensive. Areas have been identified in which there have been

important developments within the last decade that have yielded significant new understanding. There is a focus on molecular compounds rather than the more traditional field where subvalent elements occur in solid-state compounds. This discussion include advances in both inorganic and organometallic chemistry. There is a greater focus on the chemistry of groups 13 and 14 where much of the significant development, particularly in cluster chemistry and multiple bonding, has occurred. For a useful, element-by-element description of the well-established chemistry of subvalent compounds the reader is referred to the individual element entries in this reference, or to a well-known text.[2]

Finally, in terms of oxidation state formalisms subvalent compounds are often considered to be those for which $0 < N_{ox} < m$ (where m is the group oxidation state), but in some cases it is also relevant to consider compounds for which $N_{ox} \leq 0$.

2 MONONUCLEAR SUBVALENT COMPOUNDS

A discussion of subvalent main group compounds should begin by first examining group trends. In group 14, for example, a stable carbon or silicon compound formally in the oxidation state II is a rarity worthy of comment, whereas for the heaviest congener lead, the oxidation state II is the most stable. This reflects the group trend, particularly pronounced for groups 13–15, whereby the heaviest element shows a stable oxidation state 2 units lower than the group oxidation state, giving Tl(I), Pb(II) and Bi(III). The oxidation state III is accessible for all the group 15 elements, unlike oxidation states I and II, which are much less prevalent for the lighter elements of groups 13 and 14. In(I) and Sn(II) compounds are fairly well known, and Ga(I) and Ge(II) species are relatively accessible.[2]

A number of matrix-isolation studies have investigated low-valent group 13 species and, in conjunction with computation, have given insights into their properties.[9,10] However, some important breakthroughs have occurred over the last two decades that have resulted in new classes of stable, isolable, low-valent compounds of the lighter elements, particularly of groups 13 and 14. For group 14, the preparation and chemistry of the N-heterocyclic carbenes has opened up a wide new field of chemistry.[8] In 1991, a straightforward synthetic route to an isolable N-heterocyclic carbene was published,[11] involving deprotonation of an imidazolium ion, and synthesis of the silicon[12] and germanium members of the family soon followed (Figure 1).[13–15] The parent carbene H_2C: has a triplet ground state, whereas the heteroatom-substituted carbenes are singlets, and are extremely strong electron-pair donors. Stabilization results from the π-donation by the two adjacent nitrogen atoms into the empty orbital on the singlet carbon, and indeed these heterocyclic carbenes can be considered to be 6π electron aromatic systems. The silylene and germylene analogs have some parallels in their electronic structure, but can also be considered to resemble Si or Ge with a chelating diazabutadiene ligand.[16] A range of other stable carbenes have been reported, in general stabilized by heteroatom substituents.[17]

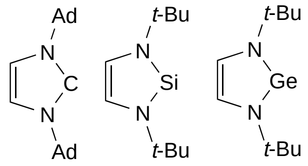

Figure 1 N-heterocyclic carbene, silylene, and germylene

Monoanionic ligands containing two or three nitrogen donors, for example, tris(pyrazolyl)hydroborate, aminotroponiminate, and β-diketiminate, have proved useful in isolating mononuclear, low-valent group 13 and 14 compounds (Figure 2). Aminotroponiminate ($L' = C_7H_5N_2i$-Pr_2) compounds of germanium, tin, and lead are known, with formulae $L'MCl$, $L'Ge^+$, $L'Sn^+$ and L'_2Sn.[18] The bulky β-diketiminate ligand ($L'' = HC(CMeNDipp)_2$) has been used

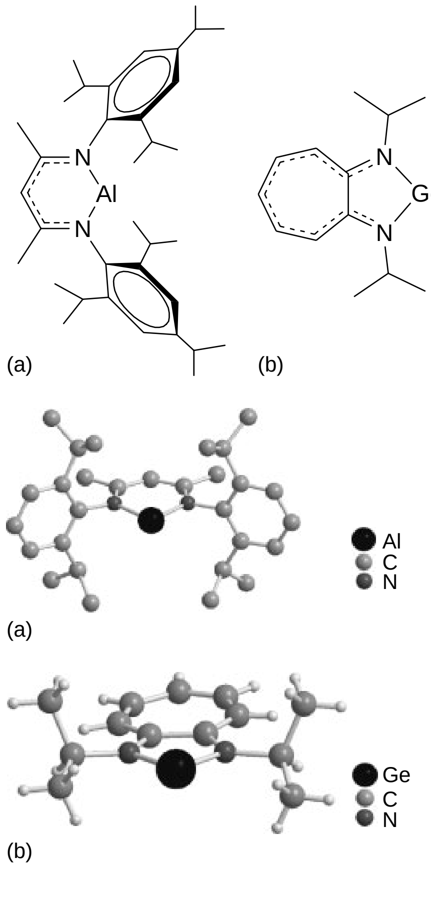

Figure 2 Sketches and molecular structures of (a) aluminum amidinate complex $Al\{HC(CMeNDipp)_2\}$ (H atoms removed for clarity) and (b) germanium aminotroponiminate cation $[Ge(C_7H_5N_2i$-$Pr_2)]^+$

to make the first stable mononuclear molecular aluminum complex, L″Al:[19,20] and also its gallium analog L″Ga:.[21] With two substitutents and a stereochemically active lone pair, these compounds can be considered to be group 13 analogs of carbenes, R_2C:.

Choice of appropriately bulky alkyl and aryl ligands has also allowed the isolation of stable, monomeric group 13 and 14 compounds.[22] The bulky terphenyl ligands (Ar* = C_6H_3-2,6-Ar_2 where Ar = Mes, Dipp, or Trip) have been used to make one-coordinate InAr* (Figure 3) and TlAr* (Ar = Trip) and divalent germanium and tin compounds $Ar*_2E$ and $(Ar*ECl)_2$ (Ar = Mes).[23] Other useful ligands are supersilyl Sit-Bu_3,[24] hypersilyl $Si(SiMe_3)_3$, and alkyls such as $CH(SiMe_3)_2$, $C(SiMe_3)_3$ and Ct-Bu_3.

Particular ligand systems have proved to be especially amenable to stabilising low oxidation state species. The cyclopentadienyl family of ligands have a rich chemistry with main group elements.[25,26] The lower oxidation state compounds contain η^5-Cp ligands, compared to η^1-coordination in the higher oxidation state complexes. 'Slipped' complexes containing an η^2- or η^3-Cp ligand are also observed. For group 13, monomeric CpE molecules have been observed in the gas phase for all five group 13 elements. In the solid state, they occur as oligomers with an intriguing range of structures depending on the substitution pattern in the cyclopentadienyl ligand. $(Cp*Al)_4$ exists as a tetrahedral cluster, while $(Cp*Ga)_6$ and $(Cp*In)_6$ are octahedral. The clusters contain a tetrahedral or octahedral core of metal atoms capped at the apexes by η^5-Cp* ligands. In contrast, the hexameric thallium complex $(Cp'Tl)_6$ (Cp′ = 1, 2-$C_5H_3(SiMe_3)_2$) is a cyclic cluster with the thallium atoms sandwiched between Cp′ units (Figure 4). Metal–metal interactions are observed in the dimers $(Cp'Tl)_2$ and $(Cp'In)_2$ (Cp′ = $C_5(CH_2Ph)_5$), which have a trans-bent Cp′E···ECp′ arrangement, although the E···E interactions are long and relatively weak. The thallium compound is especially interesting as it represented an early example of a molecular compound with a rare Tl–Tl interaction. Thallium and indium

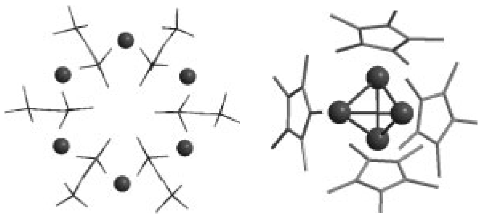

Figure 4 Molecular structures of $(Cp'Tl)_6$ (Cp′ = 1, 2-C_5H_3 $(SiMe_3)_2$, viewed with Cp′ rings side-on) and $(Cp*Al)_4$

compounds $(CpTl)_n$ and $(CpIn)_n$ containing unsubstituted Cp ligand form zig-zag polymers in the solid state.[27,28]

Divalent group 14 cations $[Cp*Ge]^+$ and $[Cp*Sn]^+$ form crystalline salts containing isolated C_{5v} cations. The cations will coordinate neutral (pyridine) or anionic (halide) ligands to form 'slipped' η^3-Cp* complexes. Bis-cyclopentadienyl compounds Cp_2E are known for all five group 14 elements. Silicocene, $Cp*_2Si$, is an important example of a stable divalent silicon compound, and crystallises in two forms within the same crystal, one with parallel (D_{5d}) and one with nonparallel (C_{2v}) Cp* rings.[29] Space-filling models of selected examples are shown in Figure 5. The bent (C_{2v}) structures observed for $Cp*_2E$ where E = Ge, Sn, and Pb have been the subject of intense theoretical study. In simple terms, the bending can be viewed as arising from the influence of a stereochemically active lone pair, although only very small energy differences ($<10\ kJ\ mol^{-1}$) separate the bent and parallel structures. Tin and lead can accommodate three Cp ligands, and a variety of oligomeric and lead anions such as $[Cp_5Pb_2]^-$ and $[Cp_9Pb_4]^-$ are known, which, along with polymeric $(CpPb)_n$, contain both bridging and terminal η^5-Cp ligands.[25,26]

Low-valent indium compounds have recently become important in mediating organic transformations in aqueous

media. The nature of subvalent gallium and indium in aqueous media has been studied experimentally.[30]

3 HOMONUCLEAR SINGLE-BONDED COMPOUNDS

The focus of this section will be molecular subvalent dinuclear compounds, rings, and chains in which the composition and structure can be accounted for by localised electron-pair (2c,2e) bonds between adjacent atoms. Cluster compounds with a 3-dimensional architecture, some of which require a more delocalized bonding description, will be discussed in Sections 4 and 5.

Boron subhalides B_2X_4 ($X = F$, Cl, Br, I) of the form X_2BBX_2 are molecular compounds with localised B–B bonds. The gallium and indium analogs Ga_2X_4 and In_2X_4, despite having the same formulation, in fact exist as the mixed valence salts $M^+[MX_4]^-$. However, when a donor ligand is added, they form the genuinely divalent complexes $X_2M\text{-}MX_2{\cdot}L_n$ such as $Ga_2Br_4(dioxane)_2$ and $InBr_4(TMEDA)_2$.[31] The dialane $Al_2\{CH(SiMe_3)_2\}_4$ was prepared by reductive coupling of the dialkyl aluminium halide and represented the first example of a molecular aluminium compound to containing a 2c,2e (2-centre, 2-electron) Al–Al bond (Figure 6).[1] Organometallic digallane and diindane derivatives have also been prepared. The diborane(4) compounds can be reduced by two electrons, and the diborane(4), dialane(4), and digallane(4) compounds by one electron to give the radical anions $[E_2R_4]^{\cdot -}$, all of which display evidence for multiple bonding (see Section 7). Trigonal planar gallium and indium compounds $M(MR_2)_3$ contain three M–M bonds linking to a central unsubstituted metal atom (Figure 6), and a small number of dithallium(II) compounds bearing bulky silyl substituents are known.[32]

Diboron compounds (RXBBXR, R_2BBR_2) are extremely well known and are widely used in organic chemistry.[33] Heavier group 13 compounds containing localised M–M bonds and with a formal $N_{ox} = 2$ now represent a mature area of study. As well as halide and organic substituents, examples with heteroatom (Si, N, O, P) substitutents, and both coordinatively unsaturated (coordination number 3) and saturated (coordination number 4) are established giving a range of compounds of the forms $[X_3MMX_3]^{2-}$, LX_2MMX_2L, RXMMXR, and R_2MMR_2 (where X is a halide or anionic ligand, L a neutral donor, and R an alkyl or silyl group).[31,32]

An extraordinary experimental breakthrough occurred in 1989 when it was demonstrated that metastable solutions of the aluminium(I) and gallium(I) monohalides could be prepared in organic solvents.[7] The monohalides halides are prepared in a high-temperature reactor by the reaction of the molten metal with HX at around 1000 °C (equation 1). The monohalides are then cocondensed at −196 °C with toluene to which a donor solvent (NEt_3, Et_2O, THF) has been added. When the cocondensate is melted at around −100 °C, deep red solutions of the monohalide AlX or GaX are formed.[27,34]

$$Al_{(l)} + HCl \xrightarrow{1000\,^{\circ}C} AlCl_{(g)} + \tfrac{1}{2}H_2 \qquad (1)$$

$$3AlCl \longrightarrow 2Al + AlCl_3 \qquad (2)$$

Metastable solutions of the monohalides AlX and GaX (X = Cl, Br, I) have been prepared using this technique, and oligomeric species $(MX)_n{\cdot}L_m$ containing a variety of donors (L) have been crystallised. The solutions disproportionate to the trihalide and the metal (equation 2) when warmed to temperatures in the range −40 to +50 °C, depending on the halide, the donor, and the concentration. Species with oxidation states both higher and lower than +1 (i.e. on the path to both disproportionation products) have been isolated. The reduced species ($0 < N_{ox} < 1$) are discussed in the section on metalloid clusters, and the monohalides and more oxidized species ($1 \le N_{ox} < 3$) are discussed here. A sonochemical synthesis of a subvalent gallium species, possibly GaI, has also been developed.[27,34]

Examples of aluminium and gallium monohalides crystallised directly from metastable AlX or GaX solutions containing a suitable donor are $Al_4X_4{\cdot}4NH_3$ (X = Cl, Br) and $Ga_8I_8{\cdot}6PEt_3$ (Figure 7). The aluminium compounds comprise a planar Al_4 ring with each four-coordinate aluminium

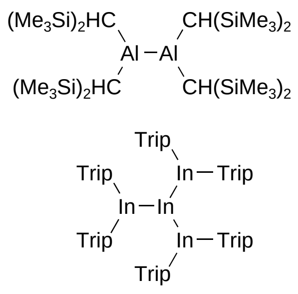

Figure 6 Dialane $Al_2\{CH(SiMe_3)_2\}_4$ and tetraindane $In(InTrip_2)_3$

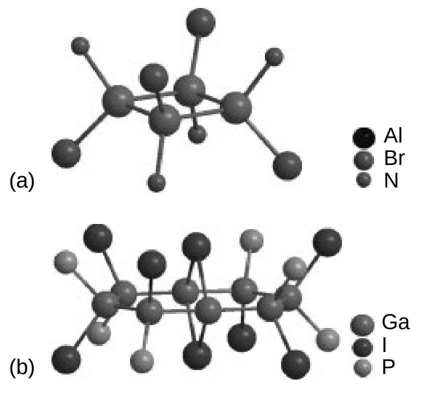

Figure 7 Molecular structures of $(AlBr)_4{\cdot}4NEt_3$ (a) and $(GaI)_8{\cdot}6PEt_3$ (b) (ethyl groups removed for clarity)

bearing a halide and NH_3 substituent. The gallium example comprises a Ga_8 ring with only 6 PEt_3 substituents, and cross-ring bridging iodo ligands complete the four-coordination at the remaining two gallium atoms. The M_2X_4 species, already described above, can also be prepared by the cocondensation technique, and a number of $Al_2X_4L_2$ and partially substituted $Al_2X_2R_2L_2$ examples have been characterised, and show staggered, ethane-like structures (X = halide, R = silyl, L = neutral donor). The gallium compound $Ga_2X_2R_2L_2$ is bridged through the halide atoms and the donors are not coordinated directly to gallium. Other subhalide complexes isolated using this process are $Ga_3I_5{\cdot}3PEt_3$, $Ga_5Cl_7{\cdot}5Et_2O$, and $Al_5Br_7{\cdot}5Et_2O$. M_3X_5 and M_5X_7 species have average metal oxidation states (N_{ox}) 1.67 and 1.40. The two M_5X_7 compounds have different structures, although they both contain $M(M)_4$ units with an unsubstituted metal atom at the centre. The gallium example can be formulated as $Ga(GaCl{\cdot}2Et_2O)(GaCl_2{\cdot}Et_2O)_3$, while the aluminium compound exists as a mixed valence salt comprising $[Al_5Br_6{\cdot}6THF]^+$ cations and $[Al_5Br_8{\cdot}4THF]^-$ anions. The bonding in all these compounds can be described by localised 2c,2e bonds and coordinatively saturated metal centres. The tetrahedral aluminium cluster $(AlCp^*)_4$ was prepared by the cocondensation route, as were other Cp* clusters $SiAl_{14}Cp^*_6$ and $Al_5I_6Cp^*_3$. Further clusters derived from this route in which the number of direct metal–metal bonds exceeds the number of metal–ligand bonds are discussed in the section on metalloid clusters.[34]

Group 13 subhalide compounds have also been prepared by partial oxidation of tetrahedral $(MR)_4$ (R = $C(SiMe_3)_3$) or $(AlCp^*)_4$ clusters using organic halogen donors or AlX_3/X_2 mixtures. For example, $(In_2X_2R_2)_2$ can be prepared from $(InR)_4$ using hexachloroethene (X = Cl) or $AlBr_3/Br_2$ (X = Br). The structure of the cluster, which formally contains In(II), can be related to the tetrahedral In_4 precursor in which two of the edges remain in the product as localised In–In bonds and the remaining four edges are occupied by bridging halide atoms. Other indium subhalides prepared in a similar fashion are $In_4Br_2R_4$ and $In_3I_2R_3$ (Scheme 1). Gallium and aluminium compounds prepared by oxidation of tetrahedral clusters are limited to $Ga_2X_2R_2$ (X = Br, I), $Ga_3I_2R_3$ and $Cp^*_3Al_5I_6$. These compounds all have formal oxidation number N_{ox} between 1.5 and 2. Further synthetic routes to group 13 subhalides have been summarised recently.[32,35]

Two thallium subhalides have been reported, Tl_3ClR_4 and $Tl_6Cl_2R_6$ both containing the supersilyl ligand R = Si*t*Bu$_3$, and with N_{ox} = 1.33. The former contains a Tl_3Cl ring, the latter two Tl_3Cl rings linked through the central Tl atoms.[36]

One category of subvalent main group compounds that are difficult to classify are persistent main group radical species.[37] Most contain homonuclear element–element bonds, many have cluster frameworks and exhibit delocalized bonding and partial multiple bond character. Examples are reduced dimers or clusters such as $[Trip_2MMTrip_2]^-$ (M = Al, Ga), $[Al_6t\text{-}Bu_6]^-$, $[Ga_4R_4]^-$ (R = $C(SiMe_3)_3$) and E_9^{3-} (E = Ge, Sn, Pb), and neutral compounds such as $R^*GaGaR^*_2$, $Ga_3R^*_4$ (R^* = Si*t*-Bu$_3$) and $(GeAr^*)_3$ (Ar = Mes) (Figure 8).[13,37]

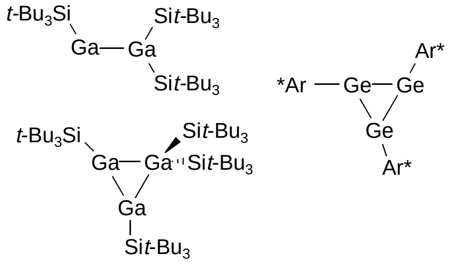

Figure 8 Sketches of radical species $R^*GaGaR^*_2$, $Ga_3R^*_4$ (R^* = Si*t*-Bu$_3$) and $(GeAr^*)_3$ (Ar = Mes)

The remarkable ability of carbon to catenate means that carbon–carbon bonds form the basis of organic chemistry, and although they could strictly be classed as subvalent compounds we do not usually apply this formalism to carbon. Homonuclear element–element bonded compounds are also extensive for silicon (the polysilanes), which show some unusual materials properties and electronic features. Catenation is observed for the heavier elements germanium, tin, and lead, but these become progressively more labile with increasing atomic weight as the element–element bond strength decreases. Element–element bonding is also prevalent in groups 15, 16, and, to a lesser extent, group 17 (e.g. the polyiodide anions) but the well-established area of simple homonuclear bonding between subvalent elements from groups 14–17 will not be discussed here in further detail. Selected recent reviews describe advances in polysilane[38,39] and group 15[40,41] compounds.

4 ELECTRON-PRECISE AND ELECTRON-RICH CLUSTERS

Subvalent main group compounds can form clusters containing element–element bonds in which the electron count corresponds exactly to the total number of lone pairs and localised 2c,2e electron bonds between adjacent pairs of atoms. When these conditions are satisfied, the cluster can be described as electron-precise and each cluster atom bears an octet of electrons. This corresponds to a cluster electron count of $3n$, once electrons in lone pairs or in 2c,2e bonds to apical substituents have been accounted for. In electron-precise clusters each atom in the cluster framework is three-connected, in other words it is bonded to three other cluster atoms. Allowed geometries that meet these constraints are a tetrahedron, trigonal prism, cube, and pentagonal and higher prisms (Figure 9). The simplest such compound that can be described as an electron-precise cluster is P_4, with 12 ($3n$) electrons corresponding to 6 electron-pair P–P bonds along the edges, after allowing for the four lone pairs located one on each phosphorus atom.

Other examples are the group 14 compounds of formula $(ER)_n$, for which the simplest carbon examples are C_4H_4 tetrahedrane, C_6H_6 prismane, and C_8H_8 cubane. Although the electron count allows for 2c,2e pair bonds between adjacent pairs of atoms, in the tetrahedral, trigonal prismatic, and cubic clusters the bond angles (60° and/or 90°) do not accord with simple sp^3 hybridisation, and a delocalized molecular orbital bonding model might be more appropriate.[3] Selected compounds $(ER)_n$ of the heavier group 14 elements are known for $n = 2$, 3, 4, 6, 8, and 10. The compounds where $n = 2$ are the alkyne analogs REER and are discussed in the section on multiple bonding (Section 7). The $n = 3$ clusters exist only for germanium, as the radical $(GeAr^*)_3$ (Ar = Mes) and the cation $[GeR^*]_3^+$ ($R^* = Si\textit{t}\text{-}Bu_3$). Germanium and silicon exhibit tetrahedral clusters $(SiR^*)_4$ and $(GeR^*)_4$, while prismanes

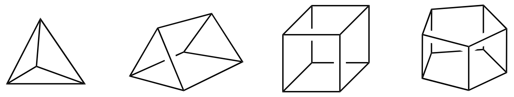

Figure 9 Geometries for electron-precise clusters: (a) tetrahedron, (b) trigonal prism, (c) cube, (d) pentagonal prism

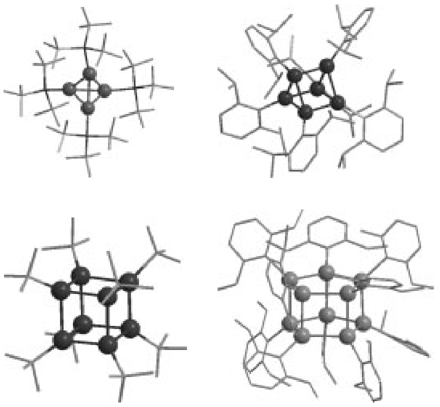

Figure 10 Group 14 clusters: tetrahedral $\{Ge(Si\textit{t}\text{-}Bu_3)\}_4$, trigonal prismatic $(SiDipp)_6$, cuboidal $(Si\textit{t}\text{-}Bu)_8$, and pentagonal prismatic $\{Sn(C_6H_3\text{-}2,6\text{-}Et_2)\}_{10}$

$(ER)_6$ and cubanes $(ER)_8$ occur for silicon, germanium, and tin, where R is a bulky aryl or alkyl group. The largest cluster $(SnAr)_{10}$ has a pentagonal prismatic structure. Representative structures are shown in Figure 10. The prismane C_6H_6 is an isomer of benzene, and for silicon $[SiDipp]_6$ has been isolated in the silicon form of Dewar benzene.[42,43]

Electron-rich clusters can be considered to be based on electron-precise clusters for which each added pair of electrons results in the breaking of an element–element bond and formation of two new lone pairs. The limiting case is a cluster count of $4n$, which simply corresponds to a ring of atoms connected by 2c,2e bonds, of which the S_8 rings and Se_8 rings are simple examples. Subvalent polychalcogenide clusters (Table 1), by virtue of being in group 16, tend to fall into the electron-rich category, and show a variety of structural arrangements, some of which can be described by classical 2c,2e bonding and lone pairs, and others show delocalized, nonclassical bonding.[44,45]

The E_4^{2+} cations can also be considered as electron-deficient *arachno* clusters (see Section 5). The S_8^{2+} and Se_8^{2+} clusters are related to the neutral E_n rings by removal of two electrons and formation of transannular E–E bonds. The six-atom E_6^{2+} clusters illustrate nicely the contrast between classical and nonclassical bonding situations. The hypothetical electron-precise cluster ($3n$ electrons) would be trigonal prismatic E_6^{6+}. Addition of four electrons to give

Table 1 Subvalent polychalcogenide clusters[44]

n	4	6	8	10	>10	oligomeric

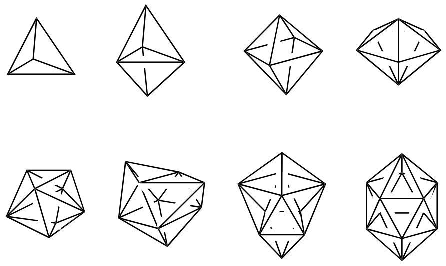

Figure 12 *Closo* polyhedra with *n* vertices: tetrahedron (4), trigonal bipyramid (5), octahedron (6), pentagonal bipyramid (7), dodecahedron (8), tricapped trigonal prism (9), bicapped square antiprism (10), and icosahedron (12)

E_6^{2+} ($3n + 4$) should result in a structure that is essentially a prism with two broken bonds, and indeed this is the case for $Te_3S_3^{2+}$ and $Te_2Se_4^{2+}$. On the other hand, Te_6^{2+} is a prism with only one broken bond, and Te_6^{4+} ($3n + 2$) a closed prism, indicative of some delocalized bonding in these cations (Figure 11).[44]

Group 15 species also form a hugely varied range of structures which can be viewed as electron-rich clusters. P_7^{3-} can be described as a tetrahedral P_4 unit with a P^- fragment inserted in three of the edges, and a selection of formally isoelectronic analogs of these (e.g. where P^- has been replaced by As or S or Se,) have been reported. Although they are formally low-valent group 15 compounds, these and a wide range of related compounds are well known and will not be discussed further here.[3]

5 ELECTRON-DEFICIENT CLUSTERS

The quintessential class of subvalent main group compounds are the polyhedral neutral borane and anionic boron hydride cluster compounds. The bonding in the clusters can be described using delocalized molecular orbitals according to Wade's rules,[4] whereby the number of cluster-bonding electron pairs can be correlated with the structure. More generally, Wade's rules are also applicable to subvalent main group 'naked' anions and cations. The term 'naked' is used in this setting as the clusters bear lone pairs at each apical atom, rather than substituents (typically hydrogen in the boranes and carboranes).[46] The clusters are based on deltahedra (Figure 12), and may be closed (*closo*), or partially open with one (*nido*) or two (*arachno*) missing vertices. A *closo* cluster with n vertices has $2n + 2$ cluster-bonding electrons, a *nido* cluster has $2n + 4$ and an *arachno* cluster has $2n + 6$. As a result, the clusters become progressively more open as the number of electrons increases. The cluster-bonding electrons are those electrons not used in 2c,2e bonds to terminal substituents or as lone pairs at the apexes of 'naked' main group cluster atoms.

Closo, nido, and *arachno* boranes form series with formulae $B_nH_n^{2-}$, B_nH_{2n+4}, and B_nH_{2n+6} confirming their status as formally subvalent compounds. Boranes and carboranes (in which one or more boron atoms in the cluster have been replaced by a carbon atom) have been extensively researched and described, and will not be discussed further here.[2,3] In an example of the application of Wade's rules to a heavier main group cluster, Sn_5^{2-} uses 10 of the total 22 valence electrons in 5 lone pairs. This allows 12 electrons, or $2n + 2$ for $n = 5$ for cluster bonding and specifies a *closo* structure, matching the observed D_{3h} trigonal bipyramidal structure.

A selection of 'naked' main group clusters whose structures can be described by Wade's rules are given in Table 2. Different strategies are required for the isolation of these. The polyanionic clusters (e.g. Sn_9^{4-} and Pb_5^{2-}) prepared by alkali metal reduction of the metals require effective chelating agents such as cryptands for the alkali metal countercations. This class of compounds are known as Zintl ions, named after Zintl's pioneering work on the composition of solutions of group 14 metals treated with sodium in liquid ammonia.[47] The stability of the cationic clusters (e.g. Bi_5^{3+}) is limited by their tendency to disproportionate to the metal and higher oxidation state (Bi^{3+}) species, but can be successfully isolated as the salts of weakly basic halo anions.[48,49] Finally, many of the clusters bearing higher net charges exist only the solid phase, stabilised by electrostatic interactions within the crystal.

Symmetries given in Table 2 are idealized (and refer to the symmetry of the cluster without taking into account heteroatoms) and many of the clusters show distortions from these ideal symmetries. For example, the group 14 clusters Ge_9^{4-}, Sn_9^{4-} and Pb_9^{4-} have $2n + 4$ cluster electrons and exist as the expected *nido* clusters with C_{4v} monocapped square antiprismatic geometry. On the other hand, the bismuth cluster Bi_9^{5+}, which also has a $2n + 4$ electron count, instead exists in the *closo* D_{3h} form with a tricapped trigonal prismatic structure. In fact, all these 9-atom clusters show some distortions from the idealised symmetry, and the energy differences between different geometries are small.[46,50] The *arachno* clusters Sb_4^{2-}, Bi_4^{2-}, Se_4^{2+} and Te_4^{2+} (square planar), and Sb_8^{2+} and Bi_8^{2+} (square antiprismatic) have

Table 2 Examples of *closo*, *nido*, and *arachno* Zintl ions

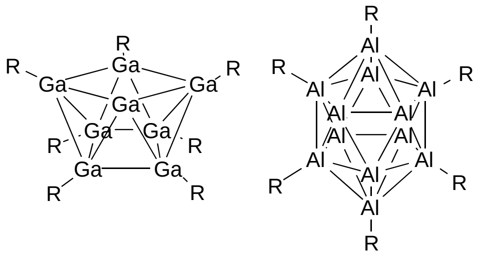

Figure 14 Substituted gallium and aluminium clusters $[Ga_8R_8]^{2-}$ (R = fluorenyl) and $[Al_{12}i\text{-}Bu_{12}]^{2-}$ (not all i-Bu groups shown)

each lost a pair of trans-related vertices from the *closo* parent clusters, rather than two adjacent vertices as occurs for the *arachno* borane clusters. The 14-electron clusters Sb_4^{2-}, Bi_4^{2-}, Se_4^{2+} and Te_4^{2+} can also be described as Hückel aromatic systems, comprising four element–element σ bonds and 6π electrons, and this might contribute to the stability of the square-planar arrangement. Selected clusters are shown in Figure 13.[51–53]

Further examples of formally subvalent main group compounds that contain element–element bonds but not necessarily clusters are the Zintl phases. The bonding in these has been described as the 'octet rule for all atoms'. The archetypal Zintl compound is NaTl, in which charges are assigned as Na^+ and Tl^-, representing a formal transfer of electrons from the more to the less electropositive element. The Tl^- ion can be considered to be a group 14 pseudoelement, and in fact exists in NaTl as a three-dimensional polyanionic diamond framework $(Tl^-)_n$ stuffed with Na^+ cations. The Zintl concept is extended more broadly to other binary and ternary solid-state compounds, whose structures show the formation of element–element bonds in one, two, or three dimensions.[47]

The clusters discussed above are described as 'naked', in other words without substituents at the apical atoms. This contrasts with the borane and carboranes, which bear hydride or other substituents at each apical atom. Extension of substituent-bearing borane-type clusters to heavier elements provides another category of electron-deficient subvalent clusters. Simple examples contain a single aluminium atom occupying one vertex in a borane or carborane cluster, for example, in the *closo* compounds $[MeAlB_{11}H_{11}]^{2-}$ and $EtAlB_9C_2H_{11}$.[54–56] However, the prime example is the aluminium cluster $[Al_{12}i\text{-}Bu_{12}]^{2-}$, which is an alkyl-substituted analog of the borane anion $B_{12}H_{12}^{2-}$, and has the expected *closo* icosahedral geometry in the solid state (Figure 14). The gallium anion $[Ga_8R_8]^{2-}$ (R = fluorenyl) has a $2n + 2$ electron count, but exhibits square antiprismatic rather than the expected dodecahedral geometry (Figure 14), illustrating the same phenomenon observed for some of the heavier naked main group clusters for which different geometries have very similar energies. A number of carbaalanes comprising a carbon and aluminium framework have been reported, for example, $(AlMe)_8(CCH_2Ph)_5H$ and $(AlEt)_7(CCH_2Ph)_4(C{\equiv}CPh)H$, which have Al_8C_5 and Al_7C_4 cluster cores and electron counts corresponding to *arachno* and *closo* compounds.[54]

Group 13 clusters with electron counts less than the $2n + 2$ electrons corresponding to *closo* deltahedra have also been described. The classic examples of these are the boron subhalides, B_nCl_n where $n = 4$, 8–12 (and a more limited set of bromides and iodides), which have an electron count of $2n$ and are known as *hypercloso* clusters. These are based on the same *closo* structures expected for the $2n + 2$ electron clusters, namely, tetrahedral, dodecahedral, and tricapped trigonal prismatic for $n = 4$, 8, and 9. The $2n + 2$ dianions $B_nCl_n^{2-}$ also show the expected deltahedral structures. The stability of the B_nCl_n clusters has been attributed to a combination of the π-donor properties of the halides and steric effects.[2,57]

Of the heavier group 13 elements, a number of organoelement(I) compounds $(ER)_n$ with $2n$ cluster electron counts have been identified. Those with Cp* ligands, tetrahedral $(AlCp^*)_4$ and octahedral $(GaCp^*)_6$ and $(InCp^*)_6$ have already been discussed (Section 2).[27] The electron-rich and sterically shielding Cp* ligands contribute to their stability and the M–M interactions are long and weak. More generally, a range of tetrahedral M_4R_4 clusters for the four elements Al–Tl have been described, with t-Bu (Al), $C(SiMe_3)_3$, $Si(t\text{-}Bu)_3$ or $Si(SiMe_3)_3$ ligands. Delocalized bonding utilising the $2n$ cluster electrons is involved, and the clusters become progressively less stable with increasing atomic number. For example, the Tl–Tl interactions in $\{TlC(SiMe_3)_3\}_4$ are very long. The aluminium compounds exhibit a varied range of colors, for example, $(AlCp^*)_4$, $\{AlC(SiMe_3)_3\}_4$, and $(AlSiR_3)_4$ are yellow, orange, and violet, correlating with the Al–Al distances and the HOMO-LUMO gap. The largest of the $(ER)_n$ clusters are $(Ga\text{-}t\text{-}Bu)_9$ and its monoanion $[(Ga\text{-}t\text{-}Bu)_9]^-$, which both adopt the *closo*-type bicapped trigonal prism geometry, although with some differences in the Ga–Ga bond lengths for each.[35]

Hypoelectronic clusters have also been identified in solid phases. Hypoelectronic clusters have electron counts less

than $2n + 2$, for example $2n$ in Tl_n^{n-} ($n = 6$, 7, 9) and $2n - 4$ in M_{11}^{7-} (M = Ga, In, Tl). A further new category of naked group 13 subvalent clusters are the centred clusters, for example, $Tl_{10}Zn^{8-}$, which contains a zinc atom in the centre of a bicapped square antiprism, giving an overall $2n - 2$ electron count.[53]

6 METALLOID CLUSTERS

The preparation of metastable solutions of the aluminium(I) and gallium(I) monohalides was outlined in Section 3.[7,28,34] These solutions disproportionate to the trihalide and the metal (equation 2) when warmed to temperatures in the range −40 to +50 °C, depending on the halide, the donor, and the concentration. Substitution of the halide by other suitable anionic ligands can also occur in the same temperature range, adding another variable to the conditions for the disproportionation reaction. The most effective group for these substitution reactions is the $N(SiMe_3)_2$ group, shown in equation (3).

$$AlCl + LiNR_2 \longrightarrow AlNR_2 + LiCl \quad (R = SiMe_3) \qquad (3)$$

Careful control of these conditions allowed the isolation of clusters that form on the path to the completed precipitation of the metal.[58–60] They have been termed 'metalloid' clusters, referring to the fact that the core arrangement of the cluster atoms resembles that in the bulk metals. (This use of the term 'metalloid' should not be confused with its use to refer to elements such as silicon, germanium, and arsenic, which lie on the metal/nonmetal border within the periodic table.) The clusters have the general formula $M_nR_m^{x-}$ where $n > m$, and thus the clusters comprise $m - n$ 'naked' metal atoms together with m MR fragments (M = Al, Ga; R = $N(SiMe_3)_2$) and the average $N_{ox} < 1$. Cluster size increases with increasing temperature, indicating that as the temperature increases the system has moved further along the path to complete disproportionation to the metal. For example, warming a solution of AlCl produces $[Al_7R_6]^-$ at −7 °C, $[Al_{12}R_6]^-$ at 25 °C, and $[Al_{69}R_{18}]^{3-}$ after warming briefly to 60 °C. A solution of the less reactive AlI produces $[Al_{14}R_6I_6]^{2-}$ at room temperature and $[Al_{77}R_{20}]^{2-}$ after brief warming to 60 °C. As the cluster size increases, the mean oxidation state (N_{ox}) of the metal decreases, again indicating further progress along the path to the metal. For example, N_{ox} values for the Al_7, Al_{12}, and Al_{69} clusters are 0.71, 0.42, and 0.22. Views of the Al_7 and Al_{12} clusters and the relationship of the clusters to the cubic close packing in aluminum metal are shown in Figures 15 and 16.

The structures of the clusters comprise inner 'naked' aluminium atoms, which for the larger clusters are layered in concentric shells with the substituted AlR groups occurring on the outside of the cluster.[59] The most significant feature of the clusters is that the aluminium cluster core resembles a distorted fragment of the structure of metallic aluminium and can be viewed as 'metalloid' fragments protected by a shell of AlR groups. In the largest cluster, $[Al_{77}R_{20}]^{2-}$, the structure comprises a single inner Al atom surrounded by a distorted icosahedral Al_{12} shell.[5] This, in turn, lies inside a shell of 44 Al atoms, and finally the outermost layer consists of 20 $AlN(SiMe_3)_2$ groups (Figure 17). On moving from the innermost, single Al atom to the fourth, outermost Al_{20} shell both the coordination number of the Al atoms and the mean Al–Al distances decrease, indicating that the Al–Al bonds become more localised and have more molecular character closer to the surface of the cluster. A comparison of the closely related $[Al_{69}R_{18}]^{3-}$ and $[Al_{77}R_{20}]^{2-}$ structures shows that despite overall broad similarities in their structures, there are significant differences in the packing of the aluminium atoms within each cluster, including the environment around

the central aluminium atoms. This finding indicates that even slight variations on the surface of nanostructured materials can affect the arrangement of atoms for several layers towards the centre of the nanoparticle.

Only one solid-state structure is known for aluminium metal, contrasting with gallium metal, which can exist as a number of solid-state modifications. Starting with solutions of gallium halides GaX, a variety of clusters containing 6, 8, 12, 18, 19, 22, 26, or 84 gallium atoms can be prepared through the controlled disproportionation reactions.[61] These clusters show a variety of arrangements of gallium atoms in the cluster core, in parallel with the several modifications of gallium metal itself. The Ga_{84} cluster, $[Ga_{84}\{N(SiMe_3)_2\}_{20}]^{4-}$, is the largest metalloid cluster synthesised to date, and comprises 64 unsubstituted gallium atoms within a shell of 20 $GaN(SiMe_3)_2$ groups (Figure 18).[6] Like the Al_{77} cluster, the gallium cluster is comprised of successive concentric layers of gallium atoms. A remarkable feature is that a dumbell-shaped Ga_2 unit with a very short Ga–Ga distance of 2.34 Å lies at the centre of the cluster, surrounded by a rugby ball-shaped Ga_{32} shell. The next 30 gallium atoms form a cylinder around the widest part of the rugby ball, with the remaining 20 ligand-bearing $GaN(SiMe_3)_2$ groups distributed on the surface of the cluster.

Overall, the metalloid aluminium and gallium clusters bear some relationship to fragments of the bulk metals, protected and stabilised by the ligands on the surface, and as such can be considered intermediate between molecules and metals. They show a marked sensitivity to preparative conditions and the steric influence of the ligands on the surface. Spectroscopic studies and theoretical calculations on the clusters are not discussed here but are summarised in recent review articles, and these additional studies provide a

greater depth of understanding of these unique molecules.[62] The Ga_{84} cluster has recently been demonstrated to become superconducting at ca. 7 K, indicating further unusual features and potential applications of these remarkable clusters.[63]

A small number of heavier group 13 clusters containing naked metal atoms are known, although nothing on the scale of the large aluminium clusters. In_4Ar_6, Ga_4Ar_6 and $[Ga_4Ar_6]^{2-}$ (Ar = Trip) each contain a trigonal planar unsubstituted metal bonded to three MAr_2 groups. $In_8Ar^*_4$ (Ar = Mes) comprises an In_8 cube with alternating substituted and naked indium atoms.[64] Ga_8R_6 (R = $C(SiMe_3)_3$) and $Ga_{10}R_6$ (R = $Si(SiMe_3)_3$) consist, respectively, of two tetrahedra linked by a Ga–Ga bond, and two octahedra sharing one edge.[60] The largest cluster, $In_{12}R_8$ (R = $Si(CMe_3)_3$) is an ellipsoidal polyhedron that can be loosely described as two In_6 octahedra linked through In–In interactions between the four naked indium atoms, the core of which has a structural relationship to elemental indium.[65]

Comparable metalloid clusters of the group 14 elements are much less well developed. The metastable subhalide route has just been established for germanium, with the preparation of GeCl.[66,67] A small number of examples are known of the type E_nR_m where $n >$ m and formal $N_{ox} < 1$. These clusters contain 2, 3, or 4 unsubstituted metal atoms, and can be considered to lie on the path approaching the metal, but not to the extent observed for the much larger group 13 clusters. The $Sn_8R^*_6$ (R^* = Si*t*-Bu3) and Ge_8R_6 (R = $N(SiMe_3)_2$) clusters contain a cuboid E_8 core with six substituted and two unsubstituted atoms. The $M_4(GeAr^*)_2$ (M = Ge, Sn; Ar = Dipp) and $Sn_4(SnAr^*)_4$ (Ar = Mes) clusters have as a common structural element a square-planar unsubstituted M_4 core capped on the square faces by GeAr′ groups in the former case and Ar*SnSnAr* groups in the latter (Figure 19). The germanium cation $[Ge_{10}R^*_6I]^+$ contains a trigonal $Ge_3{}^+$ core capped above and below by Ge_4R_3I and Ge_3R_3 units. Two further tin clusters, Sn_5Ar_6 and Sn_7Ar_8 (Ar = C_6H_3-2,6-Et_2), although with a higher formal oxidation state, each contain two unsubstituted tin atoms in a propellane moiety.[42,43]

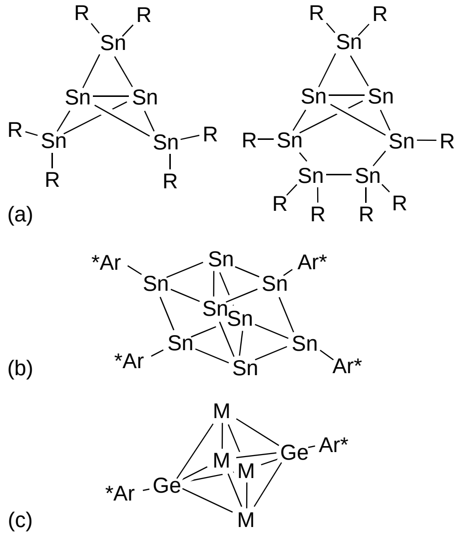

Figure 19 Group 14 clusters (a) Sn_5Ar_6, Sn_7Ar_8 (R = C_6H_3-2, 6-Et_2), (b) $Sn_4(SnAr^*)_4$ (Ar = Mes), and (c) $M_4(GeAr^*)_2$ (M = Ge, Sn; Ar = Dipp)

7 MULTIPLE BONDING IN MAIN GROUP SUBVALENT COMPOUNDS

Until the early 1980s, the predominant view was expressed by the so-called ‘double bond rule’, which stated that elements with a principal quantum number greater than 2 do not form multiple bonds with themselves or with other elements.[68] Exciting events in 1981 saw this ‘rule’ overturned, with the announcement of the first silene Si=C[69] and disilene Si=Si[70] double bonds, followed not long after by a P=P double bond in Mes*P=PMes*.[71] In the 25 years since that time, a phenomenal advance in experimental results has taken place in this area, accompanied by a parallel advance, which has not been without controversy, in the understanding of the phenomenon of multiple bonding in the heavier main group elements.

A table of hypothetical multiply bonded main group compounds based on isoelectronic analogs of carbon can be easily drawn up. The challenge then arises in designing and synthesising target compounds. One of the keys to success in this area has been the use of bulky substituents to aid in kinetic stabilisation of very reactive molecules, and with each new generation of bulky ligands further advances have been made. For example, simple substituted arenes such as the mesityl group provide sufficient steric protection for alkene analogs containing boron and silicon, whereas bulkier arenes bearing isopropyl (Trip) and tertiary butyl (Mes*) substituents are required for aluminium, gallium, and phosphorus analogs. (Although phosphorus is smaller, its alkene analogs bear only one substituent at the main group atoms.) Alkyne analogs of the group 14 elements are stabilised using the new generation terphenyl ligands C_6H_3-2,6-Ar_2 in which the Ar groups are themselves bulky arenes such as Dipp, Trip, or Mes.[23] Sterically encumbering alkyl groups that have also proved useful are, for example, *t*-Bu, $CH(SiMe_3)_2$, Si*t*-Bu_3, and $Si(SiMe_3)_3$.

The target hypothetical multiple bonded main group compounds are shown in Table 3, in which the entries shown correspond to types for which at least one example has been prepared, and also show a selection of other analogs that differ from the simple target compounds by a one-electron redox change. The group 14 alkene analogs are simply the heavier element compounds R_2EER_2. Group 13 elements contain one electron less than their group 14 counterparts, so the isoelectronic boron analog of an alkene is $[R_2BBR_2]^{2-}$.

Table 3 Main group element compounds potentially containing multiple bonds

Alkene analogs					
Group 13 (and singly oxidized analogs)		Group 14			Group 15

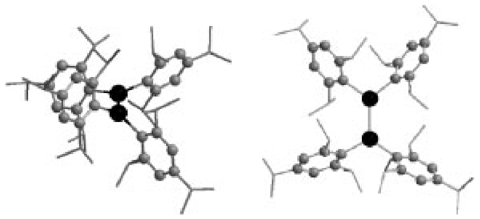
		RSnSnR	$[RSnSnR]^{-}$	$[RSnSnR]^{2-}$	
		RPbPbR			

Group 15 elements each contain one more electron, giving the well-known imines RN=NR as the nitrogen examples but more exotic species RE=ER containing the heavier elements. Once the compounds have been successfully prepared the next challenge is to determine whether their structural, spectroscopic, and chemical properties are indeed in accord with the existence of a multiple bond.[72]



(a) (b)

Figure 20 (a) Neutral $Trip_2AlAlTrip_2$ showing the torsion angle around the Al–Al bond and (b) the singly reduced anion $[Trip_2AlAlTrip_2]^-$ containing a partial Al–Al π bond

7.1 Alkene Analogs

The diboron dianion $[Mes_2BB(Mes)Ph]^{2-}$, prepared by lithium metal reduction of the neutral diborane precursor $Mes_2BB(Mes)Ph$, does indeed show a much reduced torsion angle about the B–B bond (the angle between the two C_2B planes) of 7°, relative to 79° in the neutral precursor, and a B–B bond length of 1.636 Å, some 7% shorter than the 1.706 Å distance in the neutral compound. Spectroscopic evidence (^{11}B NMR and observation of a π-π^* transition in the electronic spectrum) add further evidence for the existence of a B=B double bond in this compound with a π bond strength estimated to be around 40 kcal mol^{-1} (compared to 60 kcal mol^{-1}) in an alkene. The bond shortening is less than the 13% decrease observed for the C–C bond in an alkene relative to an alkane, but this is probably a result of electrostatic effects arising from the 2- charge. Support for this idea can be derived from the singly reduced compound $[Mes_2BB(Mes)Ph]^-$, which has only a half-occupied π orbital and a net B–B bond order of 1.5, yet has almost the same B–B bond length, 1.649 Å, as the doubly bonded dianion.[73] Only the singly reduced aluminium and gallium alkene analogs could be prepared, $[R_2AlAlR_2]^-$ and $[Trip_2AlAlTrip_2]^-$, but like their boron counterpart they show small torsion angles and E–E bonds some 7% shorter than the neutral precursors (Figure 20). EPR evidence indicates that the single electron occupies an orbital of π symmetry in each case, consistent with a partial π bond and E–E bond order of 1.5.[74–76]

The complete set of group 14 alkene analogs R_2EER_2 are known for carbon, silicon, germanium, tin, and lead. These include two landmark compounds, the disilene $Mes_2SiSiMes_2$ prepared in 1981,[70] and the tin compound $\{(Me_3Si)_2CH\}_2SnSn\{CH(SiMe_3)_2\}_2$ prepared in 1976[77] (Figure 21). The silicon compound was a breakthrough because its structural and spectroscopic characteristics were overwhelmingly in accord with its formulation as a Si=Si double-bonded compound, representing the first of its type. The tin compound, on the other hand, has the stoichiometry of an alkene analog, but its structural and chemical properties did not seem to be in accord with the presence of a double bond. The Sn–Sn bond (2.77 Å) is only marginally shorter than an Sn–Sn single bond (2.81 Å), the compound is not planar but rather the two C_2Sn planes are tilted 41° away from the Sn–Sn

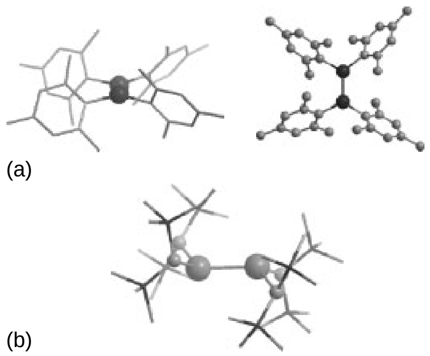


Figure 21 (a) Two views of the disilene $Mes_2Si{=}SiMes_2$, with the left view emphasising the planar geometry; (b) the trans-bent tin alkene analog $\{(Me_3Si)_2CH\}_2SnSn\{CH(SiMe_3)_2\}_2$

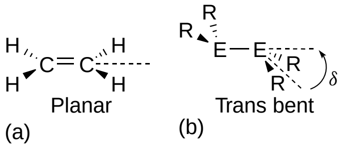

Figure 22 Geometry of alkene and alkene analogs: (a) planar geometry, angle between CH_2 plane and C–C bond = 0°; (b) trans-bent geometry, angle between ER_2 plane and E–E bond > 0°

axis, in a trans-bent geometry (Figure 22), and the compound dissociates into $(Me_3Si)_2CH\}_2Sn$ monomers in solution.

The characteristics observed for the group 14 alkene analogs are summarised in Table 4.[13,15,19,78–80] The extent of bond shortening (relative to an E–E single bond) decreases down the group – in fact some of the tin and lead 'double' bonds are *longer* than the corresponding single bonds. The occurrence of trans-bending increases down the group, and some of the germanium, and all of the tin and lead compounds are dissociated into monomers in solution. In fact, the enthalpy of association for the tin monomers ($2SnR_2$ forming R_2SnSnR_2) was calculated to be 10–12 kcal mol^{-1}, comparable to the energy of a hydrogen bond and much weaker than the value of 35 kcal mol^{-1} calculated for the energy of an Sn–Sn single bond. On the other hand, the disilene complexes can exist as *cis* and *trans* isomers with high barriers to

Table 4 Group 14 alkene analogs

	Number of compounds	E–E/Å	δ/°	E–E (single)	%[a]

[a]% shortening relative to single bond.

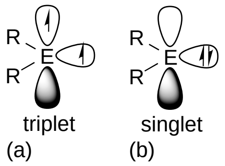

Figure 23 Group 14 diyl fragments: (a) triplet lower in energy for E = C; (b) singlet lower in energy for E = Si, Ge, Sn, Pb

rotation around the Si–Si bonds.[81] In summary, the group 14 compounds appear to range from true alkene-type compounds for the lighter elements carbon and silicon to compounds with quite different characteristics for tin and lead, which show chemistry consistent with a stannane- or plumbanediyl, $:ER_2$. The germanium examples are intermediate between silicon and tin: some behave more like a digermene, others more like a germanediyl. The challenge has been to derive an understanding of the bonding in these compounds that effectively rationalises these characteristics.

Two electronic effects have been identified that can help account for the observed experimental results.[79] The first is the singlet-triplet energy gap in the sp^2–hybridised group 14 diyl fragments ER_2. For carbon (in other words a carbene), the triplet state is lower in energy, while for the heavier elements the singlet is the ground state (Figure 23). If the $\sigma + \pi$ bond combination in ethene is considered to arise from coupling of two triplet fragments, then the singlet to triplet promotion energy is an energy cost to forming an alkene-like double bond in the heavier elements. On descending the group, the energy gained from E–E bond formation is increasingly unable to offset the higher energy required for accessing the triplet state prior to forming the double bond. The chemistry of the double bond increasingly (especially for tin and lead) resembles that of two singlet monomers associated through dative bonding.

In molecular orbital terms, the C–C bonding in an alkene comprises one σ and one π bond. On descending the group 14 elements, the energy gap between the antibonding E–E σ^* orbital and the π orbital decreases, and mixing of these two orbitals ($\sigma^* + \pi$) increases in the order Si, Ge, Sn, Pb, with the mixing most marked for the heavier elements. This effect is related to the tendency for increased pyramidalization in the heavier main group elements. The $\sigma^* + \pi$ orbital mixing lowers the energy of the original π orbital, but at the same time increases its lone pair character and weakens the π bond. As a result of the bending and orbital mixing, it increasingly resembles a nonbonding, lone pair orbital rather than a π bonding orbital. The nonbonding orbital is distributed over the two E atoms but contains two electrons and can be described by the resonance forms shown in Figure 24. The E–E σ bond is also weakened as the orbital overlap is not as favourable in the bent geometry. The bonding in the tin and lead compounds is weakened to the extent that they dissociate to monomers in solution. Overall, the E–E bond orders are probably greater than one but less than two, and the correlation between bond

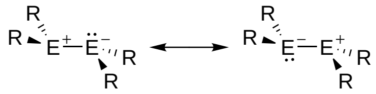

Figure 24 Resonance forms arising from $\sigma^* + \pi$ mixing in trans-bent group 14 alkene analogs

order and bond length is not as reliable as in the true alkene type ($\sigma + \pi$) double bonding.[79]

Isoelectronic analogs of alkenes containing group 15 elements contain one substituent (very bulky) and one lone pair at each E atom.[79,82–84] The homologous series shown in Table 5 (all containing the Ar* terphenyl ligand with Ar = Mes) gives a view of the trends down the group. Molecular structures of the phosphorus and bismuth compounds are shown in Figure 25. The % E–E bond shortening and C–E–E angles decrease. In orbital terms, the *s* character decreases in the E–E bond, and increases in the lone pair, so that for the bismuth examples, the C–Bi and Bi–Bi bonding is mainly *p* in character (as bond angles approach 90°) and the lone pair occupies a predominantly *s* orbital.

For the group 15 elements, both experimental and theoretical studies indicate that there is a double bond with both σ and π components. For example, both *cis* and *trans* isomers are isolable for the phosphorus compounds. The σ:π bond strength ratio for P (48:34 kcal mol^{-1}) is similar to that for C (81:62 kcal mol^{-1}). The ratio of σ:π bond strengths decreases down the group, but is still consistent with presence of both σ and π bonds for each compound. Overall, bonding in the group 15 analogs of alkenes can be described as full-fledged double (σ and π) bonds.[79]

Table 5 Group 15 alkene analogs Ar*EEAr* (Ar = Mes)

	E=E/Å	C–E–E/°	%
Ar*PPAr*	1.985(2)	103.7(av)	10.6
Ar*AsAsAr*	2.276(3)	98.5(4)	6.7
Ar*SbSbAr*	2.6558(5)	94.1(1)	6.5
Ar*BiBiAr*	2.8327(14)	92.5(4)	5.3

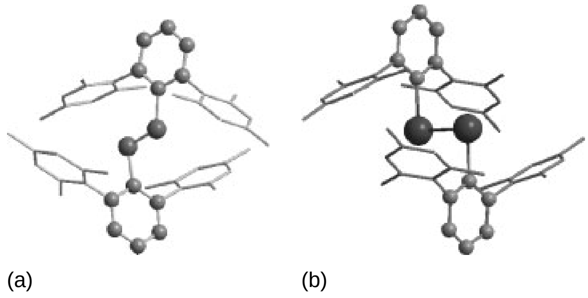

Figure 25 Group 15 alkene analogs (a) Ar*PPAr* and (b) Ar*BiBiAr* (Ar = Mes)

7.2 Alkyne Analogs

In 1997, a digallium dianion was reported that sparked off a controversy regarding the nature of the bonding between the two gallium atoms. The compound, Na_2[Ar*GaGaAr*] (Ar = Trip), was prepared by sodium metal reduction of Ar*$GaCl_2$. The compound is formally a triple bond (ethyne) analog, $[RM{\equiv}MR]^{2-}$. Although it has a short Ga–Ga bond of 2.319(3) Å, it is not significantly shorter than the shortest Ga–Ga single bond, and the molecule is not linear as might be expected, but has C–Ga–Ga angles of 131°. The two sodium cations are sandwiched between pairs of opposing phenyl rings from the terphenyl substituents, and theoretical studies indicate these interactions are significant in stabilising the molecule.[82,85,86]

Several isomeric forms can be written for group 13 'triple' bonds, shown in Figure 26. Bending of the C–Ga–Ga angle away from 180° is evidence for the presence of lone pairs, and calculations on a variety of model compounds are consistent with a Ga–Ga bond order of 2. The isomeric form with one π bond and one delocalized lone pair (as in the group 14 alkene analogs) is possibly the best description of this molecule.[76]

Neutral compounds of the form Ar*EEAr* are known for germanium, tin (Ar = Dipp), and lead (Ar = Trip) (Figure 27).[87,88] The lead compound Ar*PbPbAr* has a Pb–Pb bond length of 3.19 Å, even longer than a Pb–Pb single bond (2.88 Å). The C–Pb–Pb angles of 94° suggest that the orbitals involved in Pb–Pb and Pb–C bonding are almost pure *p* in character. A formulation with the Pb–Pb bond order close to 1 and a lone pair occupying a 6*s* orbital on each Pb atom is likely to be the most appropriate for the dilead compound (type c in Figure 26).

The germanium and tin compounds Ar*EEAr* have different characteristics, with C-E-E angles in the range 125–129°, and some bond shortening evidenced by the Ge–Ge and Sn–Sn bond lengths of 2.285 and 2.667 Å, compared to 2.44 and 2.81 Å for the corresponding single bonds, suggesting some multiple bond character. The trans-bending in these compounds can be explained using the same molecule orbital argument used for bending in the alkene analogs, based on mixing of the π and σ^* orbitals. In the linear, alkyne-like

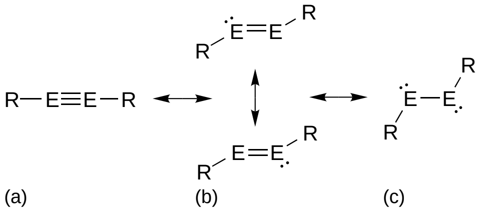

Figure 26 Resonance forms for E–E bonds in $[REER]^{n-}$ (E = group 13, $n = 2$; E = group 14, $n = 0$): (a) bond order 3; one σ bond, two π bonds; linear geometry; (b) bond order 2; one σ, one π bond, one lone pair; trans-bent geometry; (c) bond order 1; one σ bond, two lone pairs; strongly trans-bent geometry

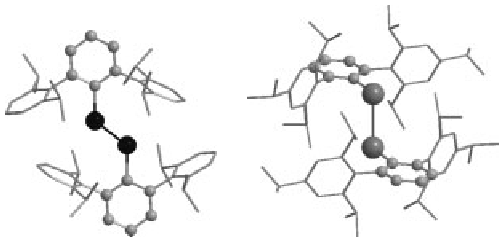

Figure 27 Group 14 alkyne analogs (a) Ar*GeGeAr* (Ar = Dipp) and (b) Ar*PbPbAr* (Ar = Trip)

form (type a in Figure 26), the bond order is three, with one σ and two π bonds. In the trans-bent form, one of the two π bonds has been converted into an essentially nonbonding orbital. Thus, the bond order is reduced from 3 to 2 (one σ and one π bond), or even less since the remaining σ and π bonds are weakened in the bent form (type b in Figure 27). The nonbonding orbital is distributed over the two atoms, and contains two electrons that from recent evidence might be formulated as a singlet diradicaloid.[87]

The lightest member of the series, containing silicon, has only just been reported in 2004.[89] The compound RSiSiR (R = Si*i*Pr(Si*t*Bu$_3$)$_2$) has an Si≡Si bond length of 2.06 Å, some 3.8% shorter than an Si=Si double bond, and 13.5% shorter than an Si–Si single bond. The compound is trans-bent with an Si–Si ≡Si angle of 137°.

The germanium and tin compounds can be further reduced to form mono- and dianions, $[ArEEAr]^-$ and $[ArEEAr]^{2-}$. In formulation c (Figure 26), each E atom bears an unused p orbital that can overlap to form a molecular orbital of π symmetry. For the reduced tin compounds, in particular, there is evidence that the additional electron(s) populate this π orbital, whereas for the germanium compounds, best described by b (Figure 26), the LUMO is nonbonding and the additional electron(s) have little direct effect on the Ge–Ge bonding.[90]

Multiple bonding in subvalent main group compounds has been discussed above primarily using examples of homonuclear element–element bonds. There are an increasing number of examples of heteronuclear pairs of elements for which there is evidence for multiple bonding. These will not be discussed here but some recent reviews are cited as follows: boron–carbon,[91] silicon–carbon,[92] silicon–nitrogen,[93] silicon–phosphorus and silicon–arsenic,[94,95] germanium and tin multiply bonded compounds,[96,97] group 14–group 16 compounds,[98,99] phosphorus,[100] and phosphorus-carbon.[101]

Finally, aromaticity is a hallmark of carbon chemistry that has received only limited attention among the heavier main group elements. Stable aromatic compounds containing the heavier group 14 elements[102] and also a small number of group 15 examples have been reported.[85]

1 INTRODUCTION

Since silicon represents the next homolog to carbon in the periodic table, the question about the analogy between carbon and silicon has existed for a long time, and many chemists have studied the chemical similarities and differences between them. Unsaturated species of the second row main group elements, such as olefins, carbonyl compounds (aldehydes, ketones, esters, amides, etc.), imines, aromatic compounds, azo compounds, carbenes, and so on, play very important roles in organic chemistry. On the other hand, the chemistry of heavier elements' homologs of these low-coordinated species has been undeveloped so far most probably owing to their extremely high reactivity and inherent instability under ambient conditions, while these unsaturated compounds have been postulated in many reactions only as reactive intermediates. Prior to the 1970s, all attempts at synthesizing the low-coordinated species of elements of the third period and downward (namely, heavier main group elements) proved unsuccessful, leading to the formation of cyclic oligomers or polymers containing only single covalent bonds even under the conditions without any oxygen and water. Therefore, it came to be believed that 'elements having a principal quantum number greater than two should not be able to form pπ–pπ bonds with themselves or with other elements', that is, the so-called 'double-bond rule'.[1] It should be most likely interpreted in terms of the poor overlap of p orbitals, owing to either a large distance between the two bonding atoms (e.g. Si–Si bond) or a poor size match (e.g. Si–C bond), precluding favorable bonding interactions. However, this rule came to be doubted during the 1970s with the reports on the preparations of such low-coordinated compounds of heavier main group elements in the gas phase and the trapping reactions of them at low temperature.[2] Then, the first phosphaalkene (P=C, in 1978),[3] diphosphene (P=P, in 1981),[4] silene (Si=C, in 1981),[5] and disilene (Si=Si, in 1981)[6] were successfully synthesized as stable compounds by taking advantage of steric protection, where the 'double-bond rule' was completely disproved. These compounds are significant landmarks in the chemistry of kinetically stabilized low-coordinated compounds of heavier main group elements, and many examples have been reported so far.[1,7]

For the stabilization of highly reactive compounds such as low-coordinated compounds of heavier main group elements, there are two conceivable methodologies, that is, thermodynamic and kinetic stabilization. The former is defined as stabilization of the ground state by the mesomeric effect of neighboring heteroatoms, that is, introduction of electron-donating or -withdrawing substituents, and/or complexation with transition metals. The latter is stabilization resulting from raising the transition state by taking advantage of steric protection using bulky groups, which suppress self-oligomerization and side-reactions with other reagents such as oxygen and water. Kinetic stabilization is obviously superior to thermodynamic stabilization, since the latter perturbs the intrinsic nature of the species to a greater extent than the former. Since some review articles are now available on the history of the synthesis of low-coordinated heavier main group elements,[8] the contents in this section will be restricted to deal with the synthesis and properties of unsaturated compounds of heavier group 14 elements. We delineate here especially the systematic comparison of their structures and properties from the viewpoint of elemental chemistry.

2 THEORETICAL ASPECTS

Theoretical calculations have played an important and/or crucial role in providing valuable information for establishing general concepts. Recent progress in theoretical methods, efficient computer programs, and powerful computers has greatly advanced the scope of applicability of ab initio and DFT

calculations. Although large-scale calculations are generally required for systems of experimental interest, it is important to understand simple conceptual frameworks before extensive calculations. The concept of 'hybridization' is most helpful for an intuitive understanding of the essential difference in the chemical bondings between carbon and heavier group 14 elements.[9]

2.1 The Hybridization of Atomic Orbitals

The valence ns and np electrons play important roles in the chemistry of main group elements, in contrast to the d electrons in the chemistry of transition metals. In Figure 1 are shown the radii of atomic orbitals (maximal electron-density), which are calculated for group 14 elements.[10] It should be noted that the valence ns and np atomic orbitals show great difference in their sizes for the heavier atoms (Si, Ge, Sn, Pb), though the size of the 2s atomic orbital of carbon is almost equal to that of the 2p atomic orbitals. Therefore, the heavier atoms have a lower tendency to form s-p hybrid orbitals with high p character and they prefer to retain the ns^2np^3 valence electronic configuration, in contrast to the case of carbon.

In addition, it may be expected that the sizes of the ns and np orbitals increase monotonously going down the periodic table from C to Pb, since the principal quantum number (n) increases. Unexpectedly, however, one can see that the sizes of orbitals change irregularly. The irregularity in Si → Ge and Sn → Pb is most likely interpreted in terms of so-called 'd-block contraction' and 'relativistic effect'.[11,12] Anyway, one can see obviously two boundary lines drawn between carbon and silicon, and between germanium and tin. The first boundary line indicates the preference of heavier atoms for ns^2np^3 valence electronic configuration to the hybridization of s and p orbitals as described above. Taking into consideration the second boundary line, that is, the large difference of the orbital sizes between Ge and Sn, it should be expected that the properties of silicon and/or germanium compounds may differ from those of tin and/or lead compounds.

2.2 Doubly Bonded Systems Between Heavier Group 14 Elements

It is a well known fundamental property of the second row elements that they can form very stable double bonds,

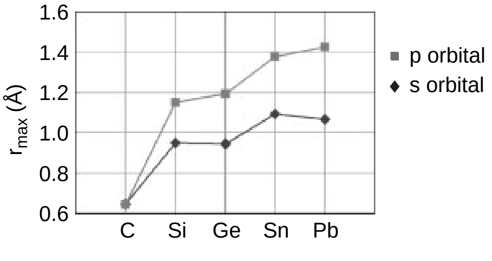

Figure 1 The sizes of valence ns and np orbitals of group 14 atoms

for example, ethylene ($H_2C{=}CH_2$). In addition, every chemist knows that ethylene has a planar D_{2h} structure. On the other hand, many chemists have desired synthesis of ethylene analogs of heavier group 14 elements, that is, disilenes, digermenes, distannenes, and diplumbenes (called as dimetallenes). However, no example of dimetallenes has been known until the first isolation of kinetically stabilized disilene ($Mes_2Si{=}SiMes_2$; Mes = mesityl) by West and coworkers.[6] The reason for difficulty in forming stable double bonds between heavier group 14 elements is most likely interpreted in terms of smaller π bond energy than the corresponding σ bond energy due to the long bond distance that leads to a small overlapping of p orbitals. Examples of calculated σ and π bond energies are shown in Table 1,[9] from which one can see the following points pertinent to the intrinsic character of the double bonds in dimetallenes. First, the π bond energies for homonuclear double bonds between carbon atoms are more than twice as large as those between the heavier atoms (Si and Ge). Second, the σ bond energies are significantly larger than the corresponding π bond energies in the case of heavier atoms. Here, somewhat exceptional is the C=C double bond, in which the s and p bond energies are of roughly the same magnitude. Therefore, the heavier double-bond compounds easily undergo oligomerization and/or addition reactions with oxygen, water, and so on, forming σ bonds at the expend of π bonds. It should be noted that the features of s and p bond energies of a disilene (Si=Si) and a digermene (Ge=Ge) show little difference from each other. The deduction that the properties of silicon and germanium compounds might be similar to each other, described in Section 2.1, is reasonably demonstrated here.

Much effort has been expended on the calculation of bonding properties of dimetallenes so far. Although several bonding models have been suggested,[13–15] it will be simply interpreted here for clarity. When the parent double-bond systems $H_2M{=}MH_2$ (M=Si, Ge, Sn, Pb) are homolytically cleaved, the resulting two H_2M: units may exist in a triplet or a singlet state. In contrast to the case of carbon atom, the heavier group 14 atoms have low ability to form hybrid orbitals; therefore, they prefer ns^2np^2 valence electronic configuration in their divalent species. Since two electrons remain to be as a singlet pair in the ns orbital, the ground state of H_2M: is singlet, unlike the case of H_2C:, the ground state of which is triplet.[16] As a result, severe repulsion between the closed-shell orbitals of two H_2M: units prevents dimerization, leading to $H_2M{=}MH_2$ in the planar form as shown in Figure 2. However, the two H_2M: units can form unique double bonds not only elongated to avoid the repulsion but also in trans-bent

Table 1 Bond energies of double bonds between group 14 elements (in kcal mol^{-1})

Bend energy (kcal mol^{-1})	C=C	Si=Si	Ge=Ge
σ	80	46	39
π	70	28	26

configuration,[17] where each of H_2M: units donates a lone pair of electrons to an empty p orbital of its bonding partner to form double donor-acceptor bonds as shown in Figure 2. These bond elongation and trans-bending properties increasingly appear as M becomes heavier from Si to Pb. Sn and Pb atoms are very reluctant to form the distinct double-bond structure, $H_2Sn{=}SnH_2$ and $H_2Pb{=}PbH_2$. The bridged dimer of H_2M: and 1,2-H-shifted isomer, $HM\text{-}MH_3$, are more stable in the case of Sn and Pb (Figure 3),[18] since at least one atom in these isomers can maintain ns^2np^2 valence electronic configuration as two valent species without hybridization of orbitals, leading to the formation of four valent species.

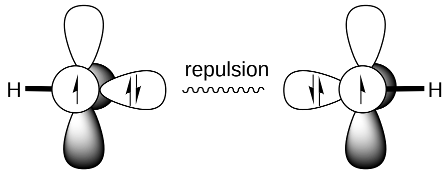
2.3 Triply Bonded Systems between Heavier Group 14 Elements

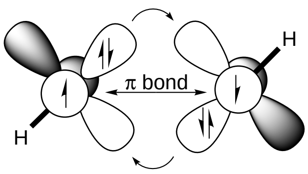
Recent remarkable progress in the theoretical calculations has revealed the bonding properties of heavier group 14 element analogs of acetylenes.[19–21] The understanding of triply bonded systems of heavier group 14 elements can be rationalized as that conceptually similar to the case of doubly bonded systems.[15]

It is most simple to view $HSi{\equiv}SiH$ as being composed of two SiH units. Similar to the case of a $H_2Si{=}SiH_2$ system, two interaction modes between SiH units are conceivable for $HSi{\equiv}SiH$ as shown in Figure 4.[22] The SiH unit has a doublet ground state more stable by 42.6 kcal mol^{-1} than the quartet state, since the quartet state unfavorably requires sp^3 hybridized orbitals in the Si atom.[22] That is, the more stable doublet states of the SiH unit originates from the strong tendency of heavier atoms to keep the valence electronic configuration of $ns^2np^1np^1$. This feature contrasts with the case of a CH unit, where the quartet state is less stable only by 17.9 kcal mol^{-1} than the doublet states.[23]

It should be noted that the trans-bent configuration of $HSi{\equiv}SiH$, in which two SiH units come up to each other in a way to form two donor-acceptor bonds together with a π bond using the singly occupied p orbital, is more stable than the linear configuration. In addition, the trans-bent disilyne ($HSi{\equiv}SiH$) was found by theoretical calculations to isomerize easily to a more stable 1,2-H-shifted isomer ($:Si{=}SiH_2$) (Figure 5), while the 1,2-H-shifted isomer of acetylene



(a) Linear structure of $HSi{\equiv}SiH$



(b) Trans-bent structure of $HSi{\equiv}SiH$

Figure 4 Interaction of doublet HSi

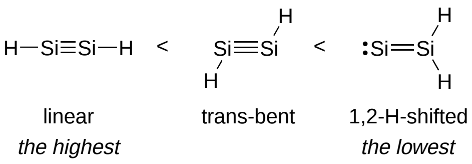


Figure 5 Relative energy of isomers of $HSi{\equiv}SiH$

(:C=CH_2) is very unstable and not a minima in calculations.[22] For the purpose of synthesis and isolation of these heavier triple-bond compounds, theoretical calculations suggest that bulky substituents should be necessary to prevent the 1,2-substituent-shift of the triply bonded heavier group 14 atoms.[24]

2.4 Concluding Remarks

Theoretical approach to multiple bonds between heavier group 14 elements revealed essential properties of their chemical bondings. Summarizing the theoretical findings leads to the following conclusion: The classical multiple bond indicators, that is, the shorter bond lengths and higher bonding energies, have almost no meaning for the multiple bonds between heavier atoms and they are valid for only an exceptional element, carbon. The bonding characters of the heavier multiple bonds described above are reasonably interpreted in terms of unfavorable s-p hybridization between the heavier atoms. The understanding of the feature of heavier atoms suggested that the electropositive and bulky substituents might be required in order to stabilize and isolate the heavier multiple bonds.[22,24,25] The advantage of electropositive substituents over electronegative ones is based on the fact that the increased negative charges on the low-valent heavier atoms decrease the size difference between s and p orbitals and make the s-p hybridization favorable. A merit of introducing bulky substituents is the kinetic stabilization of such highly reactive, unsaturated compounds. In addition, bulky substituents should prevent the 1,2-substituent-shift of $R_2M{=}MR_2$ and RM≡MR, leading to a more stable isomer, R_3M–(R)M: and $R_2M{=}M$:, respectively. Indeed, the concept of kinetic stabilization using bulky substituents led to the significant progress in the chemistry of unsaturated compounds with heavier main group elements.

3 DOUBLE-BOND COMPOUNDS BETWEEN GROUP 14 ELEMENTS

Problems for the synthesis of unsaturated compounds of group 14 elements due to their inherent instability and high reactivity have made many chemists to believe the ‘classical double-bond rule’[1] described above. The first stable disilene, $Mes_2Si{=}SiMes_2$, which was prepared by West and coworkers in 1981,[6] opened the modern chemistry of doubly bonded systems of heavier group 14 elements, and it has been recognized that the concept of kinetic stabilization should certainly be of great use for the construction of these reactive, unprecedented chemical bondings without strong electronic perturbation. Since 1981, a great deal of M=M (M = Si, Ge, Sn, Pb) double-bond compounds have been synthesized by taking advantage of kinetic stabilization. Since several excellent reviews have been published covering a variety of aspects for these unsaturated compounds of heavier group 14 elements so far,[2,7,8,26–29] this review is intended to describe the synthesis and properties of kinetically stabilized double-bond compounds of heavier group 14 elements in this section.

3.1 Synthesis

3.1.1 Synthesis of Stable Disilenes

Previous studies on silicon chemistry show that the photolysis of poly- or oligosilanes or the reductive metalation of dihalosilanes are useful methods to generate oligosilanes, which might be formed by oligomerization of the transient silylenes (R_2Si:) or disilenes. However, the situation is drastically changed by the introduction of bulky substituents to the central silicon atom. As the size of substituents increases, the length of the silicon chain of the produced oligosilanes decreases. Based on this principle, West and coworkers have succeeded in the synthesis of $Mes_2Si{=}SiMes_2$, the first stable disilene, by the photolysis of linear trisilanes.[6]

Many stable disilenes have been prepared by the photolysis of linear trisilanes as well as the initiative work of West *et al.* (Scheme 1).[30,31] When trisilanes bearing two different substituents on the central silicon atom were photo-irradiated, a mixture of *E*- and *Z*-isomers of disilenes were obtained.[32,33] In addition, photolysis

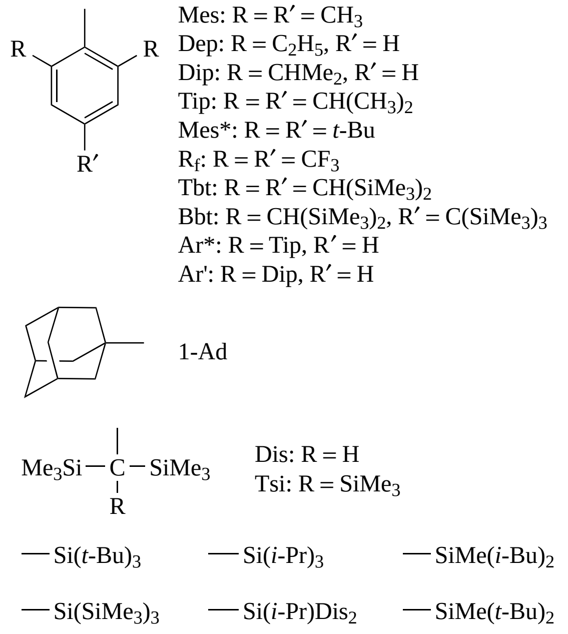
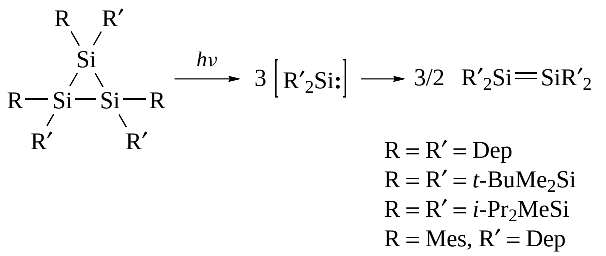


Scheme 4



Scheme 5

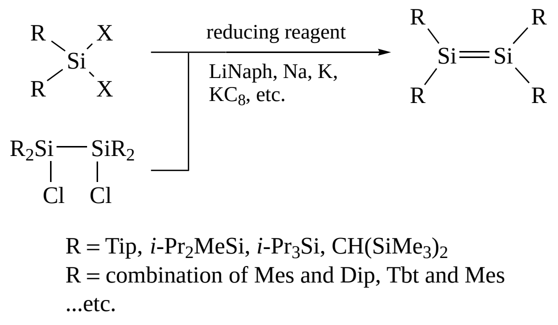
of a mixture of two types of trisilanes, for example, $R_2Si(SiMe_3)_2$ and $R'_2Si(SiMe_3)_2$, afforded a mixture of disilenes, which contained unsymmetrically substituted disilene, $R_2Si{=}SiR'_2$,[2,34,35] together with symmetrically substituted disilenes (Schemes 2 and 3). The unsymmetrically substituted disilene was identified spectroscopically but was difficult to isolate under these conditions. The bulky substituents used for the synthesis of these disilenes include a variety of combinations of bulky aryl groups (e.g. mesityl, 2,4,6-triisopropylphenyl, etc.), bulky alkyl groups (*t*-Bu, 1-Ad, etc.), bulky silyl groups $[Si(i\text{-}Pr)_3$, $Si(t\text{-}Bu)Me_2$, etc.], $N(SiMe_3)_2$, and so on (depicted in Scheme 4).

Up-to-date, a variety of disilenes have been reported, owing to the improvement of several synthetic methods. For example, the photolysis of cyclic trisilanes[28,36] (Scheme 5) and the reduction of dihalosilanes[37] or 1,2-dihalodisilanes[38] (Scheme 6) were found to be useful approaches to the corresponding stable silylenes when the precursors are available as stable compounds.

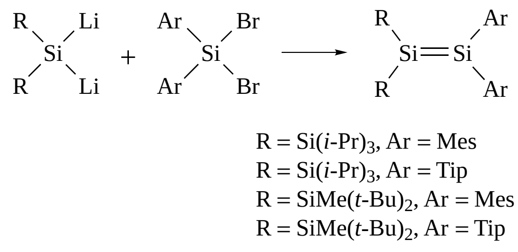
Recently, an innovative synthetic method for disilenes using dilithiosilanes was reported. Dilithiosilanes were prepared by the exhaustive reduction of the corresponding dihalosilanes when it was well kinetically stabilized.[39,40] Since the dilithiosilanes have two nucleophilic Si–Li bonds on one silicon atom, it is thought to be a good building block for doubly bonded compounds of silicon (Scheme 7). Indeed, the reaction of a dilithiosilane with a dihalosilane reportedly resulted in the formation of the corresponding disilene.[41] This method is valid for not only the synthesis of unsymmetrically substituted disilenes but also the synthesis of several types of heteronuclear doubly bonded systems of heavier group 14 elements (vide infra).

3.1.2 *Synthesis of Stable Digermenes*

Digermenes,[42–45] the heavier analogs of disilenes, cannot exist as monomers under normal conditions owing to



Scheme 6



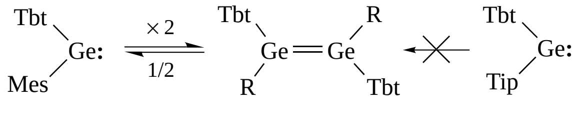
Scheme 7

their high reactivity as well as disilenes. Of course the introduction of bulky substituents into digermenes is effective for the stabilization of digermenes. It is certain that a digermene having small substituents undergoes immediate oligomerization or polymerization, whereas the introduction of too large substituents leads to the cleavage of a digermene giving two germylenes. In that case, the germylenes (σ^2, λ^2-species of germanium) are not only kinetically well-stabilized but also inherently stable because the germanium atom prefers an ns^2np^2 valence electronic configuration as silicon atom does (see Section 2). Therefore, only digermenes bearing moderately large substituents such as 2,6-diethylphenyl (Dep),[46] 2,6-diisopropylphenyl (Dip),[47] or bis(trimethylsilyl)methyl (Dis)[48–50] can exist as stable compounds with Ge=Ge double bonds. However, it should be noted that some digermenes feature their double-bond character only in the solid state, while they exist as equilibrium mixtures with the corresponding germylenes in solution. Delicate selection of the size of substituents on germanium atoms is very important for the synthesis of Ge=Ge double-bond compounds. For a typical example, a germylene having Mes and Tbt groups exists as an equilibrium mixture of germylenes and a digermene,[51] whereas that having Tip and Tbt groups completely behaves as a monomeric germylene in solution (Scheme 8).[52]

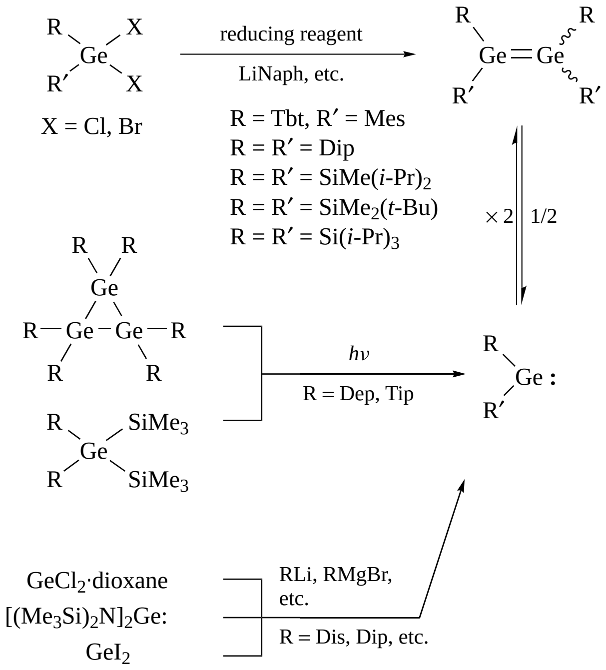
Most of the synthetic methods for disilenes are found to be applicable to digermenes (Scheme 9). For examples, the photolysis of cyclotrigermenes or bis(silyl)germanes bearing bulky substituents affords the corresponding digermenes. The reductive coupling reaction of dihalodigermenes is also an effective synthetic method for digermenes.

In the case of digermenes, there is another synthetic route, that is, the generation of digermenes from divalent germanium compounds. Contrary to the case of silicon analogs, stable divalent germanium species ($GeCl_2$·dioxane, $[(Me_3Si)_2N]_2Ge$:, GeI_2, etc.), which are potentially good precursors of digermenes, are available. Many digermenes are synthesized by the substitution reactions of such divalent species of germanium with a Grignard reagent or an organolithium reagent.

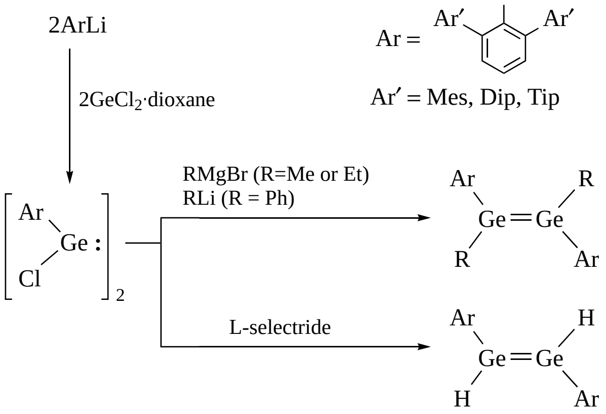
Recently, a new class of stable chlorogermylenes (ArGeCl) kinetically stabilized by a bulky *m*-terphenyl group such as 2,6-$Tip_2C_6H_3$, 2,6-$Mes_2C_6H_3$, and 2,6-$Dip_2C_6H_3$ were reported by Power and coworkers.[53–55] The ArGeCl species can exist as a chlorogermylene form in solution but as a dichlorodigermene form (or a chlorogermylene dimer) in the solid state. After that, digermenes bearing two 2,6-$Tip_2C_6H_3$ groups together with simple organic groups, that is, dimethyl-, diethyl-, diphenyl-substituted digermenes were synthesized by the nucleophilic substitution reactions of the chlorogermylene.[56] When ArGeCl (Ar = 2,6-$Dip_2C_6H_3$) was treated with Li[B(*s*-Bu)$_3$H] (L-selectride), a dihydrodigermene derivative, which is a more fundamental digermene system, was afforded (Scheme 10) as a stable crystalline compound.[57] Thus, chlorogermylene is a good precursor of several types of digermenes.



Scheme 8



Scheme 9



Scheme 10

A dilithiogermane[58–60] is known to be generated by the exhaustive reduction of an overcrowded dihalogermane as well as the case of dilithiosilanes. The dilithiogermane can also be a good precursor for a digermene via the reaction with a dihalogermane.[60]

3.1.3 *Synthesis of Stable Distannenes and Diplumbenes*

In contrast to the extensively studied doubly bonded systems of silicon and germanium, the corresponding chemistry of tin and lead compounds, that is, distannenes and diplumbenes, has not been fully disclosed probably owing to the much higher reactivity and instability of such low-coordinated organotin and organolead compounds. In addition, the situation in the cases of distannenes (Sn=Sn)[26–28,43,61] and diplumbenes (Pb=Pb)[8,43,61] differs from those of disilenes and digermenes. Divalent species of tin and lead, stannylenes, and plumbylenes, are more stable than the corresponding doubly bonded systems, which require s-p orbital hybridizations to some extent (see Section 2). Therefore, distannenes and diplumbenes tend to undergo dissociation into stannylenes and plumbylenes immediately in solution, and even in the solid state their two donor-accepter bonds are much weaker than those of disilenes and digermenes.

The synthesis of distannenes and diplumbenes are generally achieved by dimerization of stannylenes and plumbylenes (Scheme 11). Although most of them exist as divalent species in solution under equilibrium with the corresponding double-bond compounds, the equilibrium occasionally shifted to the corresponding dimer (double-bond compounds) by crystallization. It is essential to choose the proper size of steric protection groups for the synthesis of doubly bonded systems.

Stannylenes are prepared by the treatment of tin(II) chloride or bis(trimethylsilylamino)stannylene with organometallic compounds (organolithium compounds, Grignard reagents, silylpotassium reagents, etc.).[62,63] These methods are applicable in the case of lead as well, that is, using $PbCl_2$ or bis(trimethylsilylamino)plumbylenes instead of tin compounds leads to the formation of the corresponding plumbylenes. Alternatively, hexakis(2,4,6-triisopropylphenyl)tristannirane (cyclotristannane derivative) can afford the corresponding stannylenes by heating or photo-irradiation,[64] though triplumbirane (cyclotriplumbane) derivatives are very unstable to be isolated (the first stable cyclotriplumbane was reported very recently).[65] When a dihalostannane and a dihaloplumbane are stable enough to be treated and purified under ambient conditions, the corresponding stannylene and plumbylene can be generated via the reductive dehalogenation methods as in the case of germylenes. The only distannene, $Tip_2Sn{=}SnTip_2$, that features a double bond even in solution has been reported by Masamune and Sita.[64] On the other hand, no diplumbene stable in solution has been reported so far, while two diplumbenes stable in the solid states have been known.[66,67]

The *E*-form diplumbene, R(Tip)Pb=Pb(Tip)R [R = $Si(SiMe_3)$], was formed by the treatment of Tip_2Pb: with R_2Pb: via an interesting substituent-scrambling (Scheme 12).[67] The similar phenomenon was observed in the case of a distannene.[68] When two different stannylenes, for example, bis[2,4,6-tris(trifluoromethyl)phenyl]stannylenes and bis[tris(trimethylsilyl)silyl]stannylenes, were mixed, the corresponding unsymmetric distannene, a naturally expected product, underwent a ready rearrangement of substituents upon crystallization, leading to the formation of a symmetric, *E*-form distannene. Owing to such ready substituent-scrambling in distannenes and diplumbenes, it should be very difficult to synthesize and isolate an unsymmetrically substituted distannene or diplumbene.

A stable chlorostannylene, which was prepared by Power and coworkers,[53,69,70] is potentially a good precursor of

several distannenes as well as the corresponding germanium congeners (vide supra). However, treatment of ArSnCl ($Ar = 2,6\text{-}Tip_2C_6H_3$) with MeMgBr or PhLi afforded no double-bond compounds but stannylene $ArMe_2Sn$–Sn(II)Ar via the migration of a substituent, in contrast to the case of germanium congeners.[71–73] A similar rearrangement was observed for the lead systems. Thus, it was found that the divalent isomers, a stannylene and a plumbylene, were much more preferred than the corresponding double-bond isomers. In addition, the attempted synthesis of dihydrodistannene, that is, the reaction of chlorostannylene with DIBAL as a reducing reagent, resulted in the formation of a hydrostannylene dimer, in which the hydrogen atoms were found to make bridging bonds between the two tin atoms (Scheme 13).[74] It is interesting that the conformation of the hydrostannylene dimer differs from that of the dihydrodigermene, which features a Ge=Ge double-bond. These experimental results are most likely interpreted in terms of the difference between the inherent features of the elements (see Section 2).[57]

3.1.4 Synthesis of Heteronuclear Doubly Bonded Systems

Heteronuclear combination of double bonds, for example, Si=C, Ge=C, Si=Ge, and so on, are of particular interest, since they should provide a much greater variation in the bonding character than the homonuclear systems depending on the nature of the two low-coordinated elements. Whereas, they are more unstable than the homonuclear systems because they overlap p orbitals much less, owing to the difference of orbital size and their high reactivity toward head-to-tail dimerization promoted by their polar, twitterionic character ($M^{\delta+}=M'^{\delta-}$). In 1981, the preparation of the first stable silene $(Me_3Si)_2Si=C(OSiMe_3)$(1-Ad) (1-Ad = 1-adamantyl) was reported by Brook and coworkers.[5] Since that time, much effort has been devoted to establish the chemistry of stable silenes and other low-coordinated species of group 14 elements, and some synthetic routes have now been established for several metallaalkenes (M=C, M = Si, Ge, Sn).[75–78] Although only one example has been reported for a plumbene (Pb=C), it is not a 'plumbene' in reality because it features a completely zwitterionic Pb^+–C^- bond (Scheme 14).[79]

Many synthetic routes have been found for silenes and germenes as depicted in Scheme 15. The most frequent synthetic methods used to produce the sterically protected, stable metallaalkenes are the photochemical [1,3]-sigmatropic shift of a silyl group to an oxygen atom in acylsilanes [route (ii)] and the dehydrohalogenation reactions of the corresponding halometallanes [route (vii)].

Until quite recently, the compounds with a heteronuclear double bond between heavier group 14 elements, for example, Si=Ge, Ge=Sn, and so on, have been thought of as marginally stable or metastable species, because they are much more unstable than the C=M double-bond compounds. Indeed, tetramesitylsilagermene ($Mes_2Si=GeMes_2$), which was prepared by the photochemical reaction of a Ge–Ge–Si three-membered ring compound, was unstable under the reaction conditions and underwent immediate migration of the Mes group, leading to the formation of mesityl(trimesitylsilyl)germylene[$(Mes_3Si)(Mes)Ge$:].[80] However, a silagermene should be synthesized as a stable compound, if such a tendency to 1,2-migration was successfully suppressed. In 2000, the first stable silagermene, in which the Si=Ge double bond is incorporated in a unique three-membered ring system, was reported by Sekiguchi *et al.* (Scheme 16).[81] The strained silagermene moiety was preserved without the migration of substituents in a novel Si=Ge–C=C cyclic conjugated π system (see Section 7).[82]

One may simply think that a mixture of a pair of divalent species affords heteronuclear double-bond compounds because some germylenes, stannylenes, or plumbylenes are available as stable compounds. However, only homonuclear double-bond compounds were obtained by crystallization of a mixture of a pair of two different divalent species in many cases. Although one successful example, the synthesis of $Tip_2Ge=SnTip_2$ by the treatment of a mixture of $GeCl_2$·dioxane and $SnCl_2$ with TipMgBr, has been reported recently, the germastannene initially formed undergoes slow thermal decomposition, giving the corresponding tristannirane (cyclotristannane) and digermene (Scheme 17).[83] Thus, the divalent species of heavier group 14 elements are liable to associate with that of the same element to form homonuclear double-bond systems.

for the heteronuclear doubly bonded systems. Treatment of a dilithiometallane with a dihalometallane reasonably leads to the formation of the corresponding doubly bonded systems via the formal double nucleophilic substitution (Scheme 18).[78,84] Stable silagermene, silastannene, and germastannene were obtained by this method using a dilithiosilane and a dilithiogermane.[78,84] Interestingly, the germastannene $R_2Ge{=}SnTip_2$ [R=SiMe(*t*-Bu)$_2$] thus formed was found to undergo a ready isomerization into a symmetrically substituted germastannene R(Tip)Ge=Sn(Tip)R upon heating at 50 °C (Scheme 19).[84]

3.2 Molecular Structures

X-Ray crystallographic analyses have revealed unique molecular structures of kinetically stabilized doubly bonded systems between heavier group 14 elements. The first example of the structural characterization of a dimetallene was that of $Dis_2Sn{=}SnDis_2$ reported in 1976.[85] It has a trans-bent geometry [out-of-plane angle (depicted in Figure 6) $\theta = 41°$], which is now one of the characteristic features of dimetallenes (Section 2), and a slightly shortened Sn=Sn bond length [2.768(1) Å] as compared with the typical Sn–Sn single bond (Figure 7). As described in the previous section, it was found to dissociate into the corresponding stannylenes (Dis_2Sn:) in hydrocarbon solution. These features demonstrated the weak bonding of donor-acceptor interaction (see Section 2) in an Sn=Sn double bond. The next breakthrough was shown by the first stable $Mes_2Si{=}SiMes_2$ in 1981.[6] The X-ray crystallographic analysis (Figure 8) showed that the Si=Si double bond is ca. 0.2 Å shorter than a single bond and the out-of-plane angle (θ) is 0–18°, which is much smaller than those of the Sn=Sn double-bond compounds. In addition, it showed no tendency of dissociation into the corresponding silylenes in solution. When extremely bulky substituents are introduced into disilenes [Tbt(Mes)Si=Si(Mes)Tbt, E, Z-isomers] (Figure 9), they showed very long Si=Si double-bond lengths over 2.20 Å[37,86] and undergo ready dissociation (ΔH = ca.26 kcal^{-1} mol) into monomers in solution under very mild conditions (ca. 60 °C in benzene).[86,87]

Several dimetallenes have been structurally characterized so far,[8,28,29,44,45,88] and selected structural parameters of them are summarized in Table 2. Although the lengths of M=M

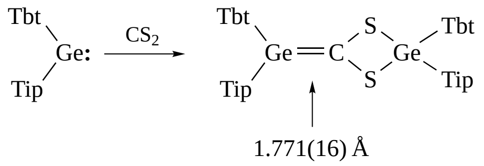
^{a}They should not be referred to as double-bond compounds because their M=M bond lengths in the solid state are too long.

(M=Si, Ge, Sn, Pb) double bonds are variable, depending on their substituents to some extents, most of them are apparently shorter than the corresponding M–M single bonds in the cases of M = Si and Ge. The Si=Si and Ge=Ge double bonds show bond shortening in the range of circa. 7–9%, while the Sn=Sn double bonds show only circa. 3% bond shortening and the Pb=Pb double-bond lengths are almost the same as or slightly longer than the Pb–Pb single-bond lengths. The tendency of bond shortening reasonably explains the feature of π-bond strength.[87] The Si=Si π-bond energy was estimated to be ca. 25.4–30.3 kcal mol^{-1},[28,87] which is almost half of the C=C π-bond energy and is consistent with the theoretical data. The Ge=Ge π bonds may be similar in strength to those on their silicon analogs, though a variable-temperature electronic spectrum of the extremely hindered species [Tbt(Mes)Ge=Ge(Mes)Tbt] shows that it exists in a monomer-dimer equilibrium in hexane with ΔH = 14.7 kcal mol^{-1} for dissociation[51] (ΔH = ca. 26 kcal mol^{-1} for the corresponding silicon derivative as described above[87]). Based on the theoretical calculations, a sharp decrease in the π-bond energy is predicted for dimetallenes upon descending the group 14 elements from Ge to Sn. The Sn=Sn π-bond strength is estimated to be only 11 kcal mol^{-1} (Ge=Ge π-bond strength = 26 kcal mol^{-1}), whereas the strength of an Sn–Sn σ-bond (35 kcal mol^{-1}) is slightly less than that of a Ge–Ge σ-bond (39 kcal mol^{-1}).[44] Pb=Pb interaction in a Pb=Pb double-bond compound is very weak, and the Pb=Pb bond energy was predicted as circa. 23 kcal mol^{-1}, being much less than those of the corresponding tin analog (35 kcal mol^{-1}). Thus, it is found that the Pb–Pb single bond is stronger (33 kcal mol^{-1} in Me_3Pb–$PbMe_3$)[89] than the Pb=Pb double bond. This surprising result is consistent with the observation that the Pb=Pb double bonds (see Table 2) are longer than the Pb–Pb single bonds (ca. 2.9 Å).

The trans-bent structures are characteristic of double-bond systems between heavier group 14 elements. The out-of-plane angles (θ, shown in Figure 6) of disilenes (Si=Si) are ca. 0–18° and much less than those of the heavier analogs (Ge=Ge: ca. 0–40°, Sn=Sn: ca. 20–42°, Pb=Pb: ca. 35–70°), while ethylene has a completely planar structure. Since the values of θ in dimetallenes are variable depending on their substituents, it is difficult to compare them systematically from the viewpoint of the difference of elements. However, it may be roughly concluded that the out-of-plane angles of dimetallenes increase as the element raw descends from Si to Pb. That is, it was experimentally established that distannenes and diplumbenes clearly feature ‘donor-acceptor dimer of divalent species’ as predicted by theoretical calculations (see Section 2). In addition, the structural features in dimetallenes revealed the resemblance between Si=Si and Ge=Ge systems and that between Sn=Sn and Pb=Pb doubly bonded systems, and the great difference between Ge and Sn systems.

Some of the heteronuclear systems containing a double bond between group 14 elements have been structurally characterized so far.[27,78] The first silene, $(Me_3Si)_2Si{=}C(OSiMe_3)$(1-Ad), showed a planar geometry at silicon and possesses a shorter Si=C bond (1.764 Å) than the typical Si–C single bond.[5] Not only the first stable silene, but most of other examples also feature Si=C double-bond character like disilenes, that is, shorter Si=C bond lengths, almost planar geometries at a silicon atom, and smaller bonding energies (ca. 35 kcal mol^{-1}) than those of C=C π bonds. The first stable germene, $Mes_2Ge{=}Flu$ (Flu = fluorenyl),[90] reported by Escudié and coworkers, has a Ge=C distance of 1.803(4) Å and almost planar geometry around the Ge=C bond. An extremely hindered germene shown in Scheme 20 possesses the shortest Ge=C bond length of 1.771(16) Å among all structurally characterized germenes.[91] Although the other germenes structurally characterized so far may have a formal Ge=C double bond, the perturbation caused by the heteroatom-substituents made most of them exhibit the properties of an ylide (Ge^-–C^+) or a germylene-carbene adduct ($>Ge\!:\leftarrow\!:C<$) species rather than the genuine Ge=C character.

Two types of boron-substituted stannenes[92,93] have been reported to show ca. 6% shortening in their Sn=C bonds



Scheme 20

(2.025 and 2.032 Å) compared with a typical Sn–C single bond. As for a stannene (Sn=C) bearing only hydrocarbon substituents around its central Sn=C double bond, one example (Tip_2Sn=Flu, Flu = fluorenyl) has been reported[94] though being structurally not characterized. As described in Section 3.1, the isolated plumbene (Pb=C) is not a genuine plumbene because it has a very long Pb–C bond length of 2.540(5) Å, indicating its completely zwitterionic character of Pb^{+}–C^{-} bond.[79]

Molecular structures of heteronuclear dimetallenes, for example, Si=Ge, Si=Sn, Ge=Sn, and so on, have attracted the attention of many chemists.[78] Although several synthetic methodologies have been developed so far, only two examples have been reported with full structural characterization. One is a cyclic silagermene, 1,5-disila-2-germacyclopentadiene derivative,[81,82] in which the Si=Ge double bond is involved as a part of a cyclic conjugated system. The effect of conjugation should be negligible, since the Si=Ge bond length [2.250(1) Å] is in excellent agreement with the theoretically calculated value of the Si=Ge bond length (2.24 Å) in H_2Si=GeH_2. The other example is a silastannene (Si=Sn) derivative [Me(*t*-Bu)$_2$Si]$_2$Si=Sn(Tip)$_2$ (Figure 10).[78] The Si=Sn double-bond length of the silastannene was determined as 2.4188(14) Å, which is almost a middle value between the typical lengths of Si=Si (2.138–2.289 Å) and Sn=Sn (2.590–3.087 Å) double bonds. In addition, it should be noted that the sp^2 Sn atom of [Me(*t*-Bu)$_2$Si]$_2$Si=Sn(Tip)$_2$ is nearly planar, whereas the sp^2 Si atom is significantly pyramidalized. Taking the structural features into consideration, the silastannene [Me(*t*-Bu)$_2$Si]$_2$Si=Sn(Tip)$_2$ could be recognized as a representative of a new structural feature involving an unsymmetrical donor-acceptor interaction, resulting in the pyramidalization of the negatively charged Si atom and planarization of the positively polarized Sn atom (Figure 11).

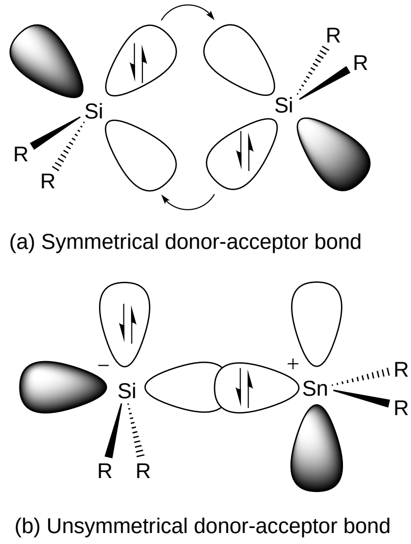

Figure 11 Interaction of R_2Si: and R_2Sn

3.3 Spectroscopic Properties

UV–vis Spectra. Disilenes and digermenes showed colors of pale yellow to orange-red in solution and in the solid state. Their color arises from the M=M (M = Si, Ge) double-bond chromophore, which appears as an absorption maxima at wavelengths longer than 300 nm.[7,45,95] These absorption maxima observed in their electronic spectra can reasonably be assigned to those of the symmetry allowed $\pi \rightarrow \pi^*$ electron transitions. In general, tetraalkyldisilenes have absorption maxima at around 400 nm, whereas those for tetraaryldisilenes are red-shifted by 20–30 nm probably owing to a weak conjugation between the aryl groups with the Si=Si π bond. The absorptions of digermenes are nearly the same or slightly blue-shifted as compared to those of disilenes. Contrary to the case of disilenes, digermenes are occasionally demonstrated to undergo thermal dissociation into the corresponding germylenes. While digermenes are reported to show their $\pi \rightarrow \pi^*$ transitions in the range of circa. 400–440 nm, weak absorptions corresponding to the n $\rightarrow$ p electron transitions of germylenes are observed at characteristically longer wave lengths (ca. 460–580 nm). The experimental observation of an equilibrium between a digermene and germylenes has been accomplished in the case of an extremely hindered digermene, *E*-Tbt(Mes)Ge=Ge(Mes)Tbt.[51] It is difficult for

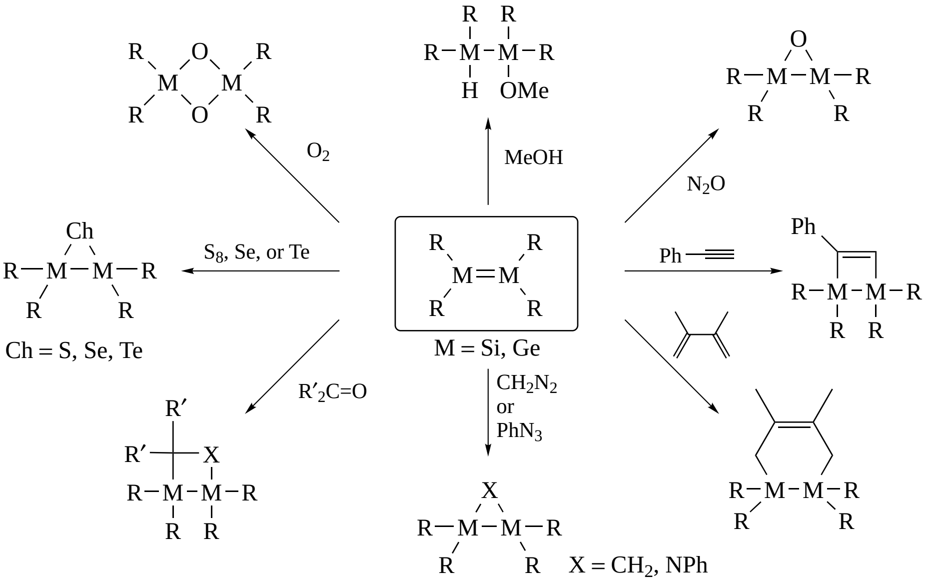
distannenes and diplumbenes to maintain their double bond in solution. Distannene $Dis_2Sn{=}SnDis_2$ shows two characteristic absorption maxima at 332 and 495 nm, of which the extinction coefficients depend on the thermal conditions.[62] The former absorption presumably corresponds to the $\pi \rightarrow \pi^*$ transition of the distannene, and the latter to $n \rightarrow p$ transition of stannylene Dis_2Sn:. $Tip_2Sn{=}SnTip_2$,[64] which is an only example showing a double-bond character even in solution, reportedly showed a characteristic absorption maximum at 495 nm. All isolated diplumbenes (in the solid state) undergo immediate dissociation into plumbylenes in solution. For example, electronic spectra of $Tip_2Pb{=}PbTip_2$ showed three bands of $\lambda_{max} = 321$, 385, and 541 nm in hexane solution, which indicate the existence of an equilibrium between $Tip_2Pb{=}PbTip_2$ and Tip_2Pb: (the equilibrium might be largely shifted toward plumbylenes).[66] Thus, the intrinsic properties of Pb=Pb systems in solutions have not been fully disclosed yet.

NMR Spectra. In the Nuclear magnetic resonance (NMR) spectra of disilenes, the ^{29}Si resonances of the doubly bonded silicon atoms are of particular interest.[2,7] The fact that disilenes exhibit relatively low-field ^{29}Si chemical shifts (δ49–155) characteristic of low-coordinated silicon compounds is in good analogy to the behavior of doubly bonded carbon atom resonances in ^{13}C NMR. The large anisotropy of the ^{29}Si chemical shielding is quite similar to that found for the C=C double bonds. The unusually low-fielded ^{29}Si chemical shifts observed for tetrakis(trialkylsilyl)disilenes, for example, $[(i\text{-Pr})_3Si]_2Si{=}Si[(i\text{-Pr})_3Si]_2$ (δ_{Si} + 154.5) and $[(t\text{-Bu})Me_2Si]_2Si{=}Si[(t\text{-Bu})Me_2Si]_2$ (δ_{Si} + 142.1), are interesting,[29] while those for carbon-substituted disilenes are generally observed at ca. δ_{Si}55–65. The unusual low-field chemical shifts for the ^{29}Si atom of silyl-substituted disilenes should be compared with the corresponding ^{13}C resonances for silyl-substituted sp^2-carbon atoms, for example, $(Me_3Si)_2C{=}C(SiMe_3)_2$ (δ_C195.3), which are much lower than that of the parent ethylene (δ_C122.8). Additionally, the ^{29}Si NMR signals for $[(t\text{-Bu})Me_2Si]_2Si{=}SiMes_2$, which is an unsymmetrically substituted disilene having two silyl groups on one sp^2-silicon atom and two aryl groups on the other, are observed at 8.2, 24.1, and 148.6 ppm.[41] The signal at δ24.1 is assigned to that for the $(t\text{-Bu})Me_2Si$ group, and the other two signals at δ8.2 and 148.6 correspond to those for the two sp^2 silicon atoms. Contrary to expectations, NMR studies for the disilene using 2D NMR techniques revealed the assignment of the up-fielded signal at δ 8.2 to that of the silyl-substituted sp^2-silicon atom and the low-fielded signal at δ148.6 to that of the aryl-substituted one. Although similar assignment was established in the case of $[(i\text{-Pr})_3Si]_2Si_A{=}Si_BMes_2$ [−0.8 (Si_A) and 152.3 (Si_B) ppm], the reason for such unusual shifts of the sp^2 Si atoms is not clear at present.

The data of ^{29}Si and ^{13}C chemical shifts for silenes (Si=C) are available for limited examples of stable silenes.[96] $Mes_2Si{=}CHCH_2(t\text{-Bu})$ shows characteristic signals at relatively low fields in the ^{29}Si and ^{13}C NMR spectrum (δ_{Si}77.6 and δ_C110.4), indicating a little contribution of $Si^+{-}C^-$ resonance structure. On the other hand, ^{29}Si and ^{13}C NMR signals of siloxysilenes $[(Me_3Si)_2Si{=}C(OSiMe_3)R]$ are usually found at characteristically low field in the range of 40–54 ppm (for ^{29}Si NMR) and 207–214 ppm (for ^{13}C NMR). These chemical shifts suggested the decreased $Si^+{-}C^-$ polarization due to the contribution of $Si^-{-}C{=}O^+$ resonance structure.

Germenes have also been characterized by ^{13}C NMR, which shows chemical shifts between ca. 80 and 125 ppm for the sp^2 carbon doubly bonded to the germanium atom, indicating features similar to those of silenes.[95] However, it is not possible to characterize sp^2 germanium atoms by multinuclear NMR spectroscopy such as ^{73}Ge NMR, which is useful only for symmetrically substituted tetracoordinated germanium atoms. On the other hand, the structures of tin-containing double-bond compounds can be easily studied by the use of multinuclear NMR spectroscopy, since tin has two NMR active isotopes: ^{117}Sn and ^{119}Sn. The chemical shifts of sp^2-Sn atoms usually appeared in the low field region around 400 ppm or lower in ^{119}Sn NMR. However, the solvated stannene (Tip_2Sn=Fluorenyl)[94] showed a signal assignable to that of the sp^2-Sn atom at higher field (δ288) owing to the complexation of a solvent molecule toward the tin center. The ^{119}Sn NMR of $Tip_2Sn{=}SnTip_2$[64] showed a signal for its sp^2-Sn atom at low field (δ427) with $^{119}Sn{-}^{117}Sn$ coupling satellites of 2930 Hz, indicating that the Sn=Sn double bond remains even in solution. Although $Dis_2Sn{=}SnDis_2$ exists as the corresponding stannylene (Dis_2Sn:) in solution showing a very low-fielded signal at the chemical shift of 2325 ppm in ^{119}Sn NMR spectrum, the room temperature CPMAS spectrum of $Dis_2Sn{=}SnDis_2$ in the solid state gave an isotropic shift of 692 ppm, indicating that it undoubtedly preserves the Sn=Sn double bond in the solid state.[97]

Raman/IR Spectra. Vibrational spectroscopy should provide useful information on the nature of doubly bonded systems, but only a few reports using IR or resonance Raman spectroscopy are available for the vibrational spectra of the doubly bonded systems of heavier group 14 elements. The Raman lines observed at 539 cm^{-1} for $Mes_2Si{=}SiMes_2$ and 525 cm^{-1} for $Mes(t\text{-Bu})Si{=}Si(t\text{-Bu})Mes$ were assigned to the Si=Si vibrations.[88] These frequencies are about 30% higher than those for the Si–Si single-bond stretching vibrations. Although no vibrational data for stable digermenes have been reported so far, a transient digermene ($Me_2Ge{=}GeMe_2$) is reported to show the Ge=Ge stretching vibrations at 404 cm^{-1} in the Raman spectrum, the value of which is much higher than those of the Ge–Ge single bond and lower than those of the Si=Si double bond.[98] It was difficult to assign the Si=C vibrations in their IR spectra of stable silenes owing to a number of bands observed in the region of 1300–930 cm^{-1},[96] while Mes_2Ge=Flu (Flu = Fluorenyl) has



Scheme 21

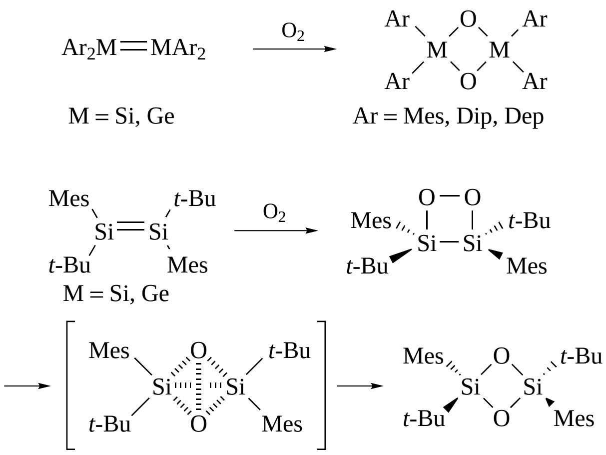
a dominant vibration at 988 cm^{-1}, which can be assigned to the Ge=C double bond.[45]

3.4 Reactivities

A variety of fundamental reactions have been investigated for the M=C and M=M double-bond species of heavier group 14 elements. In spite of the steric protection by bulky substituents, stable unsaturated compounds of heavier group 14 elements described here are often the subject of many reactions such as oxidation reactions, addition reactions, and so on.

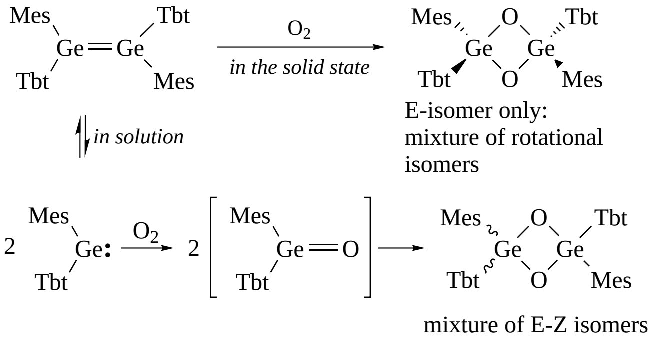
Stable disilenes and digermenes react with various reagents as shown in Scheme 21.[7,43,45,95,100] For example, the addition reaction of MeOH affords the corresponding methoxydimetallanes [$R_2M(OMe)$–$M(H)R_2$]. In the reactions with an appropriate chalcogen source, chalcogenadimetallиranes, which are [2 + 1]cycloadducts of the dimetallenes with chalcogen atoms, are obtained. Reactions with carbonyl compounds give the corresponding [2 + 2] cycloadducts. Reactions with diazomethane and phenyl azide afford the three-membered ring compounds provably via the initial [2 + 3] addition reactions followed by the extrusion of a nitrogen molecule. Thus, dimetallenes are useful building blocks for the synthesis of small-ring compounds containing an M–M bond.

In contrast to most alkenes, which do not react with triplet oxygen ($^3O_2$) under ambient conditions, $Mes_2Si{=}SiMes_2$ can be oxidized by atmospheric oxygen giving the corresponding 1,3,2,4-dioxadisiletane derivative.[101] Similar reactivity is reported for digermenes, $Dip_2Ge{=}GeDip_2$ and $Dep_2Ge{=}GeDep_2$, which eventually give 1,3,2,4-dioxadigermetane derivatives in the reactions with oxygen.[102] The mechanistic studies for the oxidation reaction of (*E*)-Mes(*t*-Bu)Si=Si(*t*-Bu)Mes[103] in solution have revealed that



Scheme 22

the corresponding [2 + 2] cycloadduct, that is, (*E*)-1,2,3,4-dioxadisiletane, was obtained stereospecifically at the initial stage of this reaction previous to the rearrangement giving the final product, (*E*)-1,3,2,4-dioxadisiletane (Scheme 22). Although the oxidation of disilenes is known to take place stereospecifically not only in the solid state but also in solution, there have been very few reports on the stereochemistry in the oxidation of a digermene probably owing to its immediate dissociation into two germylenes in solution. A unique result was reported in the oxidation reaction of (*E*)-Tbt(Mes)Ge=Ge(Mes)Tbt,[104] which undergoes dissociation in solution, giving germylenes as an equilibriated mixture (Scheme 23). The exposure of a finely powdered orange sample of (*E*)-Tbt(Mes)Ge=Ge(Mes)Tbt to atmospheric



Scheme 23

oxygen affords (E)-1,3,2,4-dioxadigermetane exclusively, suggesting that the reaction of the digermene with oxygen in the solid state proceeds stereospecifically. On the other hand, the reaction of (E)-Tbt(Mes)Ge=Ge(Mes)Tbt with oxygen in solution gave (E)- and (Z)-1,3,2,4-dioxadigermetanes in 20 and 38% yields, respectively. The most plausible reaction mechanism is that the dissociation of the digermene into the corresponding germylene [Tbt(Mes)Ge:] in solution followed by the reaction of the germylene with molecular oxygen may give the germanone [Tbt(Mes)Ge=O], which readily undergoes dimerization to afford (E)- and (Z)-1,3,2,4-dioxadigermetanes nonstereospecifically.

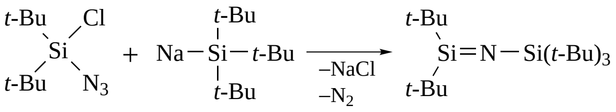
Stable silenes and germenes also react with various reagents as shown in Scheme 24.[43,75,96,99,100] Addition reactions of metallenes with MeOH lead to the formation of $R_2M(OMe)–C(H)R_2$. The reactions of α,β-unsaturated carbonyl compounds afford the corresponding $[4+2]$cycloadducts regiospecifically, reflecting the $M^{\delta+}=C^{\delta-}$ polarity.

4 DOUBLE-BOND COMPOUNDS BETWEEN GROUP 14–GROUP 15 ELEMENTS

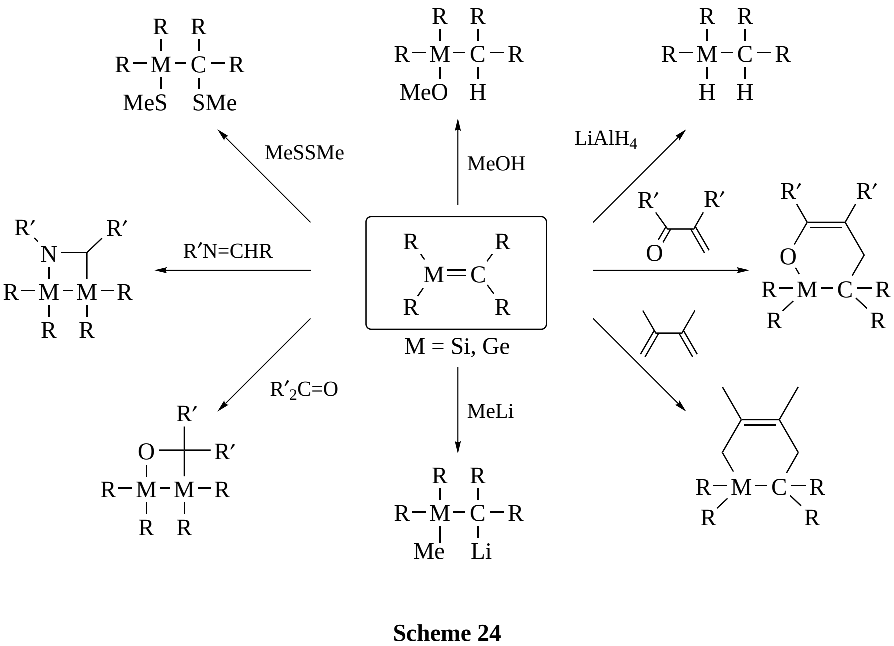
Azasilenes,[105] also called as iminosilanes, are one of the heavier analogs of imines. The difference in the electronegativity between Si (1.8) and N (3.0) gives azasilenes ylidic character ($Si^{\delta+}=N^{\delta-}$), which makes them susceptible to oligomerization and/or dimerization as in the case with silenes (Si=C).

4.1 Synthesis, Properties, and Structures

The first azasilene stable at room temperature was synthesized by taking advantage of kinetic stabilization in 1985.[106] The azasilene, $(t\text{-Bu})_2Si=NSi(t\text{-Bu})_3$, was formed in the reaction of $(t\text{-Bu})_2SiClN_3$ with $(t\text{-Bu})_3SiNa$ in $(n\text{-Bu})_2O$ at $-78\,°C$ (Scheme 25). The azasilene has a slightly yellow color and undergoes a melting decomposition at 85 °C. Its large down-field shift in the ^{29}Si NMR suggested that the azasilene features double-bond character as well as the case of Si=C or Si=Si double bonds. X-ray crystallographic analysis[107] of the azasilene revealed its monomeric structure (Figure 12) and nearly linear skeleton of Si=N–Si bond (177.8°). It was found that the Si=N bond length (1.568 Å) is apparently shorter than the N–Si bond (1.695 Å). The very wide angle



Scheme 25



Scheme 24

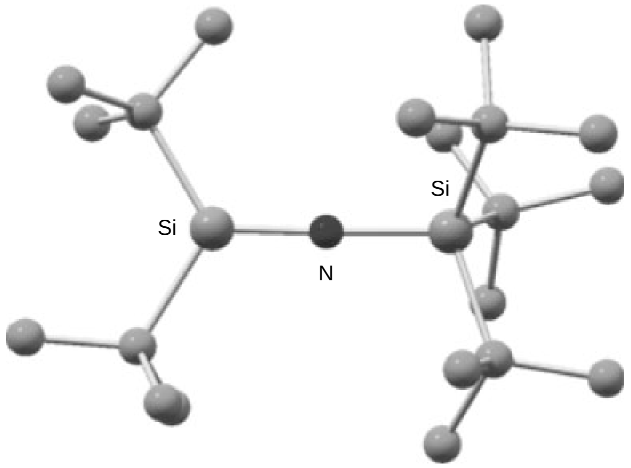


Figure 12 Molecular structure of $(t\text{-Bu})_2$ Si=NSi$(t\text{-Bu})_3$

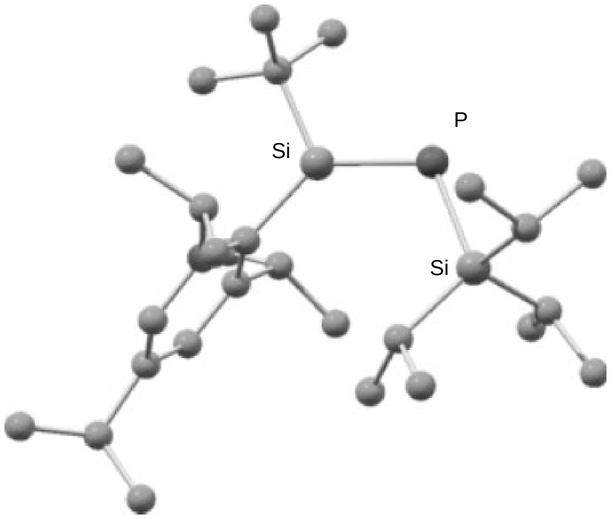

Figure 13 Molecular structure of Tip(t-Bu)Si=PSi(i-Pr)$_3$

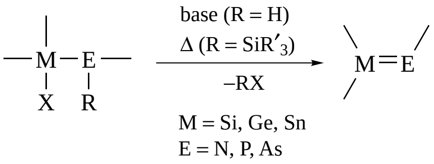
at the nitrogen atom is due to electronic reasons rather than steric effect, since the relatively electropositive silyl substituents ensure a very low barrier to cis/trans isomerization via linear inversion process.[108,109] In the case of $H_2Si{=}NH$ (Si–N–H = 125.2°)[110,111] as a model compound, the cis/trans isomerization barrier is estimated as 5.6 kcal mol^{-1} but the π bond strength, as measured by the rotational barrier, is 37.9 kcal mol^{-1}. Although carbon-substituted azasilenes are predicted by calculations to have smaller angles at the N atom and longer Si–N bond lengths, there have been no experimental data of such compounds obtained so far.

Stable azagermenes[96] and azastannenes[96] are obtained by the reactions of azides with a germylene or a stannylene as a precursor.[45,75,76,100] They feature planar geometries at the Ge and Sn atoms together with bent geometries at their N atoms. The Ge–N distances of the azagermenes lie in the range of 1.681–1.704 Å being in good agreement with the calculated values.[112,113] The observed structural parameters of azastannenes are also consistent with the features predicted by theoretical calculations.[114]

Furthermore, there are some reports on the synthesis of stable phosphasilenes and arsasilenes.[115,116] The structure of Tip(t-Bu)Si=PSi(i-Pr$_3$) showed shorter Si=P bond length (2.062 Å) and Si–P=Si bond angle of 112.79°, which is much smaller than the Si–N=Si bond angle of azasilenes (ca. 170°–178°) (Figure 13).[117] Theoretical calculations for $H_2Si{=}PH$ showed the Si=P bond length of 2.044 Å and the Si–P–H angle of 93°.[118] Other reports on the calculations for Si=P and Si=As doubly bonded species with silyl substituents at the pnictogen atoms predicted their molecular geometries with the Si=E (E = P, As) distances of 2.053 and 1.161 Å and the wide Si=E–Si angles near 100°.[118] Such relatively narrow angles compared with the Si=N–Si bond angles of azasilenes reflect the much larger barrier to linear inversion as a result of the increased s character of the phosphorus or arsenic lone pairs. The Si–E rotational barrier in $H_2Si{=}EH$ (E = P, As) are estimated as 34 kcal mol^{-1} for E = P and 30 kcal mol^{-1} for E = As.



Scheme 26

Thus, several stable compounds featuring double bonds between heavier group 14 and 15 elements are now synthesized and well characterized.[45,75,76,100,115,116] In most cases, the aza-, phospha-, and arsametallanes were found to be synthesized via the dehydrohalogenation reactions of MX–EH precursors (M = Si, Ge, Sn, E = N, P, As, X = halogen) using a base or the thermal decomposition of MX–E(SiR_3) (Scheme 26). Structures of some stable azametallenes and phosphametallanes are summarized in Table 3. Although many stable examples have been reported for azametallenes, those for heavier analogs are very scarce. Indeed, there is no example of stiba- and bismametallenes (Sb=M, Bi=M), probably owing to the instability of precursors such as SiX–SbH derivatives. Dilithiophosphine derivatives ($ArPLi_2$) are known to be applicable to the synthesis of low-coordinated phosphorus compounds, and the stable phosphagermene, $Mes_2Ge{=}PTip$, is reportedly formed by the reaction of Mes_2GeF_2 with $TipPLi_2$ directly.[119] Furthermore, the thermolysis of a linear (fluorostannyl)silylphosphine was reported to give the corresponding phosphastannene, though its structural parameters have not been determined so far.

Table 3 Selected structural parameters for >M=E– (M = Si, Ge, Sn, E = N, P, As)

$R_1R_2M{=}ER_3$	M=E/Å	M–E–R_3/°
(t-Bu)$_2$Si=NSi(t-Bu)$_3$	1.568(3)	177.8(2)

Mes(t-Bu)Ge=PMes*	2.144(3)	110.9(5)

4.2 Reactions

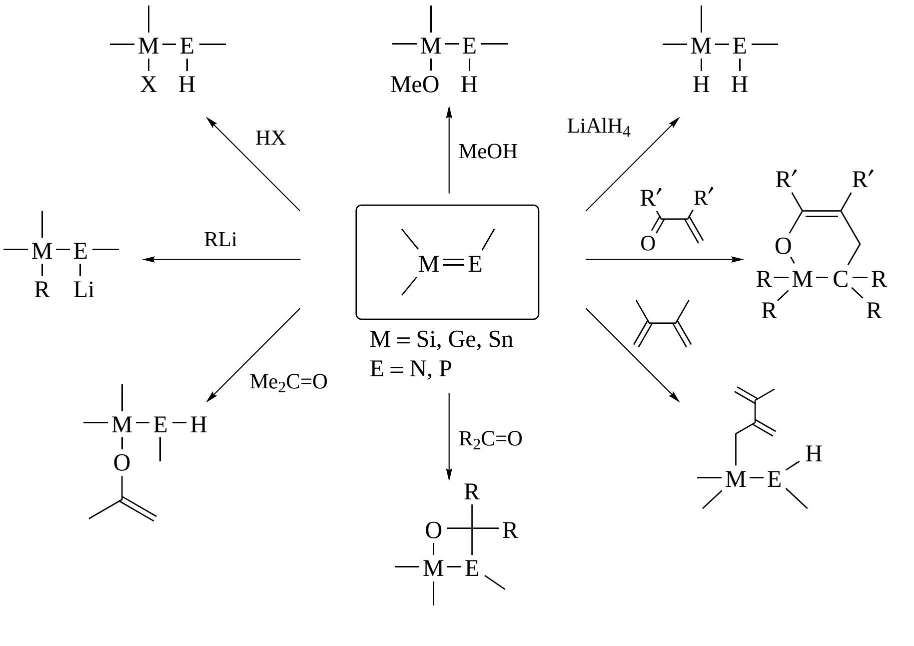
The addition of protic reagents such as an alcohol toward the double bond of unsaturated heavier group 14 elements is one of the most important reactions. The reaction usually occurs cleanly and in a high yield, and is taken as evidence for the existence of a doubly bonded compound.

The addition reactions of H_2O and MeOH (or EtOH) to azametallenes and phosphametallenes are completely regioselective with the formation of >M(OR)–E(H)–(M = Si, Ge, E = N, P) compounds, indicating their ylidic character of $M^{\delta+}{=}E^{\delta-}$. Similarly, the addition of hydrogen halides is also regioselective, giving the corresponding halometallanes.

Unsaturated carbon compounds, such as acetone and 2,3-dimethyl-1,3-butadiene, having hydrogens in the α position prefer to undergo ene reactions with the M=N (M = Si, Ge, Sn) double-bond compounds, while benzaldehyde or benzophenone react with M=N double bonds to give the corresponding [2 + 2] adducts regioselectively with the formation of M–O bonds. In addition, the [4 + 2] cycloaddition reaction of azametallenes and phosphametallenes with α,β-unsaturated aldehydes and ketones have been reported to give the six-membered ring compounds. Other cycloaddition using 1,3-dipoles such as nitrileoxide and azide derivatives were reported. The reactivities of M=E double bond are summarized in Scheme 27.[45,75,76,100,115,116]

5 DOUBLE-BOND COMPOUNDS BETWEEN GROUP 14–GROUP 16 ELEMENTS

Heavier congeners of carbonyl compounds, one of the most important and fundamental functionalities in organic chemistry, have attracted a great deal of attention from the viewpoints of double bonds between a carbon atom and a heavier group 16 elements such as sulfur, selenium, and tellurium. Although no example of a stable telluroaldehyde has been reported yet, most of the structures and properties of C=Ch (Ch = S, Se, Te) double-bond compounds have been systematically elucidated so far.[120–122] In contrast to the chemistry of the C=Ch doubly bonded systems, that of heavier congeners of ketones containing a heavier group 14 element, which are called ‘heavy ketones’, have been much less explored until recently. Probably, this is due to the much greater difficulty in the stabilization of such extremely reactive species. Since the protecting group can be introduced only onto the group 14 elements and the terminal chalcogen



Scheme 27

atoms are unfortified, it is inherently difficult to stabilize the heavy ketones using the conventional steric protecting groups as described in previous sections. Although several examples of compounds having a formal M=Ch double bond, which are thermodynamically stabilized by the coordination of heteroatoms such as nitrogen or oxygen, are known,[123] they are considerably perturbed by the coordination and hence not suitable for a study on the intrinsic nature of the M=Ch double bonds. Tokitoh and Okazaki proved that the use of an effective protecting group such as a Tbt group is crucial for the isolation of heavy ketones without electronic perturbation, because they can be kinetically stabilized by only two substituents on the group 14 elements. The chemistry of kinetically stabilized 'heavy ketones' has been extensively developed by taking advantage of this new, effective steric protecting group.[124,125]

5.1 Synthesis

The extremely high reactivity of heavy ketones, RR′M=Ch (M = Si, Ge, Sn, Pb, Ch = O, S, Se, Te), obviously results from the fact that their M–Ch π-bond energies are much smaller than the corresponding M–Ch σ-bond energies, as one can see from Table 4.[124,125] Therefore, heavy ketones RR′M=Ch are difficult to generate by simple elimination of a leaving group (HX) from a precursor (or intermediate) of RR′M(ChH)(X), which is a commonly used method for the synthesis of ketones. In the case of M=O (M = Si, Ge, Sn, Pb) double bonds, the σ-bond energies are much larger than the corresponding π-bond energies, indicating their extremely high reactivity. Until now, no stable examples of M=O double-bond compounds have been isolated even by the method of thermodynamic or kinetic stabilization except for very few examples marginally stable in very low temperature matrices. Only kinetically stabilized heavy ketones are shown here, though several examples of marginally stable species and thermodynamically stabilized heavy ketones have been reported.

Table 4 Bond energies (kcal mol^{-1}) and lengths (Å) for $H_2M{=}Ch$ species calculated at the B3LYP/TZ(d,p) level. By trial and error for years, several approaches for the synthesis of heavy ketones have been developed (Scheme 28). In particular, dechalcogenation reaction of 1,2,3,4-tetrachalcogenametallolanes ($RR'MCh_4$) using phosphine reagents proved to be most useful for the isolation of heavy ketones in a pure form. Two other methods, the chalcogenation reactions of divalent species of heavier group 14 elements (metallylenes) and the reactions of dilithiometallanes ($RR'MLi_2$) with chalcogen dihalides, were found to be successful in some cases.

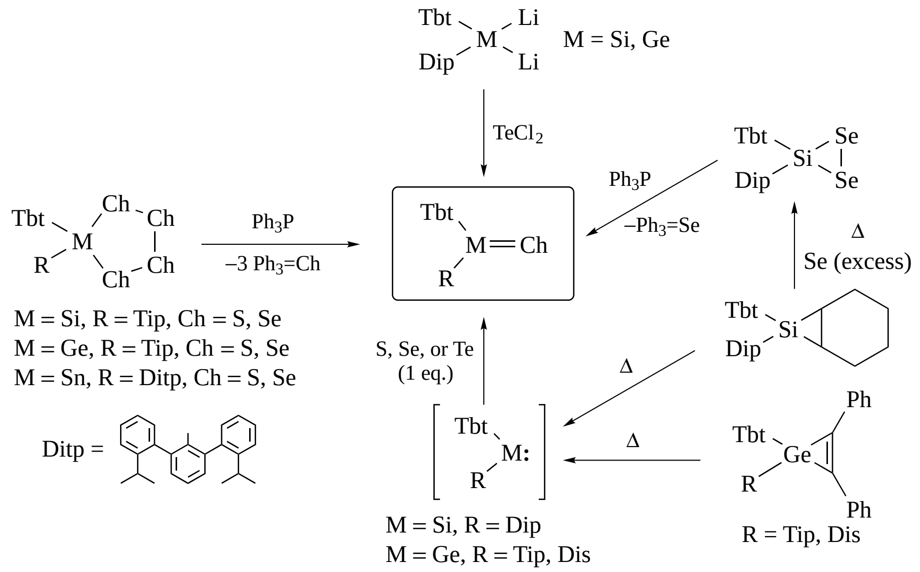
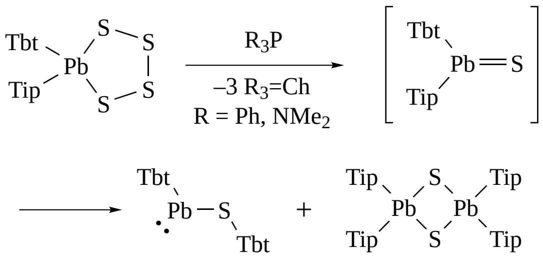
The synthetic strategy for the first stable silanethione, Tbt(Tip)Si=S, is based on a simple desulfurization of the corresponding 1,2,3,4-tetrachalcogenasilolane using a phosphine reagent.[126,127] Thus, a hexane solution of Tbt- and Tip-substituted tetrathiasilolane was refluxed in the presence of 3 molar equivalents of PPh_3 to produce the corresponding silanethione, Tbt(Tip)Si=S, as stable yellow crystals together with $Ph_3P{=}S$, which was easily separated from the reaction mixture by filtration. This dechalcogenation methodology was also successful in the synthesis of the stable germanethione, Tbt(Tip)Ge=S, and the germaneselone, Tbt(Tip)Ge=Se.[128–130] It should be noted that the combination of Tbt and Tip substituents is found to be indispensable for the stabilization of the reactive M=Ch double bond. However, it cannot prevent the dimerization of the Sn=X bond having much higher reactivity than the corresponding Si and Ge analogs. The bond lengths around the Sn atom become longer than those in the case of Si and Ge, and hence the steric protection of the tin center by the substituents become less effective.[131] Thus, desulfurization reactions of Tbt- and Tip-substituted tetrathiastannolane and tetraselenastannolane were reported to give the dimerized products of the intermediary stannanethione and stannaneselone.[131] However, the combination of Tbt with a newly developed bulky m-terphenyl type substituents (Ditp) led to the isolation of stable stannanethione and stannaneselone as red crystals.[124,125,131,132] Although desulfurization of Tbt- and Tip-substituted tetrathiaplumbolane [Tbt(Tip)PbS_4] with Ph_3P or $(Me_2N)_3P$ at −78 °C gave the corresponding plumbanethione [Tbt(Tip)Pb=S] as evidenced by the trapping experiments giving cycloadducts as in the cases of other heavy ketones,[133] the same reaction at 50 °C afforded an unexpected plumbylene and a 1,3,2,4-dithiaplumbetane derivative instead of the dimer (or oligomer) of the corresponding plumbanethione (Scheme 29).[134] The formation of the unexpected products was reasonably interpreted in terms of intermediacy of plumbylenes, Tbt–Pb–STip and Tip–Pb–STbt, which might



Scheme 28



Scheme 29

be formed by the 1,2-aryl migration of the initially produced plumbanethione.[134]

The dechalcogenation reaction of tetrachalcogenametallolanes has proven to be an excellent synthetic approach to heavy ketones, but tetrachalcogenametallolanes are not always available. In such cases, the chalcogenation of divalent species can be an alternative method.

Although the tetrathiasilolane can be synthesized by the reaction of elemental sulfur (S_8) with the transient silylene Tbt(Tip)Si: (or its equivalent) prepared by the reduction of Tbt(Tip)$SiBr_2$ with lithium naphthalenide,[126] a similar reaction using selenium instead of S_8 did not afford the corresponding tetraselenide. However, the reaction of Tbt(Dip)Si:, generated by thermolysis of a silirane derivative, with 1 equivalent of selenium gave a silaneselone, Tbt(Dip)Si=Se, as a red solid.[59,124,125] The reaction of the thermally generated silylene Tbt(Dip)Si: with an excess amount of selenium resulted in the formation of a diselenasilirane derivative, Tbt(Dip)$SiSe_2$, deselenization of which with PPh_3 gave the silaneselone, Tbt(Dip)Si=Se.[59] Since the cyclic polytellurides, the expected precursors for metallanetellones, are generally unstable, the chalcogenation method of metallylenes is thought to be effective to synthesize the corresponding metallanetellones. Indeed, stable silanetellone [Tbt(Dip)Si=Te] and germanetellone [Tbt(R)Ge=Te (R = Tip, Dip)] were successfully synthesized by the reactions of the thermally generated silylene [Tbt(Dip)Si:] and germylene [Tbt(R)Ge:] with elemental tellurium, respectively.[59,135]

In addition to the tellurization of metallylenes, another unique synthetic route has been developed for the M=Te (M = Si, Ge) double bonds. It has been reported that the exhaustive reduction of an overcrowded dibromometallanes [Tbt(Dip)MBr_2] with an excess amount (more than 4 equiv.) of lithium naphthalenide leads to the generation of the corresponding diaryldilithiometallanes [Tbt(Dip)MLi_2] (see Section 3), which was found to be very useful for the synthesis of unprecedented organometallic compounds.[39,58,59] As one of the synthetic applications of the dilithiometallanes [Tbt(Dip)MLi_2], the reactions of Tbt(Dip)MLi_2 with $TeCl_2$ were examined in Tetrahydrofuran (THF) at −78 °C to give the expected metallanetellones [Tbt(Dip)M=Te (M = Si, Ge)].[59] Thus, the synthetic route via dilithiometallanes should be noted as an alternative synthetic approach to heavy ketones. The heavy ketones obtained here are very stable at ambient temperature not only in the solid state but also in solution of hydrocarbon solvents.

5.2 Structural and Spectroscopic Properties

X-ray Crystallographic Analysis. The most important structural feature of a carbonyl compound is its trigonal planar geometry, which results from the sp^2-hybridized carbon. Since it has been revealed experimentally and theoretically that dimetallenes have a trans-bent structure in contrast to

alkenes with planar geometry (see Section 2 and 3), it is quite interesting to investigate the structural features of a series of heavy ketones. The results of X-ray crystallographic analysis of the kinetically stabilized heavy ketones are partially summarized in Table 5,[124,125] and the molecular structure of Tbt(Tip)Ge=Te[135] is shown in Figure 14 as a representative. All heavy ketones [Tbt(R)M=Ch (M = Si, Ge, Sn, Ch = S, Se, Te)] have an almost completely trigonal planar geometry and a distinct double-bond nature, as judged by the summation of bond angles around the M atom (Σ∠M) and the bond shortening (%) compared to the corresponding single bonds (Δ_{obs}). The observed double-bond lengths and Δ_{obs} values are in good agreement with the calculated values for $H_2M{=}Ch$ as listed in Table 4. These findings clearly indicate that heavy ketones have structural features similar to those of ketones, although their double-bond character is somewhat weaker than that of the corresponding carbon homologs judging from their Δ_{obs} (Table 5) as well as Δ (Table 4) values.

NMR Spectra. As in the case of ^{13}C NMR, the low-field chemical shifts are characteristic of the sp^2-hybridized nuclei of the heavy ketones. For example, the ^{29}Si NMR chemical shifts of the sp^2 silicon atoms Tbt(Tip)Si=S,[126,127] Tbt(Dip)Si=Se,[59] and Tbt(Dip)Si=Te[59] are 167, 174, and 171 ppm, respectively. This is the typical difference between kinetically stabilized Si=Ch double-bond compounds and thermodynamically stabilized ones, which showed their ^{29}Si NMR signals around 20–30 ppm, indicating the high sp^3 nature of the silicon centers.[123] The characteristic low-field ^{77}Se and ^{125}Te NMR chemical shifts of Tbt(Dip)Si=Ch (Ch = Se, Te; $\delta_{Se} = 635$ for Ch = Se, $\delta_{Te} = 731$ for Ch = Te) are also indicative of their sp^2 hybridized chalcogen atoms. Similarly, Tbt(Ditp)Sn=S and Tbt(Ditp)Sn=Se have shown their ^{119}Sn NMR signals at 531 and 440 ppm, respectively, while ^{119}Sn NMR of thermodynamically stabilized examples resonate at a much higher field in the range from −300 through −450 ppm.[123] Although such information is not available for Ge=Ch double-bond compounds because of the practical difficulty in observing ^{73}Ge NMR, the low-field resonating ^{77}Se and ^{125}Te NMR chemical shifts of Tbt(R)Ge=Se (941 ppm for R = Tip, 872 ppm for R = Dis) and Tbt(R)Ge=Te (1143 ppm for R = Tip, 1009 ppm for R = Dis) are in keeping with the sp^2 hybridization of these elements.[128–130,135]

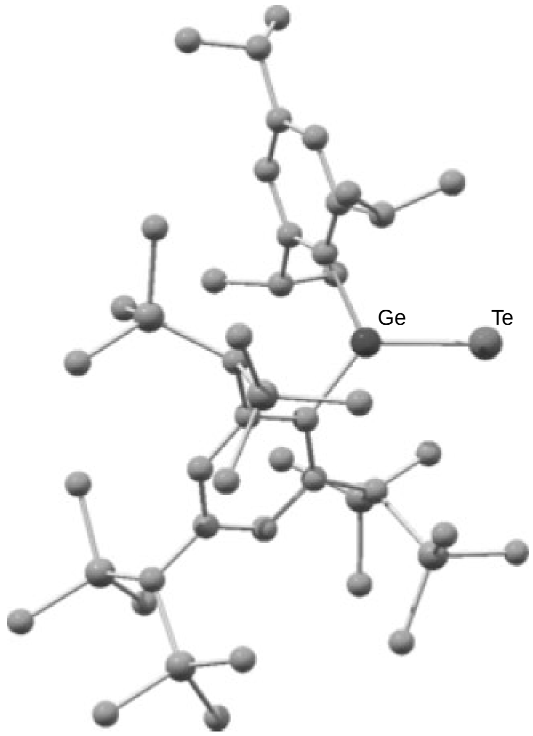


Figure 14 Molecular structure of Tbt(Tip)Ge=Te

UV–vis Spectra. In Table 6 are listed characteristic visible absorptions observed for the heavy ketones kinetically stabilized by a Tbt group. It is known that the absorption maxima attributable to the n-π^* electron transitions of a series of $R_2C{=}Ch$ (Ch = O, S, Se, Te) undergo a systematic red-shift on going down the periodic table. A similar tendency is observed for the Si, Ge, and Sn series of Tbt(R)Si=Ch (Ch = S, Se, Te),[59,126,127] Tbt(R)Ge=Ch (Ch = S, Se, Te),[128–130,135] and Tbt(Ditp)Sn = Ch (Ch = S,

Table 5 Structural parameters of heavy ketones Tbt(R)M=Ch. (*d*: lengths of an M=Ch double bond, Σ∠M: summation of the bond angles around M atom, Δ_{obs}: percent reduction in bond lengths defined as [(single-bond lengths – double-bond length)/single-bond lengths] ×100)

Tbt(R)M=Ch					
R	M	Ch	*d*	Σ∠M	Δ_{obs}
Tip	Si	S	1.948(4)	359.9	9
Tip	Ge	S	2.049(3)	359.4	9

Tip	Ge	Te	2.398(1)	359.5	9
Dis	Ge	Te	2.384(2)	360.0	8
Ditp	Sn	Se	2.375(3)	359.9	9

Table 6 Observed absorption maxima (λ_{max}/nm) in electronic spectra (n-p*) of M=Ch double-bond compounds (M = C, Si, Ge, Sn, Ch = S, Se, Te)

	Tbt(R)M=Ch		
M	Ch=S (R)	Ch=Se(R)	Ch=Te(R)
C	587 (H)	792 (H)	–
Si	396 (Tip)	456 (Dip)	593 (Dip)
Ge	450 (Tip)	519 (Tip)	640 (Tip)
Sn	491 (Ditp)	531 (Ditp)	–

Se).[131,132] One can see a very interesting trend in the absorption maxima of two series, Tbt(R)M=S and Tbt(R)M=Se (M = C, Si, Ge, Sn). In both series, their absorption maxima are greatly blue-shifted on going from C to Si congeners, whereas those of Si, Ge, and Sn congeners are red-shifted with increasing atomic number of the group 14 elements.

Raman Spectra. The stretching vibrations of the M=Ch bonds were measured using Raman spectroscopy: Silanethione Tbt(Tip)Si=S (724 cm^{-1}), germanethiones Tbt(R)Ge=S (521 cm^{-1} for R = Tip, 512 cm^{-1} for R = Dis), and germanetellones Tbt(R)Ge=Te (381 cm^{-1} for R = Tip, 386 cm^{-1} for R = Dis). These values are in good accordance with those calculated for H_2M=Ch compounds [723 (Si=S), 553 (Ge=S), and 387 (Ge=Te) cm^{-1}].[126] It is noteworthy that the observed value of Tbt(Tip)Ge=S (521 cm^{-1}) is very close to that observed for Me_2Ge=S (518 cm^{-1}) by IR spectroscopy in an argon matrix at 17–18 K,[136] indicating the similarity in the bond nature of both germanethiones in spite of the great difference in the size and nature of the substituents.

6 TRIPLE-BOND COMPOUNDS BETWEEN GROUP 14 ELEMENTS

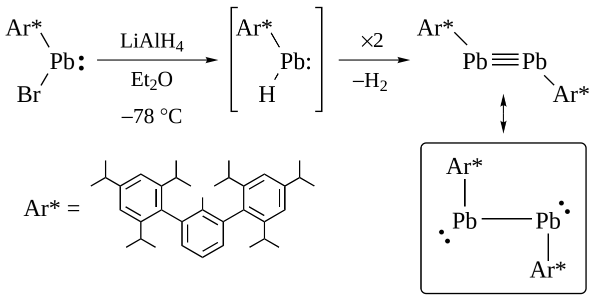
Covalent triple bonds are common unsaturated species in carbon chemistry as well as double bonds, but are rare and unusual for heavier group 14 elements. Since the real existence of heavier doubly bonded systems have been experimentally demonstrated (see Section 2), triply bonded systems of heavier group 14 elements have been major target molecules of research for these several decades.[137] However, no experimental evidence for the isolation of triple-bond compounds of heavier group 14 elements has been achieved until very recently. One of the reasons for their absence was the greater steric requirements for their substituents. Another was the scarcity of suitable precursors that could be smoothly converted to a stable triply bonded compound. Recent theoretical calculations have suggested that it should be possible to stabilize Si≡Si and Si≡C triple bonds by the use of appropriate steric protection groups (see Section 2.3). In this section, recent experimental works on the synthesis of the triply bonded systems between heavier group 14 elements (containing 'formal' triple bonds) are presented.

6.1 Triply Bonded Systems of Germanium, Tin, and Lead

The first stable compound to feature triple bonding to a heavier group 14 elements was the molybdenum–germanium derivative, (η^5-C_5H_5)$(CO)_2$Mo≡Ge–C_6H_3-2,6-Mes_2.[138] After this sensational work, it was experimentally and theoretically demonstrated that a germanium atom can form stable triple bond with group 6 metals.[138–140] Details of such unique triply bonded systems between a transition metal and a germanium atom should be omitted here.

The isolation of transition metal complexes with the triple bonds to an almost linearly coordinated germanium atom and the isolation of R–M–X species (M = Ge, Sn, Pb, X = Cl, Br),[53–56,69,70,141,142] which should be good precursors for triple bonds, suggested that stable compounds of the general formula RM≡MR (M = Si, Ge, Sn, Pb) are synthesizable and isolable target molecules.

The reduction of a halometallylene having bulky *m*-terphenyl ligand, Ar*–M–X (Ar* = C_6H_3-2,6-Tip_2, M = Ge, Sn, Pb, X = Cl, Br), was found to afford the corresponding triply bonded systems, as evidenced by Power and coworkers (Scheme 30).[140] The Pb≡Pb triple-bond compound was reportedly characterized by X-ray crystallographic analysis as the first example of a stable heavier congener of an alkyne.[143] The diplumbyne, Ar*Pb≡PbAr*, was isolated as amber-green crystals in ca. 10% yield by the reduction of Ar*PbBr with $LiAlH_4$. The isolation of the diplumbyne is in contrast to the reduction of Ar*SnCl with $LiAlH_4$ leading



Scheme 30

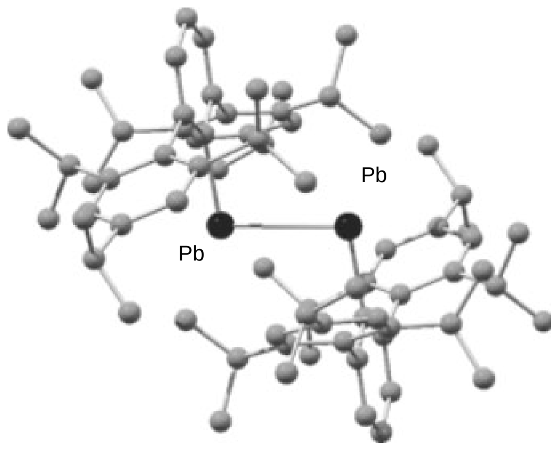


Figure 15 Molecular structure of Ar*Pb–PbAr* (Ar* = 2, 6-Tip_2-C_6H_3)

to the formation of a unusual hydride $[Sn(\mu\text{-H})Ar^*]_2$.[74] The important structural features of Ar*Pb≡PbAr* are the Pb–Pb bond length [3.1881(1) Å], the planar, trans-bent C–Pb–Pb–C core arrangement, and the Pb–Pb–C angle [94.26(4)°] (Figure 15). That is, it was found that the Pb–Pb bond is much longer than those found in diplumbenes, which are usually in the range of 2.85–2.95 Å.[144] The Pb–C bond shows high p-orbital character because the Pb–Pb–C angle is nearly 90°. Thus, it can be concluded that the diplumbyne Ar*Pb≡PbAr* features a 'bis-plumbylene character', Ar*Pb–PbAr*, rather than a triple-bond character.

Power *et al.* have further reported the synthesis and structures of digermyne[145] (Figure 16) and distannyne[146] derivatives, Ar'M≡MAr' (M = Ge, Sn), using a modified *m*-terphenyl ligand of Ar', C_6H_3-2,6-Dip_2. As shown in Scheme 31, treatment of Ar'MCl (M = Ge, Sn) with potassium afforded Ar'M≡MAr' (M = Ge, Sn) in moderate yields. The main structural features of interest are obviously the planar, trans-bent CMMC core geometries, the M–M distances, and the M–M–C angles. It can be seen that the Ge≡Ge [2.2850(6) Å] and Sn≡Sn [2.6675(4) Å] bond lengths are much shorter than the distances expected for the corresponding dimetallanes [2.44 Å (Ge) and 2.81 (Sn)]. The M–M–C bond angles are much wider than the corresponding angles in Ar*Pb–PbAr*. These observed structural parameters suggest the considerable multiple bond character of Ar'M≡MAr' (M = Ge, Sn). The Ge–Ge distance and Ge–Ge–C bond angle may also be compared to the structural features [2.22 Å and 123.0° or 124.0°] calculated for parent *trans*-HGe≡GeH.[147] Similarly, calculations for the *trans*-HSn≡SnH revealed the Sn–Sn distance of 2.65 Å and the Sn–Sn–H bond angle of 122°, which agree more closely with those measured in Ar'Sn≡SnAr'.[147] In addition, calculations on much bulkier models Ar*M≡MAr* and TbtM≡MTbt (M = Ge, Sn) reportedly show good agreement in the structural parameters with experimental data and indicate that the triple-bond forms are much stable than $R_2M{=}M$: form owing to the steric reasons.[24]

Very recently, Tokitoh and coworkers demonstrated that a 2,6-bis[bis(trimethylsilyl)methyl]-4-[tris(trimethylsilyl) methyl]phenyl (Bbt) group, which is a ligand similar to the Tbt group, is well applicable to the synthesis of a stable digermyne, BbtGe≡GeBbt. The second example of an isolable digermyne, BbtGe≡GeBbt, was prepared by the reduction of 1,2-dibromo-1,2-digermene Bbt(Br)Ge=Ge(Br)Bbt in an almost quantitative yield (Scheme 32). Two nonidentical molecules of BbtGe≡GeBbt were observed in the unit cell by the X-ray crystallographic analysis. The Ge–Ge bond lengths in BbtGe≡GeBbt are the shortest [2.2059(8) and 2.2260(7) Å] among the previously reported Ge–Ge bonds, indicating its considerable triple-bond character.

It should be concluded that the M≡M bonds in the Ar'M≡MAr' (M = Ge, Sn) can be considered as a triple bond, which consists of two donor-acceptor bonds plus a π-bond owing to the coupling between the unpaired electrons in the p orbital on each element (see Section 2.3). However, the donor-acceptor bonds are unfavorable in the case of lead. Therefore, the bonding structure of diplumbyne is being interpreted in terms of a structure of Ar*Pb–PbAr* as shown in Figure 17, in which the Pb atoms are formally linked by a single bond with their p orbitals.

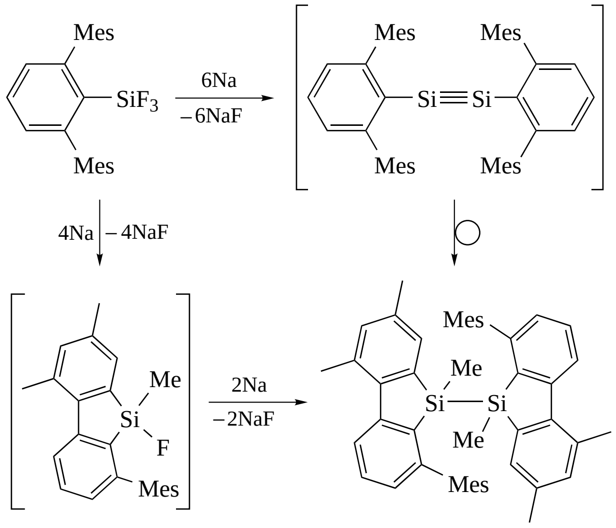
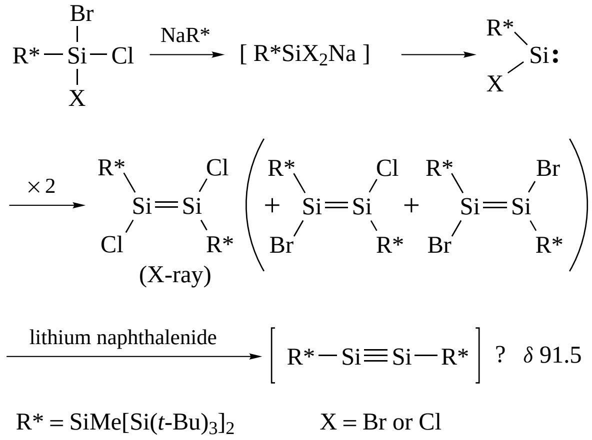
6.2 A Stable Compound Containing A Silicon–Silicon Triple Bond

A triple-bond compound between a silicon atom has increasingly attracted many chemists after the successful isolation of its heavier analogs, ArM≡MAr (M = Ge, Sn, and Pb). Although the theoretical calculations predicted the experimental accessibility of a disilyne,[24] all attempts to isolate such triple-bond compounds have been unsuccessful.[148–150] Attempted synthesis of a disilyne using a bulky *m*-terphenyl ligand, C_6H_3-2,6-Mes_2, has been published.[149] Reduction of the corresponding trifluorosilane using sodium in THF afforded no disilyne but the decomposed compounds via the intramolecular cyclization (Scheme 33). On the other hand, Wiberg and coworkers have designed a new steric protection group R*, (SiMe[Si(*t*-Bu)$_3$]$_2$), which they call as a 'megasilyl group', for stabilizing a triple bond between silicon atoms.[150] They have succeeded in the synthesis of the first stable dichlorodisilene, R*(Cl)Si=Si(Cl)R*, of which the reduction with lithium naphthalenide in THF has been reported (Scheme 34). This reaction mixture contains an unstable product with a low-field ^{29}Si NMR signal at 91.5 ppm, which was ascribed to be a Si≡Si triple-bond resonance. However, the isolation and full-characterization of the compound have not been achieved yet.

Very recently, Sekiguchi and his coworkers have succeeded in the synthesis and isolation of the first stable disilyne finally.[151] The key to success is undoubtedly the design and choice of a substituent, and they chose the original bulky silyl substituents, Si(*i*-Pr)Dis$_2$ (R_{Si}). The disilyne R_{Si}Si≡SiR_{Si} is accessed by the reduction of the corresponding tetrabrominated precursor, (R_{Si}SiBr_2)$_2$, with



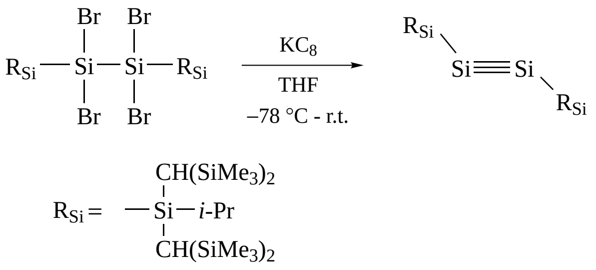
Scheme 33



Scheme 34

potassium graphite (KC_8) (Scheme 35). The disilyne can be isolated as extremely air- and moisture-sensitive emerald green crystals in 73% isolated yield. No evidence for its isomerization to R_{Si2}Si=Si: or dissociation into the two R_{Si}Si fragments was observed, indicating that the two central silicon atoms are strongly bonded.

The most informative data should be its ^{29}Si NMR data for the central triply bonded Si atoms. The resonance of sp-hybridyzed Si atom in R_{Si}Si≡SiR_{Si} is observed at 89.9 ppm and is shifted upfield compared with those of the silyl-substituted disilenes (ca. 142–155 ppm).[152] Similar up-field shift is observed in the ^{13}C NMR chemical shifts of the silyl-substituted alkenes (ca. 188–197 ppm) and alkynes (112–114 ppm).[153] The molecular structure of the R_{Si}Si≡SiR_{Si} was revealed by X-ray crystallographic analysis (Figure 18). It has a trans-bent geometry [Si–Si–Si(R_{Si})



Scheme 35

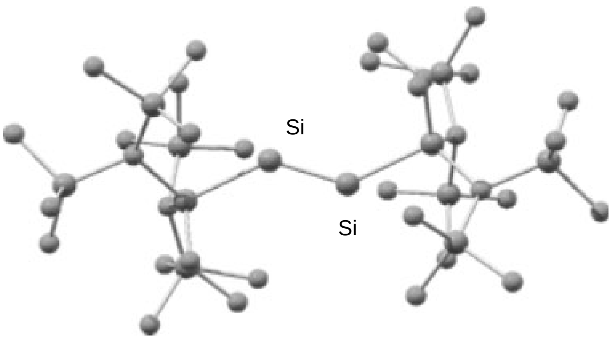


Figure 18 Molecular structure of $R_{Si}Si{\equiv}SiR_{Si}$ [R_{Si} = Si(*i*-Pr)Dis_2]

is 137.44(4)°] similar to that of Ar'Ge≡GeAr' with perfectly coplanar four silicon atoms of Si(R_{Si})–Si≡Si–Si(R_{Si}). The Si≡Si triple-bond length is 2.0622(9) Å, which is 3.8% shorter than the typical Si=Si double-bond lengths (ca. 2.14 Å) and 13.5% shorter than the typical Si–Si single bond lengths (ca. 2.34 Å). Thus, the disilyne $R_{Si}Si{\equiv}SiR_{Si}$ was characterized structurally and spectroscopically as a 'true' triply bonded compound between two silicon atoms.

7 CONJUGATED π ELECTRON AND CUMULATIVE SYSTEMS OF HEAVIER GROUP 14 ELEMENTS

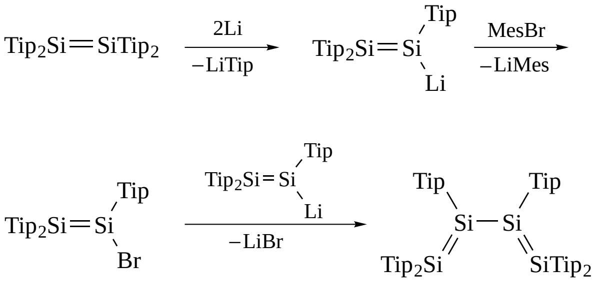
A concept of 'conjugation of π electrons' plays an important role in the chemistry of hydrocarbons. One can easily hit upon butadienes (C=C–C=C) as typical conjugated π electron systems, and their unique properties are well known. Similarly, allenes (C=C=C) are also well studied in the chemistry of hydrocarbon systems. Since it is now concluded that the doubly bonded compounds between heavier group 14 elements can be isolated when they are well kinetically stabilized, a new and exciting challenge should be the synthesis and stabilization of the heavier congeners of another class of important low-coordinated organic molecules such as butadienes and allenes. In this chapter, recent works on the synthesis of stable conjugated-π-electron systems and allenes containing Si and Ge atom(s) will be described.[26,77,154] The chemistry of heavy aromatics, which is considered as one of the most important conjugated π electron systems, will be described in detail in the next section.

7.1 Stable Conjugated π Electron Systems Containing Heavier Group 14 Elements

7.1.1 Heavier analoges of a buta-1,3-diene

Synthesis and Properties. The first stable tetrasilabuta-1,3-diene derivative was synthesized by Weidenbruch *et al.* in 1997.[155] The synthetic route is unique as follows: the disilene $Tip_2Si{=}SiTip_2$[30] was treated with an excess amount of lithium to give the putative disilenyllithium compound. Then, mesityl bromide (MesBr) was added in the expectation that the bulk of this aryl group and the poor solubility of MesLi would favor halogenation over the competing transarylation. Thus, the intermediary bromodisilene $Tip_2Si{=}Si(Br)Tip$ was formed, and the intermolecular reaction of $Tip_2Si{=}Si(Br)Tip$ and $Tip_2Si{=}Si(Li)Tip$ with the elimination of LiBr furnished the tetrasilabutadiene $Tip_2Si{=}Si(Tip)–Si(Tip){=}SiTip_2$ in 60% yield (Scheme 36).

The reddish-brown crystals of $Tip_2Si{=}Si(Tip)–Si(Tip){=}SiTip_2$ are thermally very stable but extremely air-sensitive. The structure of $(Tip)_2Si{=}Si(Tip)–Si(Tip){=}Si(Tip)_2$ was revealed by X-ray crystallographic analysis, which showed the s-gauche configuration with a dihedral angle for the Si_4 framework of 51° in the solid state (Figure 19). The Si=Si double-bond lengths are slightly elongated [2.175(2) Å] as compared with those of the previously reported disilenes, while the central Si–Si bond lengths of 2.321(2) Å is remarkably short in view of its bulky substituents. The preference of the s-gauche form for $(Tip)_2Si{=}Si(Tip)–Si(Tip){=}Si(Tip)_2$ is in sharp contrast to that of the corresponding carbon compounds such as butadienes, which mostly prefer the s-trans configuration. Conjugation between the two Si=Si double bonds has been confirmed



Scheme 36

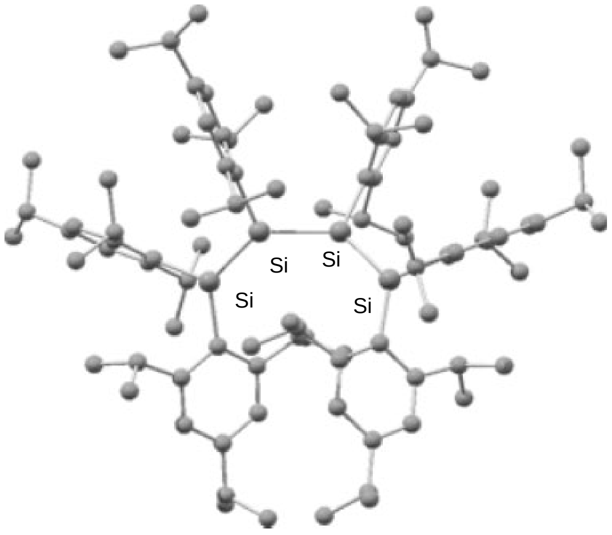


Figure 19 Molecular structure of Tip_2 Si=Si(Tip)–Si(Tip)=$SiTip_2$

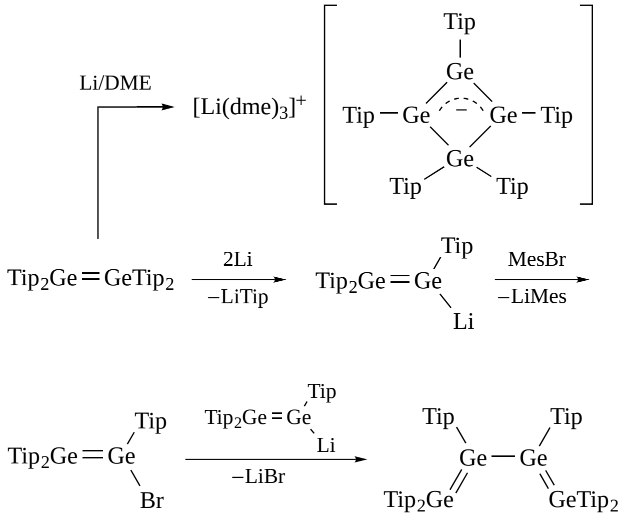
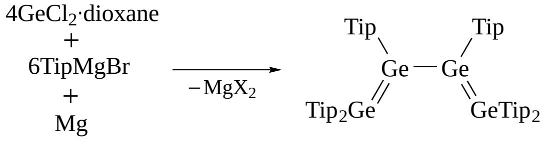
by the electronic spectrum, where the band at the longest wavelength assignable to the corresponding $\pi-\pi^*$ transitions showed a considerable bathochromic shift of more than 100 nm in comparison to those of diaryldisilenes.

In contrast to the case of silicon, treatment of $(Tip)_2Ge{=}Ge(Tip)_2$[47] with an excess amount of lithium afforded no tetragermabutadiene derivative, but dark-red crystals of anionic species, tetragermacyclobutenide derivative, which contains an allyl-like Ge_3 anion as a part of the four-membered ring.[156] Shortening the reaction time to such an extent that most of the digermenes had reacted before the formation of the tetragermacyclobutenide could make the main reaction to proceed more efficiently leading to the formation of $(Tip)_2Ge{=}Ge(Li)Tip$. Subsequent reaction with MesBr afforded the expected tetragermabutadiene, $(Tip)_2Ge{=}Ge(Tip)–Ge(Tip){=}Ge(Tip)_2$, in ca. 10% yield (Scheme 37). An alternative synthetic method for the tetragermabutadiene has been developed. That is, the reaction of $GeCl_2$·dioxane with TipMgBr affords the tetragermabutadiene in one step and in a yield of more than 30% (Scheme 38).[157]

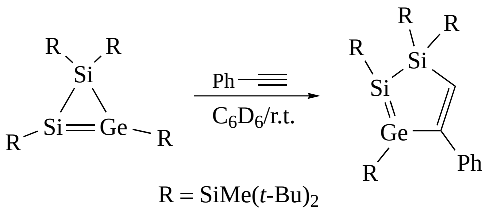
Similar to the case of the tetrasilabutadiene, the tetragermabutadiene adopts an s-gauche form with a dihedral angle of the Ge_4 framework of 22°. The Ge=Ge double bonds [2.3568(6) and 2.3439(5) Å] and the Ge–Ge single bond [2.4581(5) Å] are in the typical ranges for such bond lengths. Although the crystal structure of $(Tip)_2Ge{=}Ge(Tip)–Ge(Tip){=}Ge(Tip)_2$ gave no distinct information about a possible conjugation between two Ge=Ge double bonds, the electronic spectrum revealed its conjugation. That is, the dark blue solution of the tetragermabutadiene showed the longest wavelength absorption at 560 nm in hexane. Compared with the yellow or orange color of digermenes, this absorption is bathochromically shifted by ca. 140 nm.



Scheme 37

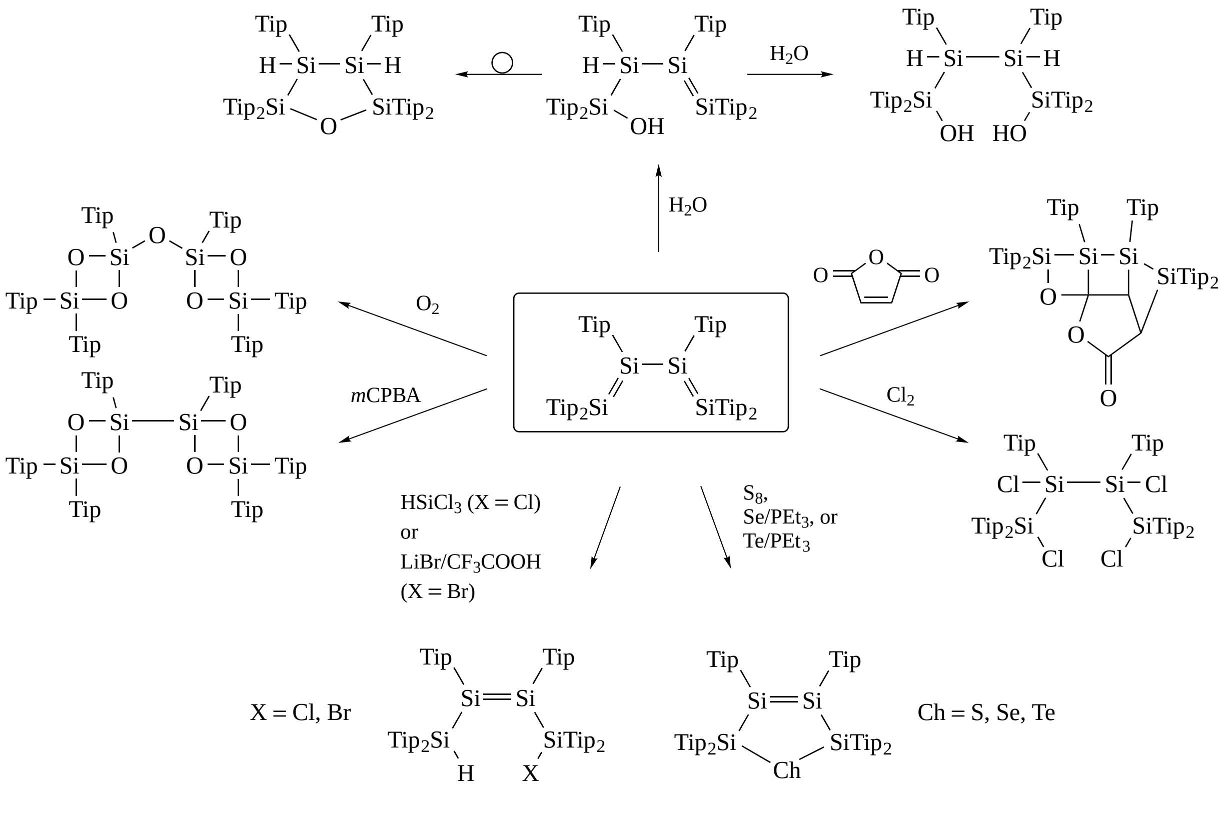


Scheme 38



Scheme 39

Furthermore, a stable 1H-1,2,3-disilagermole system of Si–Si=Ge–C=C was synthesized as the first example of a structurally characterized silagermene (Scheme 39).[82] This is afforded by the reaction of a unique three-membered ring system, a 1*H*-disilagermirene derivative, with phenylacetylene via the initial [2 + 2] addition followed by the rearrangement. The length of the Si=Ge bond is 2.250(1) Å, which lies between the typical values of Si=Si and Ge=Ge bond lengths. The Ge–C and C=C bond lengths lie in the normal range of the corresponding single and double bonds. Thus, no structural evidence of conjugation between Si=Ge and C=C π bonds is obtained. However, the existence of the conjugation in the 1*H*-1,2,3-disilagermole was confirmed at least in solution by the result of its electronic spectrum in hexane.[82]



Scheme 40

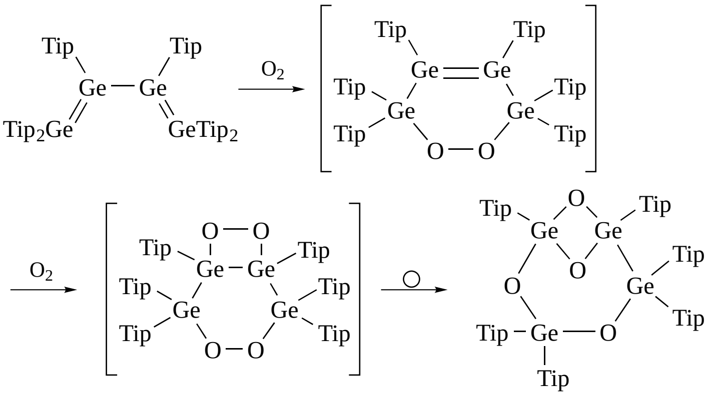
Reactions. Experimental results of reactions of $(Tip)_2Si{=}Si(Tip){-}Si(Tip){=}Si(Tip)_2$ are summarized in Scheme 40. Treatment of the tetrasilabutadiene with a small amount of water gave an analog of tetrahydrofuran, an oxatetrasilolane derivative, probably via the 1,2-addition and the following rearrangement. Addition of an excess amount of water resulted in the formation of the tetrasila-1,4-diol derivative, which showed no tendency to eliminate water with the formation of the oxatetrasilolane derivative.[158]

Although the tetrasilabutadiene exists in the solid state as that with an s-gauche configuration, which should favor [4 + 2] cycloadditions, no successful reactions with alkenes, acetylenes, and carbonyl compounds have been reported so far, probably owing to the steric reason. It should be noted that the tetrasilabutadiene underwent a formal [4 + 4] cycloaddition with maleic anhydride leading to the formation of a tetracyclic compound.[159] In addition, the treatment of the tetrasilabutadiene with elemental sulfur afforded a five-membered ring compound, 2,5-dihydrothiatetrasilole derivative, via the formal [4 + 1] cycloaddition.[160] Upon the addition of a catalytic amount of PEt_3, elemental selenium and tellurium react with the tetrasilabutadiene to give the corresponding five-membered ring compounds.[160] Similarly, the reaction of the tetragermabutadiene with elemental sulfur reportedly gave the corresponding 2,5-dihydrothiatetragermole derivative.[157]

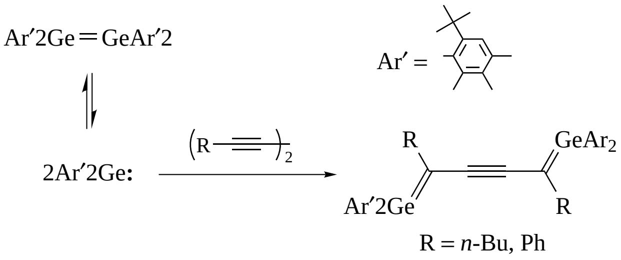
On the other hand, oxidation reaction of the tetrasilabutadiene with dry air was found to give a unique compound, which consists of two 1,3,2,4-dioxadisiletane rings linked by an oxygen atom. It is in a sharp contrast to the oxidation reaction using mCPBA, which gives an oxidation product consisting of two 1,3,2,4-dioxadisiletane rings connected with an Si–Si single bond.[158] Furthermore, the oxidation reaction of the tetragermabutadiene with dry air afforded a bicyclic compound depicted in Scheme 41.[157] Reaction mechanisms of such oxidation reactions have not been proven experimentally so far.

7.1.2 Acetylene-Linked Bis(germenes)

The reactions of the diarylgermylene Ar’$_2$Ge: (Ar$'$ = 2-*t*-Bu-4,5,6-trimethylphenyl), which is generated from the corresponding digermene $Ar'_2Ge{=}GeAr'_2$ in solution, with 1,3-diynes $(R{-}C{\equiv}C{-})_2$ (R = *n*-Bu, Ph) gives the first molecules having conjugated Ge=C double bonds as depicted in Scheme 42.[161] The conjugation of the two Ge=C double bonds across the linking acetylene unit is reflected in the electronic spectra rather than in the bond lengths. Their λ_{max} values at the longest wavelengths are 518 (R = *n*-Bu) and 595 (R = Ph) nm, and shifted bathochromically by ca. 100 nm compared with those for the previously reported germenes (see Section 3.1.4). The conjugation between the two double



Scheme 41



Scheme 42

bonds probably decreases their reactivity. For examples, these conjugated compounds cannot react with phosphaalkynes or dienes, whereas simple germenes form the corresponding addition products.[96] Addition reactions of conjugated Ge=C double bonds occur with only compounds containing electron poor multiple bonds.[162]

The successful synthesis of the acetylene-linked bis(germenes) posed a question whether analog compounds with conjugated Si=C double bonds could be isolated by the reaction of a silylene with 1,3-diynes. Although attempted reactions can postulate the existence of intermediary compounds consisting of bis(silenes) linked by an acetylene unit, no stable compounds having Si=C–C≡C–C=Si conjugated systems have been obtained by such a synthetic strategy.[163]

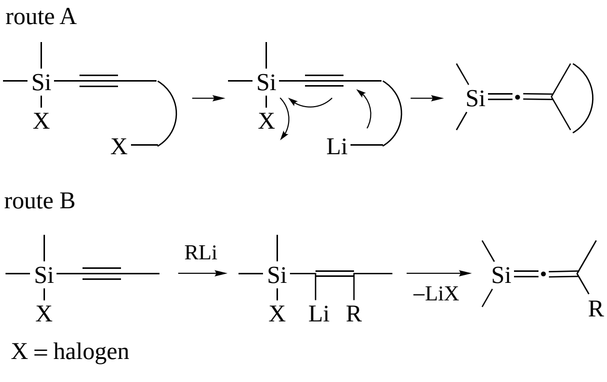
7.2 Stable Allenes Containing Heavier Group 14 Elements

Several kinds of cumulative double bonds containing heavier atoms such as Si=C=C, Si=C=C=C, N=C=Si (precisely, RN=C → SiR_2), Si=C=P, and so on, and their heavier congeners have been synthesized and reported as stable or marginally stable compounds.[154] Here, the main topic in this section is limited to the stable and isolable examples of allene derivatives containing heavier group 14 elements, that is, silaallenes, germaallenes, tristannaallene, and trisilaallene.

7.2.1 1-Silaallenes (Si=C=C) and 1-Germaallenes (Ge=C=C)

Since the first isolation of stable 1-silaallene synthesized by West and coworkers in 1993,[164] six stable examples of Si=C=C compounds have been reported.[154] Si=C=C compounds were mainly synthesized by two methods, that is, the dehalogenative intramolecular cabometalation-elmination method (route A) and the addition of an organolithium reagent at the triply bonded carbon atom of fluoroalkynylsilanes followed by the LiF elimination (route B) (Scheme 43).

The structures of some stable silaallenes have been revealed by X-ray crystallographic analysis (Figure 20).[164,165] The geometries of their Si=C=C skeletons are nearly the same with shorter Si=C double bonds (ca. 1.70 Å) than the typical Si=C bond lengths (see Section 3.2). Such a short distance is conceivable to be affected by the sp-hybridized central carbon atom. The C=C bond lengths (ca. 1.325 Å) in these Si=C=C allenes are in normal range of C=C double bonds. It is worthy of note that the Si=C=C bond angle is not completely 180°



Scheme 43

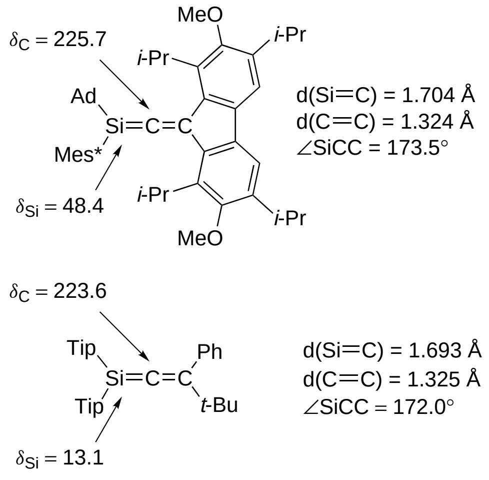


Figure 20 Properties of stable silaallenes

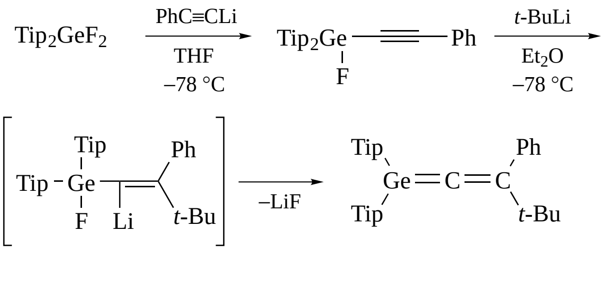
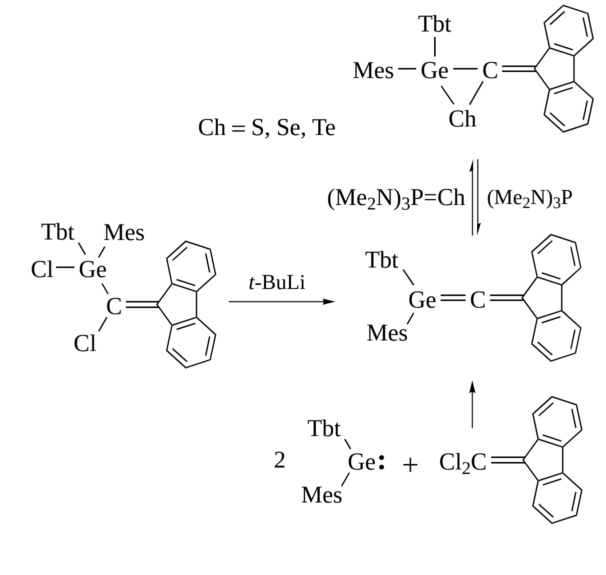
but slightly bent (ca. 172–174°) unlike the case of C=C=C. In addition, the silicon atoms are slightly pyramidalized [the sum of angles around Si atoms are ca. 357°], whereas the terminal sp^2 carbons are essentially planar. Such structural features of Si=C=C compounds reflect the fundamental character of low-coordinated heavier group 14 elements (see Section 2).

In ^{13}C NMR of stable silaallenes are observed highly deshielded signals (216–237 ppm) assignable to their central sp-carbon atoms. ^{29}Si NMR chemical shifts of silaallenes vary in the range of 13.1–58.6 ppm, depending on the properties of substituents on the silicon atom as in the case of those of silenes (Si=C).

The first compounds with a Ge=C=C allene unit were reported by two groups, Tokitoh *et al.*[166] and R. West *et al.*[167] in 1998. Germaallene Tip_2Ge=C=CPh(*t*-Bu) was synthesized by the reaction of Tip_2GeF_2 with PhC≡CLi followed by the treatment of *t*-BuLi as a base (Scheme 44). This synthetic method is the same as that used for the preparation of silaallene Tip_2Si=C=CPh(*t*-Bu) (route B in Scheme 43). On the other hand, the stable germaallene Tbt(Mes)Ge=C=C(fluorenylidene) was obtained by the addition of an excess amount of $(Me_2N)_3P$ to the corresponding alkylidenetelluragermirane derivative[168] as an equilibrium mixture. Alternatively, the dechlorination



Scheme 44



Scheme 45

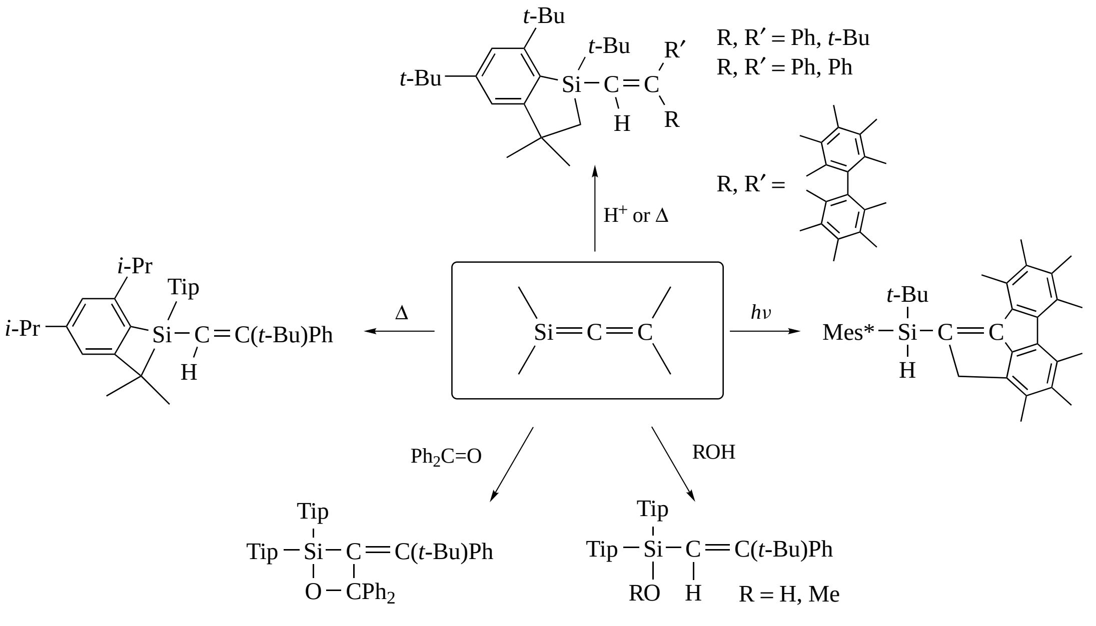
of Tbt(Mes)Ge(Cl)–C(Cl)=C(fluorenylidene) with *t*-BuLi at −72 °C allowed the isolation of the germaallene as a stable crystalline compound (Scheme 45). The two examples of germaallenes have characteristic low-field chemical shifts for the central allenic carbons [235.1 pm for Tip_2Si=C=CPh(*t*-Bu) and 243.5 ppm for Tbt(Mes)Ge=C=C(fluorenylidene)] as in the case of silaallenes.

The reactivities of sila- and germaallenes are summarized in Schemes 46 and 47,[154] respectively. Two silaallenes depicted in Figure 20 are stable for days under ambient conditions and in the presence of air, water, and even in refluxing ethanol. This is in striking contrast to all other multiply bonded silicon compounds, particularly silenes (see previous sections). Addition reactions of protic reagents or unsaturated compounds onto the M=C bond of sila- and germaallenes and their acid-catalyzed intramolecular cyclization have been reported. These reactivities reflect the properties of highly reactive M=C unsaturated bonds, therefore they showed reactivities similar to those of silenes and germenes.

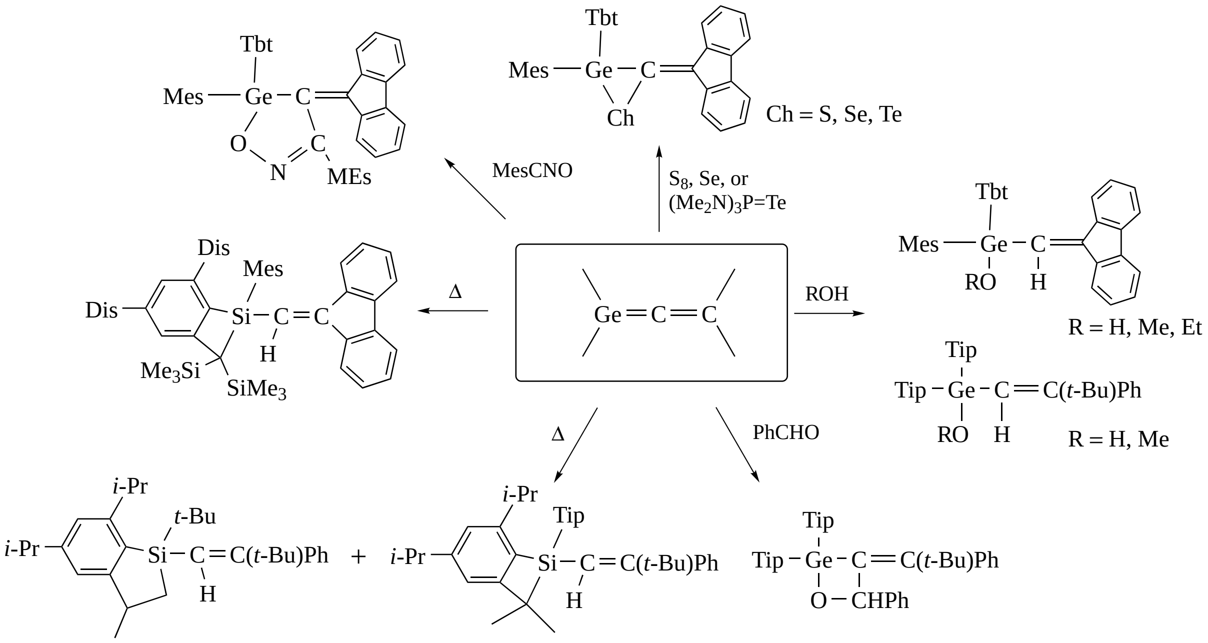
7.2.2 *Tristannaallene (Sn=Sn=Sn) and Trisilaallene (Si=Si=Si)*

The successful isolation of 1-silaallenes and 1-germaallenes raises the expectation of synthesis of a novel class of allenic compounds having an sp-hybridized silicon unit, that is, 2-silaallene derivatives. Although the generation of 2-silaallene (*t*-Bu)–CH_2–CH=Si=CH–CH_2–(*t*-Bu) was postulated in the reaction of $(H_2C{=}CH)_2SiCl_2$ with 2-equivalent of *t*-BuLi,[169] no distinct evidence on the generation of such a compound has been obtained so far.

In the case of Sn, Wiberg *et al.* have reported the synthesis of a marginally stable tristannaallene, $R^*_2Sn{=}Sn{=}SnR^*_2$

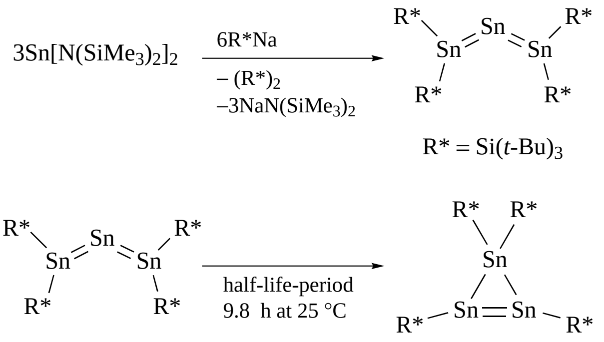


Scheme 46



Scheme 47

[R* = Si(*t*-Bu)$_3$] (Scheme 48).[170] Treatment of diamino-stannylene[(Me$_3$Si)$_2$N]$_2$Sn: with R*Na in pentane at −196 °C afforded the tristannaallene R^*_2Sn=Sn=SnR^*_2 together with disilane R^*_2. Unfortunately, the tristannaallene is too unstable at ambient temperature (the half-life period is 9.8 h at 25 °C in pentane) to undergo a rearrangement reaction giving the isomeric cyclotristannene. The structural feature of R^*_2Sn=Sn=SnR^*_2 was revealed by X-ray crystallographic analysis and NMR spectroscopy at −25 °C. The most striking structural features of the tristannaallene are the bent angle of Sn=Sn=Sn (155.9°) and the shorter Sn=Sn bond lengths (ca. 2.68 Å) than those observed in stable distannenes (see Section 3.2). The ^{119}Sn NMR spectrum showed two signals at 503 and 2233 ppm, which are attributed to the terminal and central tin atoms, respectively. Since stable stannylenes R$_2$Sn: are known to show their ^{119}Sn NMR chemical shifts in a range of ca. 2000–2300 ppm,[98,132,171] chemical shifts observed in the tristannaallene indicate the stannylene character of



Scheme 48

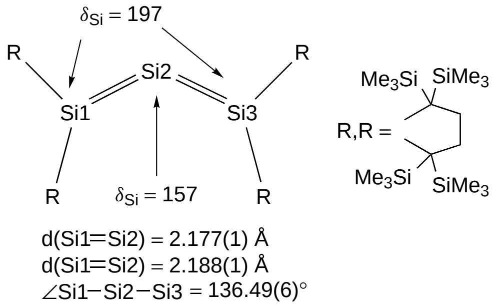


Figure 21 Properties of stable trisilaallenes $R_2Si{=}Si{=}SiR_2$. The central silicon atom (Si2) in the crystal was disordered at four positions. The structural parameters shown here are those of the major part of disordered atoms

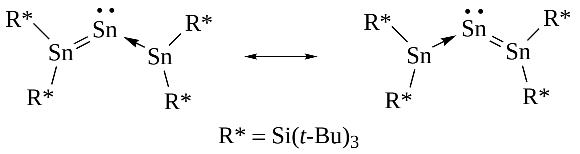
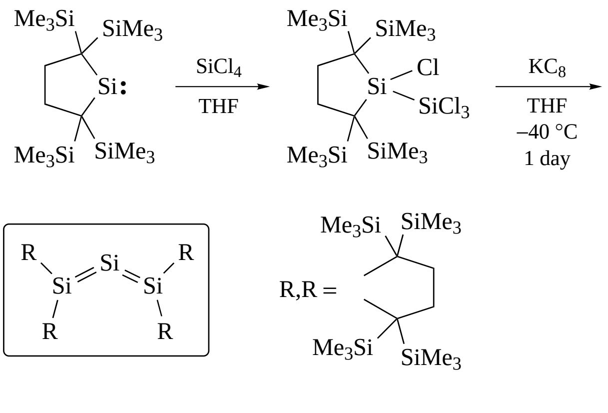
its terminal tin atoms. Consequently, the tristannaallene should not be represented as 'real' homologs of an allene but understood in accordance with the resonance formulae depicted in Scheme 49.

The interesting structural feature of the tristannaallene prompted many chemists to take on the challenge of synthesizing stable trimetallaallenes. Finally, in 2003, Kira and his coworkers succeeded in the synthesis of the first stable trisilaallene with Si=Si=Si unit.[172] The trisilaallene, $R_2Si{=}Si{=}SiR_2$ (R_2 = -C(SiMe$_3$)$_2$–CH$_2$–CH$_2$–C(SiMe$_3$)$_2$-), was synthesized and isolated as a green solid via two-step reactions from the corresponding stable silylene R_2Si: in overall 42% yield as shown in Scheme 50.

X-Ray crystallographic analysis shows a quite unusual structural feature of the trisilaallene (Figure 21). In contrast to allenes, the trisilaallene skeleton is not linear but significantly bent with an Si=Si=Si bond angle of ca. 136°, indicating that the bonding property of the central =Si=atom cannot be interpreted in terms of simple sp-hybridization. The two Si=Si bond lengths [2.177(1) and 2.188(1) Å] are in the range of those for typical stable disilenes (2.14–2.29 Å, see Section 3.2). In addition, the geometry around the two terminal silicon atoms is not completely planar but slightly pyramidalized (the sums of the bond angles around terminal Si atoms are 354.1° and 354.9°). All these structural features indicate that trisilaallene $R_2Si{=}Si{=}SiR_2$ consists of two trans-bent Si=Si double bonds that share the central silicon atom. Additional information of theoretical calculations on trisilaallenes also supported such structural features.



Scheme 49



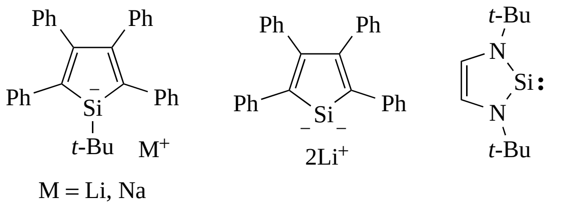
Scheme 50

The ^{29}Si NMR spectrum of the trisilaallene showed two signals at 157 and 197 ppm in C_6D_6, which are assigned to the central silicon atom (Si2) and the terminal silicon atoms (Si1, Si3), respectively. Such low-field shifted resonances indicate the sp^2-character of the three silicon atoms in the trisilaallene $R_2Si{=}Si{=}SiR_2$, though it shows a highly bent structure in the crystalline state.

The reaction of $R_2Si{=}Si{=}SiR_2$ with water gave the corresponding 1,3-dihydrotrisilane $R_2Si(OH)–SiH_2–(HO)SiR_2$ in an almost quantitative yield. This product reflects the intrinsic, bent allenic feature of the trisilaallene supported by the calculated electronic feature as $Si^{\delta+}{=}Si^{\delta-}{=}Si^{\delta+}$.

8 HEAVY AROMATIC SYSTEMS

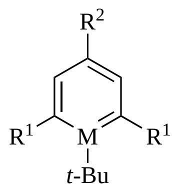
Metallaaromatic compounds, that is, M-containing [4n + 2]π ring systems (M = Si, Ge, Sn, Pb), have attracted much attention in recent decades, since they represent the heavier congeners of carbocyclic aromatic compounds, which play very important roles in organic chemistry. Although the aromatic character of silole anions and dianions[173] as well as that of cyclic diaminosilylene[174] (Scheme 51) was recently revealed from both experimental and theoretical standpoints, simple neutral silaaromatic compounds are known to be highly



Scheme 51 Silaaromatic species of siloles and a silylene

reactive. Such silabenzenoids have only been characterized in low-temperature matrices or postulated as transient intermediates in some trapping reactions.[175] While nonconjugated, Si-containing doubly bonded compounds have already been synthesized as stable molecules by taking advantage of kinetic stabilization as described in the previous sections, no silabenzenoid compounds stable at ambient temperature have ever been reported until the first isolation of a stable 2-silanaphthalene derivative by Tokitoh *et al.* in 1997.[176] The situation for the chemistry of germaaromatics is almost the same as that of silaaromatics.[177–179] The syntheses of several examples of stable ionic species and the dimerization and intermolecular trapping of heavy aromatic systems have been reported (Scheme 52), while stable neutral metallaaromatics have been still elusive until quite recently.[178,179]

Meanwhile, many theoretical calculations have been reported for sila- and disilabenzenes,[180,181] and the recent study indicates that silabenzenes have a π-electron-delocalized structure and considerable aromaticity.[178,179,182] This implies that silaarenes might exist as stable molecules if their high reactivity could be suppressed by an appropriate protection. Since it has been fully demonstrated that Tbt group is very effective to stabilize the highly reactive, low-coordinated species of heavier main group elements (see previous sections), Tokitoh *et al.* applied the Tbt group to the kinetic stabilization of an unexplored class of low-coordinated species of heavier group 14 elements such as sila- and germaaromatic compounds.[178,179] Up to now, several kinds of silaaromatic compounds bearing a Tbt group on the sp^2-silicon atom such as silabenzene,[183,184] 1- and 2-silanaphthalenes,[176,185] 9-silaanthracene,[186,187] and 9-silaphenanthrene were successfully synthesized and isolated as stable compounds (Scheme 53). Furthermore, the first stable germabenzene[188] and 2-germanaphthalene[189] were also synthesized using a similar synthetic approach. The recent progress in the chemistry of stable metallaaromatic systems is outlined in this section.



M = Si, R^1 = H, R^2 = *t*-Bu

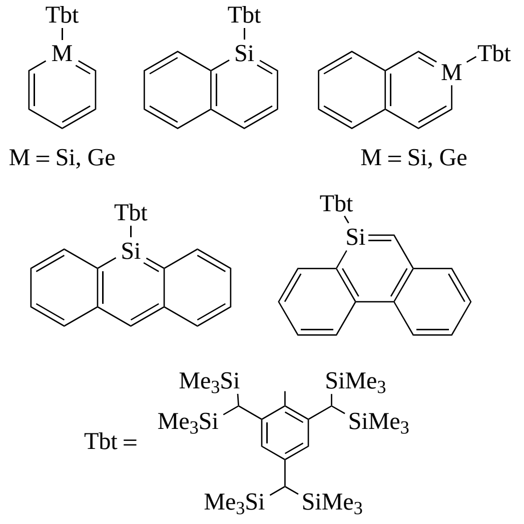


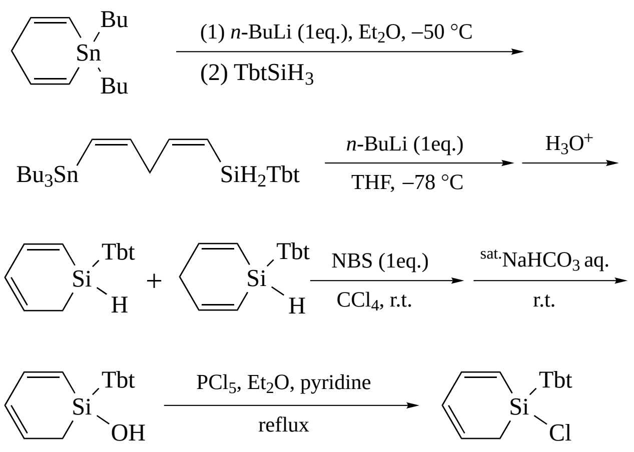
Scheme 53

8.1 Synthesis and Isolation

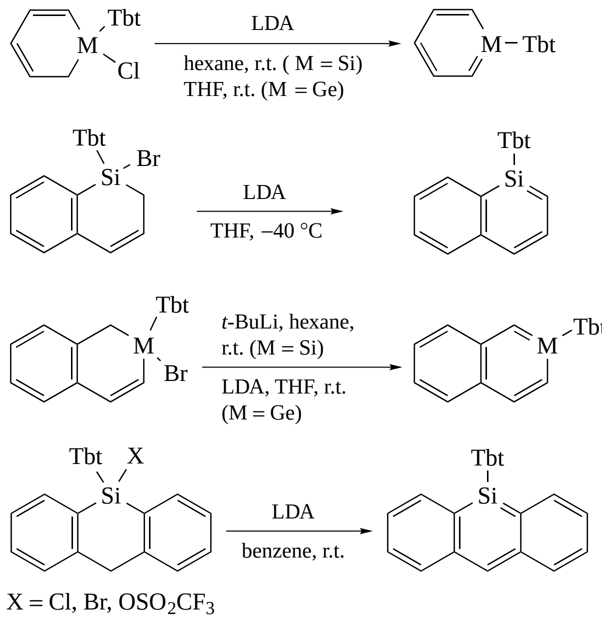
In view of the isolation of such a highly reactive species in a pure form, it is necessary to develop suitable synthetic methods (e.g. high yields and mild reaction conditions). Simple 1,2-dehydrohalogenation reactions of the corresponding cyclic halometallane precursors using an appropriate base (LDA was chosen in most cases) were proved to be effective for the synthesis and isolation of silabenzene, 1- and 2-silanaphthalenes, 9-silaphenanthrene, germabenzene, and 2-germanaphthalene. The synthetic route for the precursor of silabenzene is shown as a representative in Scheme 54.

In addition, in the case of 9-silaanthracene,[186] the leaving ability of the substituent on the silicon atom played a very crucial role. Although the use of the corresponding chloro- and bromosilanes as precursors resulted in very low yields of the 9-Tbt-9-silaanthracene as judged by the trapping experiments with MeOH, the treatment of the corresponding silyltriflate derivative with LDA in benzene gave the expected 9-silaanthracene quantitatively (Scheme 55).

Except for 1-Tbt-1-silanaphthalene,[185] which was found to undergo gradual dimerization in solution at room temperature, all other metallaaromatic compounds in Scheme 55 were isolated as stable crystalline compounds, indicating the high ability of the Tbt group as a steric protecting group. Recently, the matrix isolation and intermolecular trapping reactions have been described for the 9-silaanthracenes having a



Scheme 54



Scheme 55

2,4,6-triisopropylphenyl (Tip) or 2,4,6-tri-t-butylphenyl group (Mes*), but these species are reportedly not isolable.[190] This fact implies the indispensability of an extremely bulky substituent such as Tbt for the isolation of kinetically stabilized metallaaromatic compounds.

In contrast to the successful isolation and characterization of the kinetically stabilized sila- and germaaromatic compounds described here, their heavier congeners such as stannabenzene or plumbabenzene are still elusive and neither their isolation nor spectroscopic detection has been achieved. In addition, the synthesis of aromatic systems containing multiple heavier group 14 elements (polymetallabenzenes) still remain as the next target molecules in future. The concept of kinetic stabilization should certainly be of great use for the synthesis of these unprecedented heavy aromatic species.

8.2 Structures and Spectroscopic Properties

X-ray Crystallographic Analysis. The most important structural features of aromatic compounds are the planarity for their aromatic rings and the ring-bond lengths lying between those of the typical double and single bonds, which result from the delocalization of π-electrons of their aromatic rings. From the viewpoint of systematic comparison, it is of great significance to perform the X-ray crystallographic analysis of the stable metallaaromatic compounds obtained so far. Fortunately, most of them were isolated as stable crystalline compounds reflecting the high crystallinity of the Tbt-substituted compounds. The structural parameters of the analyzed metallaaromatics are summarized in Table 7 together with their atom-numbering schemes in Scheme 56. As a representative, the molecular structure for the silabenzene is shown in Figure 22, which clearly indicates the planar silabenzene ring nicely protected by the bulky Tbt group.

All metallaaromatic ring systems examined here have an almost planar aromatic ring, and the geometry around the central silicon or germanium atom is completely trigonal planar, suggesting the delocalization of π-electrons in these ring systems. Almost equal distances were observed for the group 14 metal−carbon bonds in both sila-[184] and germabenzenes,[188] while a small extent of bond alternation was recognized for 2-sila-[176] and 2-germanaphthalenes,[189] as in the case of parent naphthalene. Taking into account the fact that the C–C bond lengths in these metallaaromatic rings are comparable with those reported for parent benzene and naphthalene,[191] it should be concluded that replacement of one carbon with a heavier group 14 element such as a silicon or germanium atom does not disturb the delocalization of π-electrons in the monometallaaromatic ring systems. Furthermore, the crystallographically revealed structural features of these new metallaaromatic species are in good agreement with those obtained by the theoretical calculations with B3LYP/6-31G(d) level for some model compounds, suggesting the little steric and electronic influence of the Tbt group.

NMR Spectra. As for the silaaromatic compounds, ^{29}Si NMR spectroscopy gives useful information for the electronic and structural environments of their central silicon atom. All the stable silaaromatics showed characteristically low-fielded signals in the ^{29}Si NMR spectra [93.6 (silabenzene[183]), 91.7 (1-silanaphthalene[185]), 87.3 (2-silanaphthalene[176]), 87.2 (9-silaanthracene[186]), and 86.9 (9-silaphenanthrene) ppm in C_6D_6], suggesting the sp^2 character of their ring silicon atoms. These chemical shifts are more low-fielded than that for the previously reported marginally stable silabenzene of 1,4-di-t-butyl-2,6-bis(trimethylsilyl)silabenzene shown in Scheme 52

Table 7 Structural parameters of Tbt-substituted heavy aromatics. (ΣM: summation of the bond angles around the M atom, $\Sigma\angle MC_5$: summation of the internal angles of the MC_5 ring sketeton)

compounds		silabenzene	germabenzene	2-silanaphthalene	2-germanaphthalene	9-silaanthracene

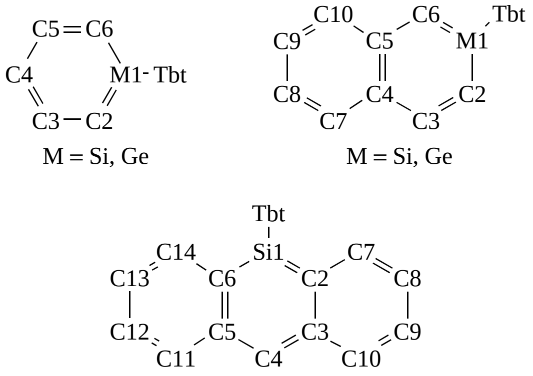

Scheme 56 Atom numbering schemes

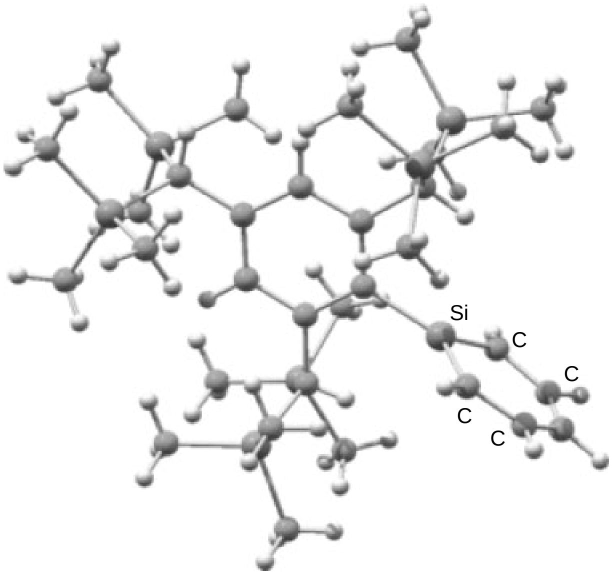

Figure 22 Molecular structure of 1-Tbt-silabenzene

(δSi = 26.8),[192] and almost no spectral change was observed even on measurement in the presence of an ethereal solvent such as that in THF:C_6D_6 = 6:1. These results strongly indicate not only the sp^2 character for their ring silicon atoms but also the effective steric protection afforded by the bulky Tbt group, which completely prevents their silicon atoms from coordination of the ethereal solvent. In other words, the marginally stable silabenzene reported by Märkl (Scheme 52) might be stabilized with the bulky substituents (*t*-Bu and Me_3Si groups) together with the coordination of Lewis-basic, ethereal solvents such as ether and/or THF.[192]

^1H and ^{13}C NMR spectral data of these stable metallaaromatics having a Tbt group also supported their molecular structures. The nice agreement of the observed chemical shifts with those obtained by theoretical calculations of several model compounds indicated that little perturbation with the aromatic Tbt group occurred on the central heavier atom. Of particular note among the ^1H NMR spectral data is that the chemical shifts for the ring protons of them are all shifted to lower field by ca. 0.5 to 1.0 ppm compared with those of precursors. This distinct low-field shift of the ring protons should be noted as one of the pieces of experimental evidence for the ring current effect of these metallaaromatic systems.

UV–vis and Raman Spectra. In order to examine the similarities and differences between metallaaromatic compounds and the parent aromatic hydrocarbons, the UV–vis and Ramam spectra of the stable metallaaromatics bearing a Tbt group were measured.[146,183–189] In the electronic spectra, all silaaromatic compounds showed a remarkable red-shift for their ^1B, ^1L_a, and ^1L_b bands as compared with those reported for the corresponding parent aromatic hydrocarbons. In Table 8 are summarized the experimentally observed absorption maxima at the longest wavelength for the metallaaromatics together with those for the carbon analogs. Interestingly, the absorption maxima of the germabenzene and the 2-germanaphthalene showed almost no shift compared with their silicon analogs though being clearly red-shifted in comparison with those of the parent aromatic hydrocarbons. These results indicate the π–π^* energy gap of the cyclic $[4n+2]\pi$ electron systems containing a heavier group 14 element is much smaller than that of the corresponding hydrocarbons but almost similar to each other as for the silicon and germanium analogs. Although the silaaromatic species examined here have an extremely bulky Tbt group on the central silicon atom, their electronic spectra closely resembled

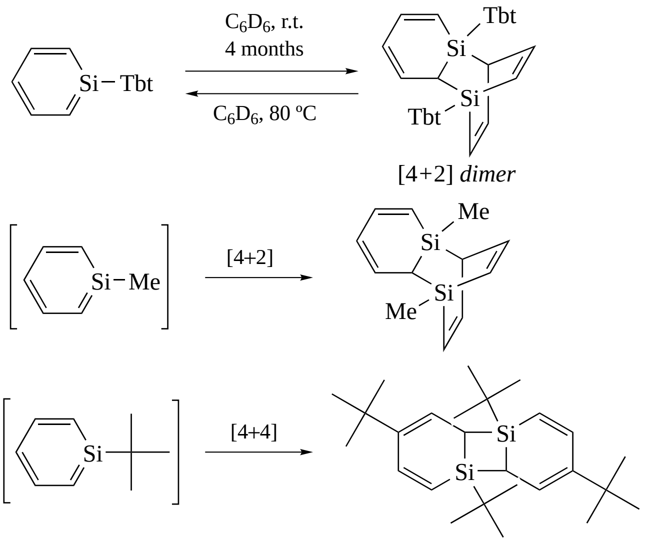
those reported for the transient silaaromatics measured in the low-temperature matrices,[190,193] indicating the very little perturbation by the steric protection afforded by Tbt group.

The strongest Raman lines observed for them and the corresponding aromatic hydrocarbons are also summarized in Table 8. The experimentally observed Raman shifts for the metallaaromatic species and the parent hydrocarbons are reasonably reproduced by theoretical calculations. Although the vibrational frequencies for metallaaromatics were observed at somewhat smaller wave numbers than those of the carbon analogs, the similarity among their in-plane vibrational modes is clearly confirmed by calculations.

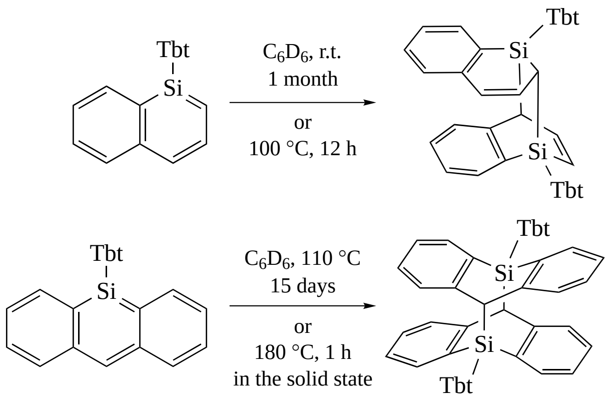
Consequently, it is experimentally evidenced again that the replacement of one of the ring carbons in the aromatic hydrocarbons with a heavier group 14 element does not have a big influence on the spectroscopic properties of the resulting $[4n + 2]\pi$ conjugated metallacycles as compared with the parent carbon analogs.



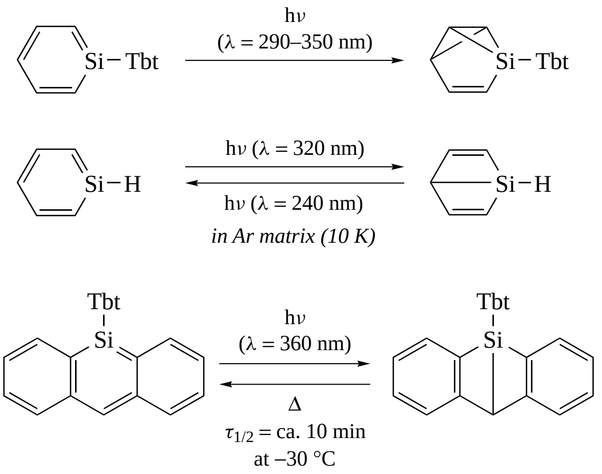
Scheme 57

8.3 Reactivities

Thermal and Photochemical Stability. Kinetically stabilized silaaromatic species shown in Scheme 53 showed some difference in their stability in solution (Schemes 57 and 58). Tbt-substituted silabenzene has high thermal stability in solution and no dimerization was observed on heating in hexane at 100 °C for a long time. However, standing its hexane solution in C_6D_6 for 4 months resulted in the formation



Scheme 58



Scheme 59

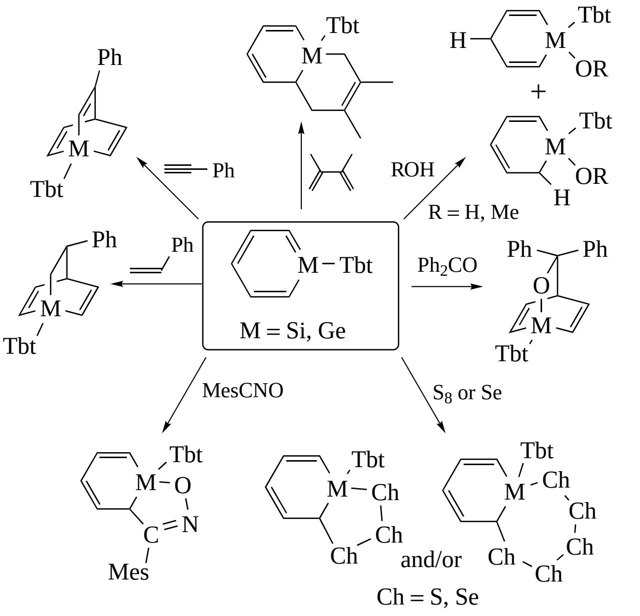
(ca. 50%) of the corresponding [4 + 2] dimer, the structure of which was confirmed by X-ray crystallographic analysis (Scheme 57). The formation of the [4 + 2] dimer of 1-Tbt-silabenzene is interesting because the transient silatoluene reportedly undergo immediate dimerization to afford a [4 + 2] dimer[194] but the transient 1,4-di-*t*-butylsilabenzene is known to dimerize to give a [4 + 4] dimer.[192] Tbt-substituted 1-silanaphthalene also undergoes thermal dimerization in C_6D_6 to give the corresponding [4 + 2] dimer (at room temperature for 1 month in an almost quantitative yield or at 100 °C for 12 h in 49%), and the dimer is quite stable even on heating in C_6D_6 at 120 °C.[185] On the other hand, Tbt-substituted 2-silanaphthalene does not undergo any dimerization even on heating or standing.[176] Tbt-substituted 9-silaanthracene was found to be stable at room temperature either in solution or in the solid state, but it underwent thermal dimerization at higher temperatures (110 °C in C_6D_6 for 15 days or 180 °C in the solid state within 1 h) to give the [4 + 4] cycloaddition product quantitatively, and no thermal dissociation of the dimer to the initial 9-silaanthracene was observed even on heating at 300 °C.[186] It is very interesting that the thermal stability of the Tbt-substituted silaaromatics varies depending on the fused ring skeletons and/or the position of the silicon atom.

Photochemical isomerization was also examined for the kinetically stabilized silaaromatics (Scheme 59). When the silabenzene was irradiated with the light of $\lambda = 290-350$ nm in C_6D_6, a novel photochemical valence isomerization took place to give the corresponding silabenzvalene as a sole product. The highly shielded ^{29}Si chemical shift of −71.6 ppm observed for this silabenzvalene indicates the three-membered ring character of its central silicon atom.[184] This result is in sharp contrast to the photochemical valence isomerization of the matrix-isolated parent silabenzene into the Dewar-type silabenzene, the formation of which was only evidenced by the IR spectroscopic data indicative of sp ^{3}-SiH moiety.[195] Since DFT calculations (B3LYP/6-31G(d) level) on the relative stability of several valence isomers of silabenzene showed that the energy difference between the Dewar-type silabenzene and silabenzvalene is very small,[184] it is very difficult to assign the photo-isomerized product of the parent silabenzene as the Dewar-type silabenzene absolutely. On the other hand, the irradiation of 9-Tbt-9-silaanthracene in C_6D_6 with the light of $\lambda = 300-500$ nm resulted in the almost quantitative formation of 9-Tbt-9,10-Dewar-9-silaanthracene.[187] Its molecular structure was supported by the ^{1}H, ^{13}C, and ^{29}Si NMR data and chemically confirmed by the ready thermal interconversion to the initial 9-silaanthracene. 9-Tbt-9,10-Dewar-9-silaanthracene was found to be marginally stable at low temperature and the half-lifetime in hexane at −30 °C is estimated as about 10 min.

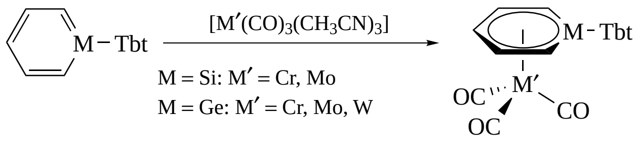
Addition Reactions. All the metallaaromatic species kinetically stabilized by a Tbt group showed considerably high reactivity toward the reagents such as water, methanol, styrene, phenyl acetylene, mesitonitrile oxide, benzophenone, and 2,3-dimethyl-1,3-butadiene. Some of them were allowed to react with elemental chalcogen such as sulfur and selenium to give several kinds of unique cyclic chalcogenides as the cycloadducts. In Scheme 60 were summarized the reactions of the sila- and germabenzenes as the representative.

Interestingly, Tbt-substitued metallabenzenes and 1-silanaphthalene were found to undergo 1,2- and/or 1,4-addition reactions depending on the character of the reactants, while Tbt-substituted 2-metallanaphthalenes afforded only 1,2-addition reaction products. The remarkable reactivity of the metallaaromatic species towards addition reactions implies that their aromatic stabilization energies are insufficient to suppress the inherent high reactivity of the M=C bonds (M = Si, Ge).

Transition Metal Complexation as an η^6-Arene Ligand. Unfortunately, owing to the instability of the substrates under the reaction conditions used, clear experimental evidence has



Scheme 60



Scheme 61

not been obtained yet for the electrophilic substitution reactions of the metallaaromatic species, which may be the greatest point of interest among the reactivities of such novel aromatic systems. However, it was found that the complexation of the sila- and germabenzenes with some tricarbonyl complexes of group 6 metals resulted in the formation of the corresponding η^6-metallabenzene–transition metal complexes as stable crystalline compounds (Scheme 61).[196]

These metallabenzene complexes are thermally quite stable either in the solid state or in solution under argon atmosphere, and no detectable change was observed in the thermolysis in C_6D_6 at 120 °C in a sealed tube for a few days. These complexes were found to be more stable than the Tbt-substituted metallabenzenes toward air and moisture. However, they are still moisture-sensitive and undergo ready addition of water exclusively to their 1,2-positions to give the corresponding 1,2-adduct quantitatively in all cases in spite of the thermodynamic stabilization afforded by the coordination to the tricarbonyl metal center of group 6 metals. The high regioselectivity observed for the water addition to the metallabenzenes complexes is in sharp contrast to the competitive 1,2- and 1,4-addition of water to the Tbt-substituted free metallabenzenes.

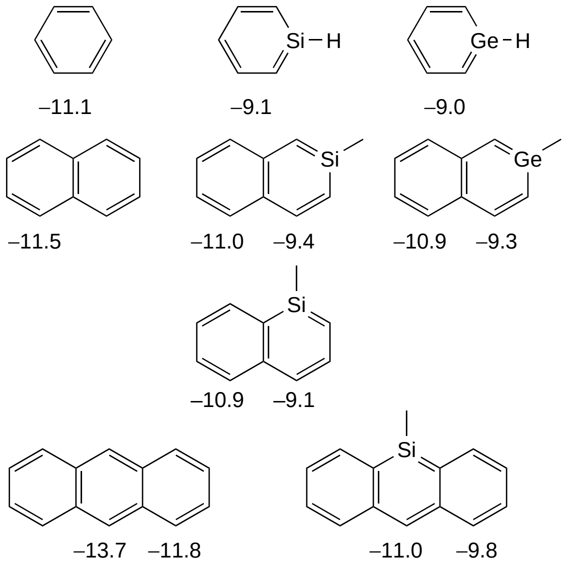


Figure 23 NICS(1) values (ppm) for aromatic systems and their heavier congeners calculated at the B3LYP/6-311G(d) (6-311G(3d) on Si, Ge)//B3LYP/6-31G(d) level

The successful complexation of the metallabenzenes with tricarbonyl transition metals of group 6 is of great importance from the viewpoint of the experimental evidence for the typical reactivity of aromatic compounds.

8.4 Nucleus Independent Chemical Shifts (NICSs)

As described above, the structural and spectroscopic features of the kinetically stabilized metallaaromatic species with Tbt group are in good agreement with those obtained for the less hindered model compounds by theoretical calculations, strongly suggesting that the bulky aromatic substituent (Tbt) does not perturb the intrinsic characters of the metallaaromatic species. As for their aromaticity, further theoretical calculations of NICS(1)s (Nucleus Independent Chemical Shifts)[197] were performed and it was found that monometallaaromatic species have considerably large absolute values as compared with the parent aromatic hydrocarbon systems (Figure 23). Despite the high aromaticity suggested by the NICS calculations, it should be noted again that the isolated metallaaromatics showed high reactivity toward a variety of addition reactions across the metal–carbon double bonds.

9 CONCLUDING REMARKS

Following the pioneering work on the first stable disilene, Mes_2 Si=SiMes_2, several kinds of multiply bonded compounds of heavier group 14 elements have been

successfully synthesized by taking advantage of kinetic stabilization. Thus, the doubly bonded compounds and even triply bonded ones containing heavier group 14 elements are no more imaginary species but are those of real existence when they are appropriately protected by bulky substituents. The construction of a series of such multiply bonded systems of heavier group 14 elements revealed the feature of the core-like nature of the ns electron, namely, the so-called 'inert s-pair effect' or 'nonhybridization effect' of the heavier group 14 elements. With such novel π electron systems of heavier group 14 elements in hand, many chemists have a dream of finding unprecedented useful functions for them. Since all the properties of such attractive compounds have not been revealed satisfactorily, further studies from both experimental and theoretical standpoints should be performed on the chemistry of unsaturated bond species of heavier group 14 elements.

The concept of kinetic stabilization should certainly be of great use for the construction of these unprecedented chemical bondings. Also, cooperation of theoretical calculations with experiments has been shown to be very important to elucidate the intrinsic nature of new interelement linkages of heavier main group elements. We hope the recent remarkable progress in the chemistry of unsaturated heavier group 14 elements introduced here will lead to further progress in the isolation of a unique class of compounds having low-coordinated main group elements and the systematic elucidation of the intrinsic nature of chemical bondings of main group elements.

1 INTRODUCTION

Responsible for the deep reds and vibrant yellows found in the exquisite stained glasses that have adorned medieval cathedrals for more than half a century, Au and Ag nanocrystals (NCs) have experienced an illustrious history even before their unique spectroscopy was understood. NCs are the links that bridge individual molecules (<1 nm) and bulk materials (>100 nm), and their properties result from their finite sizes in this regime. In fact, Au and Ag NCs enjoy distinct optical characteristics *because* of their restricted dimensions, which lead to pronounced optical resonances associated with collective oscillations of surface charges (surface plasmons). While the NC-doped glasses of the Middle Ages can be appreciated for their splendor, the interesting optical properties of these materials have led to a resurgent interest in analogous glasses from a twenty-first century technological perspective, as they have found application in areas like nonlinear optics, sensing, and catalysis.

Methods for embedding metal NCs (*see* ***Metal Nanoparticles, Synthesis of*** and ***Metal Nanoparticles, Organization & Applications of***) and semiconductor NCs (*see* ***Semiconductor Nanocrystal Quantum Dots***) in glasses include such techniques as high-temperature precipitation in molten materials, sputtering, ion implantation, ion exchange, ion irradiation, laser ablation, and sol–gel processing.[1,2] Among the various routes to these composites, sol–gel processing has the distinction of being a 'wet chemistry' approach, and as such, it stands out as the method by which adverse side-effects, such as photodarkening in semiconductor-doped glasses, can be avoided.[2] Sol–gel syntheses have led to the fabrication of composites of better optical quality, smaller NC size dispersities, and larger NC volume loadings than alternative methods, and these improvements are important factors in NC-doped glass applications.

Sol–gel processing relies on the hydrolysis and condensation reactions of metal compounds to afford three-dimensional polymeric networks (*see* ***Sol–Gel Synthesis of Solids***).[3] In contrast to the more traditional ways of making glasses (i.e. from clays or sands at high temperatures), sol–gel syntheses are generally mild routes that employ high purity precursors, which are converted to inorganic oxides through a series of chemical reactions. Sol–gel reactants are typically metal alkoxides or metal salts, and the reactions proceed in organic or aqueous environments, respectively:[4]

$$Si(OR)_4 + 4H_2O \xrightarrow[\text{catalyst}]{\text{MeOH}} 4ROH + Si(OH)_4 \xrightarrow{-2H_2O} SiO_2 \qquad (1)$$

At the sol stage, the solution can be spin-coated or dip-coated to make films. As the reaction progresses, the viscosity of the reaction mixture increases, and the sol solution eventually 'gels', assuming the shape of its containment vessel. Under normal drying conditions, the wet gel gives rise to a xerogel; a supercritical drying environment yields aerogels. This chemistry can be applied to a wide variety of metal precursors, including salts or alkoxides of silica, titania, zirconia, and alumina. Most importantly, the mild reaction conditions allow for the ready incorporation of assorted organic and inorganic molecules, affording the opportunity to fabricate a wide variety of glasses with tailored properties.

By employing these mild sol–gel routes for metal and semiconductor NC encapsulation, the prospect exists for producing NC-based glasses of high optical quality. While a general goal is to prepare optical quality, uniform NC-sol–gel composites with high NC volume loadings and narrow NC size dispersities, the specific requirements of the materials will vary from application to application. This article focuses on two main routes to noble metal and semiconductor NC-sol–gel composites. The first method involves the direct growth of the NCs within the host matrix, and this work has been extensively reviewed in recent articles.[2,4] The latter process concentrates on a decoupled procedure in which the synthesis of the NCs is independent of the fabrication of the composite material.

2 DIRECT GROWTH METHOD FOR NC-SOL–GEL COMPOSITES

Before mild chemical routes to high quality NCs were widely available, NCs were prepared in glasses by such strategies as precipitation, ion implantation, and laser ablation, which typically rely on high-temperature processing

steps (>500 °C).[1,2] Glasses provide a durable, rigid, stable environment for the NCs, and their optical properties can be extensively explored in these transparent hosts. In fact, effects of quantum confinement in semiconductor NCs were first observed in such NC-doped glasses.[5] Despite some successes, drawbacks, including poor material reproducibility, broad NC size distributions (generally greater than 15%), and surface defects, which are particularly damaging for nanoscale semiconducting materials where poor surface quality leads to inferior optical properties, have hindered the wide use of these materials in applications.[2] More recently, the high-temperature routes to NCs have given way to an emphasis on moderate to low-temperature synthetic strategies, which afford colloidal NCs that can be purified and manipulated into larger arrays.

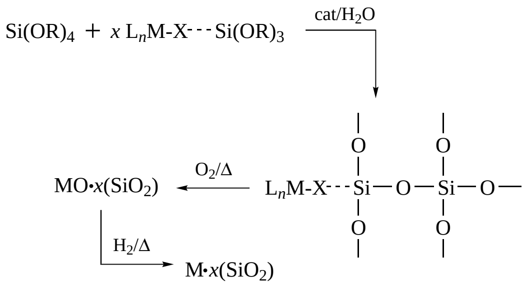
Glassy materials still present an attractive medium for encapsulating NCs because of the stability these environments provide. Direct syntheses of metal and semiconductor NCs in sol–gel glasses have been researched for more than a decade as low temperature, chemical routes to optical quality samples that provide an alternative to high-temperature paths and to the more involved processing that decoupled methods require, which use colloidal NCs as starting materials.[4] The resulting composites have been investigated for their unique catalytic,[4] magnetic,[4] and optical properties,[2,4] including enhanced optical nonlinearities that are important for, for example, all-optical switching. In fact, a significant amount of work on NC composites has been conducted in the context of their nonlinear optical applications. The performance of these materials can be characterized in terms of a resonant, Kerr-type, third-order nonlinear susceptibility that describes the changes in the absorption coefficient and refractive index of a material under the influence of intense light.[6] The changes in susceptibility, $\chi(\omega)$, induced by a monochromatic field at a frequency ω can be presented as $\Delta\chi = \chi^{(3)}(\omega)I(\omega) + \chi^{(5)}(\omega)I^2(\omega) + \cdots$, where $I(\omega)$ is the field intensity and $\chi^{(n)}$ is the nonlinear susceptibility of the nth order. Nonlinear optical properties of a material are often characterized by $\chi^{(3)}$, which describes the modifications in χ that are linear in field intensity.

2.1 Noble Metal NCs Grown in Sol–Gel Networks

The direct growth method of metal NC-sol–gel fabrication is the most straightforward approach to these materials. Many avenues have been explored in the context of this methodology, yielding a variety of NC-glass composites, including Cr, Fe, Os, Ni, Co, Pd, Pt, Cu, Rh, Ru, Au, and Ag NCs in silica, titania, zirconia, and alumina networks.[4] Refinements in some of the preparations have led to improvements in NC size dispersities, NC volume loadings, and sample homogeneity. Strict control over the size and stability of the resulting NCs within the transparent hosts is an advantage for the subsequent applicability of the composites.

Very simply, metal salts can be directly added to common sol–gel precursors like tetraethylorthosilicate (TEOS) in alcohol.[2,4] Polymerization reactions are initiated, and a porous gel forms in which the metal salt is embedded within the metal-oxide framework. Reduction reactions are then used to give the corresponding metal NCs, and these treatments can involve exposure to gases such as hydrogen at elevated temperatures (usually >500 °C, although lower temperatures have been reported),[4] interaction with chemical agents (e.g. borohydride or dextrose, which generates H_2 in situ following thermal decomposition),[7–9] or irradiation with UV light.[7] This approach has been successfully applied for the sol–gel synthesis of, for example, Co, Fe, Cu, Ni, Au, and Ag NCs,[4] and particle sizes can be tuned by changing hydrolysis conditions and reduction times and temperatures.

The drawbacks associated with this method of NC-sol–gel fabrication are broad NC size dispersities and sample inhomogeneities. Improvement in these features, particularly the latter, is critical for effective heterogeneous catalysis to be realized. Efforts in enhancing these important parameters have led to the design of new approaches, one of the more popular focusing on organically modified gels as depicted in the following equation:[10]



(2)

In this strategy, metal salts are tethered directly to the sol–gel matrix through bifunctional ligands of the type X···Si(OR)$_3$, where X is capable of coordinating to the metal center and the siloxy group co-condenses with silica precursors like TEOS or tetramethylorthosilicate (TMOS) to afford a composite in which the metal salt is intimately connected to the silicon-oxide network.[10] Under oxidative conditions, metal-oxide particles are formed and organic components are removed. These particles can then be reduced under a stream of hydrogen at elevated temperatures. Using this procedure, composites containing a uniform distribution of metal NCs throughout the sol-gel matrix are prepared. In addition, the particle size dispersity can be fairly narrow with limits dependent upon NC composition. For example, Pd NCs with a diameter range of 2.8–5.2 nm were synthesized using this approach (Figure 1). This chemistry has been applied to form NCs of Ag, Co, Cu, Ni, Pd, and Pt in silica networks using ligands of the type $X(CH_2)_3Si(OEt)_3$, in which X is NH_2, $NHCH_2CH_2\ NH_2$, or CN.[10] The effectiveness of this linking molecule at controlling particle size distribution was determined by performing a comparative study in which

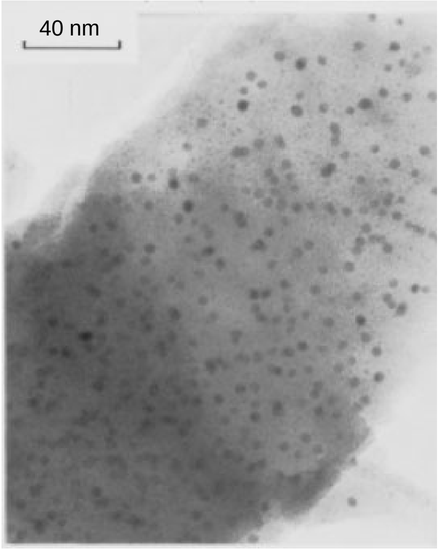


Figure 1 Scanning transmission electron micrograph of a Pd-silica composite formed via an organically modified gel. The average particle size is 3.8 nm, and the distribution range is 2.8–5.2 nm. (Reprinted with permission from Ref. 10. © 1991 American Chemical Society)

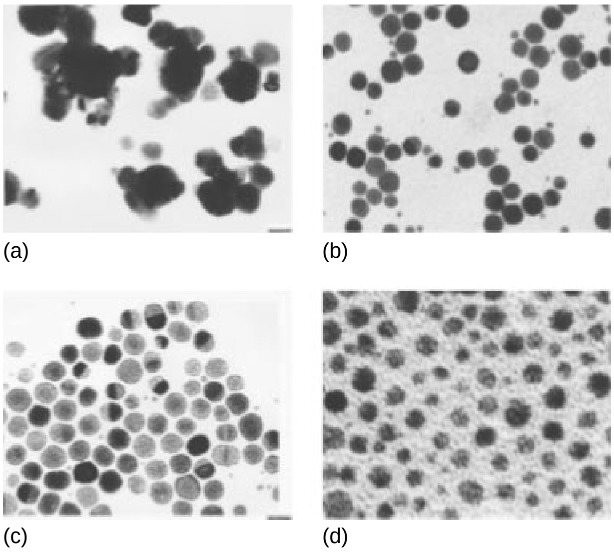

Figure 2 Transmission electron microscopy (TEM) images of EDAS-gold deposits from a sol containing EDAS:Au = 30:1 and Au = 1 mM at pH (a) 2, (b) 5, (c) 7, and (d) 9.5. At low pH, the particles are aggregated. The average particle size for (b), (c), and (d) is 5–6 nm. For pH = 5, a bimodal distribution is readily apparent. (Reprinted with permission from Ref. 8. © 1999 American Chemical Society)

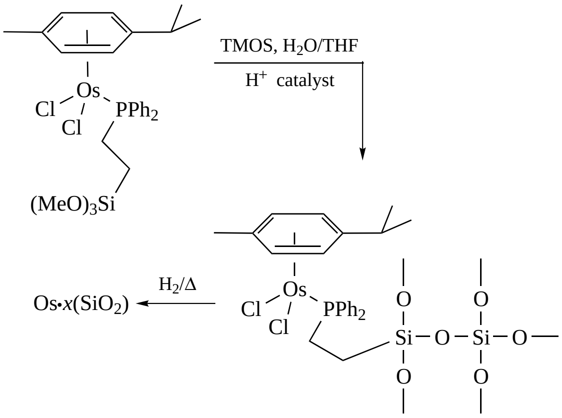
the bifunctional ligand was omitted from the reaction. In the latter case, the size distribution was significantly broadened.

This methodology has been increasingly employed for the synthesis of additional systems, thereby supplementing the results from the first investigations in the early 1990s. Single source precursors of Ag, Cu, Pd, Pt, Os, Re, Ru, and Au, whose ligands terminate in siloxy moieties, can be prepared, and these molecules then serve as the starting reagents that lead to the corresponding NC-doped sol–gel glasses.[11,12] An example of this reaction is shown in equation (3).[12] The Os-doped metal complexes were reduced directly with hydrogen, thereby avoiding oxidative treatments that would lead to the highly toxic, volatile intermediate OsO_4. By exploiting these reactions conditions, NC-silica composites were prepared in which the dopant was uniformly dispersed:



(3)

A new take on this methodology omits the TEOS or TMOS precursor from sol–gel processing and relies purely on the hydrolysis and condensation reactions of the siloxy-functionalized metal complexes. In one example, an aqueous or methanolic solution of N-[3-(trimethoxysilyl)propyl]ethylenediamine (EDAS) and $HAuCl_4$ was prepared, and the polymerization reactions were initiated with water and varying amounts of HCl.[8] Chemical reduction of the gold salt using $NaBH_4$ gave rise to Au-doped silica sols that were either dip-coated or spin-coated into films or allowed to gel in their containers. The properties of the resulting gels were dependent on pH (Figure 2), and one set of conditions afforded a NC size range as narrow as 5–6 nm in a material that was stable with respect to NC aggregation for greater than four months. The results indicate that interaction of EDAS with the Au salt reduces the rate of reduction, and that once formed, coordination of the EDAS ligands to the Au NC surface slows down particle growth.[8] The siloxy groups also have the potential to form shells around the NCs, thereby stabilizing them during sol–gel processing. This method is generally applicable to other metal NCs including Ag, Pd, and Pt, although preliminary results with Ag NCs, which have a much lower affinity for amines, suggest a wide size distribution.

The pore doping approach has also been successful in maintaining small NC size dispersities.[2] Initially, porous dip-coated alumina and titania films were fabricated and then directly immersed into aqueous solutions of $NaAuCl_4{\cdot}2H_2O$ so that the $AuCl_4$ ions could be incorporated into the pores of

the sol–gel films.[13] Following thermal treatment, Au NCs approximately 2 nm in diameter formed. These NCs are typically smaller than those particles grown in composites prepared via other routes, suggesting the size of the NCs is limited by the pore size in the dip-coated films.

2.2 Semiconductor NCs Grown in Sol–Gel Networks

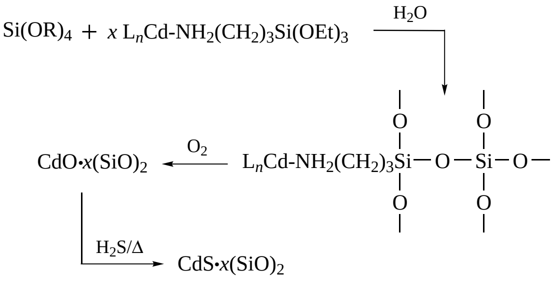
The strategies for precipitating semiconductor NCs in sol–gel composites parallel those direct growth methods utilized to fabricate metal NC-doped sol–gels.[4] A general approach involves the addition of the metal salt to the sol solution and the subsequent exposure of the resulting gel to an atmosphere of H_2S.[2,4] In the final gel, CdS NCs are embedded throughout a silica matrix. CdS growth can also proceed through a CdO intermediate. In one procedure, cadmium acetate was added to the TEOS precursor.[14] Dip-coating gave rise to a film, which was then subjected to oxidative conditions to decompose organic matter. Exposure of the sample to an H_2S atmosphere at 200 °C yielded CdS NCs. Xerogels were also prepared in this study, and a maximum value of 2.1×10^{-7} esu for the third-order nonlinear susceptibility of the sample was reported and shown to be dependent on NC concentration within the sample.

Similar methods have been used to prepare CdS NCs in optical quality borosilicate glasses.[4] Nonlinear optical characterization of one composite sample with particle sizes ranging from ∼2.5–5.5 nm yielded a range for $\chi^{(3)}$ of 10^{-7}–10^{-6} esu.[15] Optical gain measurements of a similar material afforded a value of 33 cm^{-1} at room temperature.[16] At 11 K, maximum gain values reached 200 cm^{-1}, and like the optical nonlinearities, these values were also dependent on NC concentration.[17]

Another possibility is to include both the metal salt and the chalcogenide precursor (e.g. thiourea) in the sol solution.[2,4] As an example, heat treatments of 350–400 °C for 10–15 h in air eliminated the residual organics and afforded the corresponding CdS NCs.[18] NC diameters could be tailored by controlling the ratio of Cd/Si, but size dispersities still remained large (>15%). A similar approach can be used to prepare PbS NCs in silica xerogels.[4] In one study, a mixture of TMOS, $Pb(NO_3)_2$, ammonium hydroxide, water, and thiourea in methanol was allowed to gel, during which time the PbS NCs formed.[19]

The direct growth of MSe or MTe (M is Cd, Zn, or Pb) NCs in sol–gel typically combines both the metal and chalcogenide sources in the sol solution.[2,4] Silica sol–gels prepared with cadmium acetate and H_2SeO_4 (or Se/HNO_3) yielded CdSe NC-silica composites after exposure to H_2/N_2 mixtures at temperatures from 300 to 900 °C. By controlling thermal parameters, the size of the NCs could be managed; however, the size dispersities remained broad.[20] Cadmium acetate and TeO_2 reagents added to zirconia tetrapropoxide afforded materials that upon reduction with hydrazine or stannous chloride under moderate temperatures gave CdTe.[21] Porous Cd-doped silica gels exposed to solutions of KSeCN or selenourea yielded embedded CdSe NCs with sizes tunable according to Se solution concentrations and immersion times.[18,22]

Organic ligands added to sol solutions can be used to control NC growth and size dispersities.[2,4] This approach, analogous to the method described for metal NCs in Section 2.1, employs bifunctional linkers to tether metal salts to the sol–gel network to improve the homogeneity of the sample. Silica precursors mixed with 3-aminopropyltriethoxysilane (APTES) and cadmium nitrate were allowed to gel.[23] Following oxidative treatments, the resulting CdO particles were converted to CdS upon exposure to H_2S, as shown in equation (4).[23] The size distribution of particles was much narrower under these conditions than when APTES was omitted from the reaction.



(4)

The pore doping approach has also been applied to the synthesis of semiconductor NCs in sol–gels in order to limit NC size and improve size dispersities.[2] This method, which relies on samples with well-defined pore structures, was used to fabricate waveguides.[24] Silica-titania films prepared from TEOS and tetrapropylorthotitanate were immersed in aqueous solutions of cadmium fluoride. After heating the film, the sample was exposed to H_2S gas, generating CdS NCs with maximum sizes of 2.6 nm. While small sized NCs were obtained, the major drawback to this approach was the difficulty in achieving a homogeneous dispersion of NCs throughout the sample.

3 ENCAPSULATION OF COLLOIDAL NCs IN SOL–GEL MATRICES

New routes to high quality colloidal NCs of varying compositions and shapes appear in the literature almost on a weekly basis. The most successful of these approaches to crystalline semiconductor NCs with excellent optical properties share the same basic premise of pyrolysis of metal-organic precursors in solutions of hot coordinating solvents.[25] In contrast, the syntheses of noble metal NCs typically rely on the reduction of metal salts in the presence of citrate ions (e.g. Au or Ag), in two-phase systems (e.g. Au or Ag), or under high-temperature conditions in the presence of stabilizing

agents (e.g. Co and Ni).[25] In general, the best procedures afford colloidal NCs that are highly crystalline and highly monodisperse (size dispersities <10% are generally achieved from the reaction mixture or following post-preparative, size-selective precipitation of the NCs). A unique feature of the colloidal NCs is the chemical flexibility that stems from the stabilizing agents that cap the NCs during the course of the reaction. These ligands prevent the particles from aggregating, allow for NC solubility in a variety of organic solvents, and can be exchanged for ligands of varying functionalities. The surface capping groups also play an important role with regards to the photophysical properties of semiconducting NCs, as they passivate surface trapping states, allowing for highly efficient emission properties.

While many of the direct growth methods discussed in Section 2 are express routes to NC-doped gels and glasses, the resulting materials can have low volume loadings (<1%) and large size dispersities (>15%), which may adversely affect the application of these materials. In addition, the semiconductor NCs in these composites are often beset by poorly controlled surface properties, leading to low photoluminescence (PL) quantum yields (QYs). More recently, researchers have sought to decouple the synthesis of the NCs from the fabrication of the sol–gel matrix material,[2,26] thereby exploiting the synthetic procedures already available for making high quality, highly monodisperse NCs of specific sizes and relying on mild sol–gel processing conditions to preserve these properties. This approach also furnishes the opportunity to include core/shell NCs and NCs of modified shapes, such as rods, wires, or disks, into the glass matrices, which is an advantage over direct growth methods that are typically unable to achieve precise control over these parameters.[26]

3.1 Sol–Gel Matrices as Hosts for Colloidal Noble Metal NCs

Colloidal metal NCs can be directly introduced to the sol precursors to fashion metal NC-sol–gel composites. Silica glasses fabricated from TMOS with Au NCs as the dopant and ammonia as the catalyst contained NCs with diameters ranging from 10–20 nm uniformly distributed throughout the framework and exhibited measurable third-order nonlinear susceptibilities (2.2×10^{-9} esu).[27] Gold NC concentrations could be increased to 1 wt% with no evidence of particle aggregation, even in the absence of stabilizer.[28] Polymer-protected Au NCs with broad size dispersities were also incorporated into silica matrices using ammonia as a catalyst.[29] In the absence of polymer, extensive NC aggregation was observed.

Improvements in the stability of Au colloids should lead to composites of better quality. In one approach, 15 nm Au NCs with a 10% polydispersity were synthesized and overcoated with a silica shell.[30] The Au@SiO_2 NCs were added to a methanol solution of TMOS, and a gel formed. The silica-overcoated Au NCs were incorporated into the silica network homogeneously and without aggregation of the particles, as evidenced by the retention of optical properties following sol–gel processing, even at increasing concentrations (Figure 3). Third-order nonlinear susceptibility values of 7.5×10^{-10} esu were measured in gel samples with concentrations of 0.3 wt%. While the volume loading of NCs is still quite low, the success of this approach with Au NCs indicates the potential for extending this strategy to prepare silica-overcoated NC composites comprising a variety of metal and semiconductor materials.

3.2 Sol–Gel Matrices as Hosts for Colloidal Semiconductor NCs

Sol–gel matrices can also be employed to encapsulate colloidal semiconductor NCs. In one example, CdSe and CdSe/ZnS core/shell NCs were embedded in silica matrices using octylamine as a catalyst in solutions of butanol.[31] The octylamine reagent also displaced the existing surface cap of the NCs, leading to an enhanced PL QY (the resulting CdSe-silica composites exhibited QYs between 5 and 10%). At this stage, volume loadings were less than 0.1%. In general, the CdSe/ZnS core/shell NC heterostructures are more robust than their CdSe counterparts in this system and maintain luminescence for months. More recently, QYs and

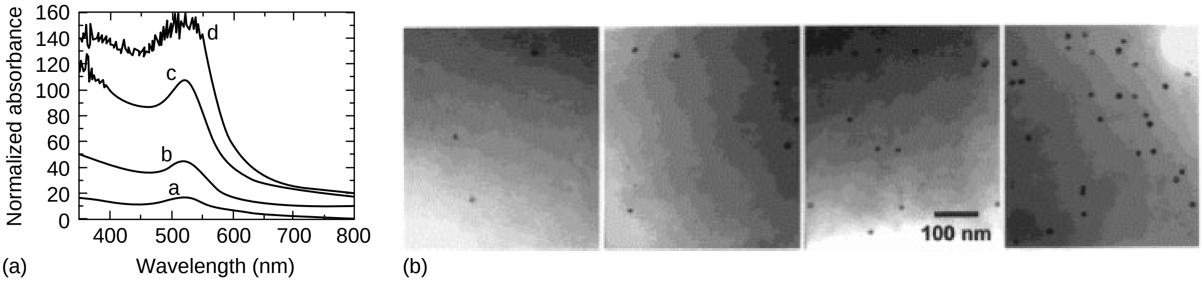


Figure 3 (a) Optical absorption spectra of thin xerogels containing Au@SiO_2 NCs at concentrations: a – 0.010, b – 0.019, c – 0.25, and d – 0.6 wt% Au. In each case, the surface plasmon resonance can be found at the same wavelength. (b) TEM images of xerogels containing Au@SiO_2 NCs at the same volume loadings as depicted in the optical absorption spectra. (Reprinted with permission from Ref. 30. © 2001 American Chemical Society)

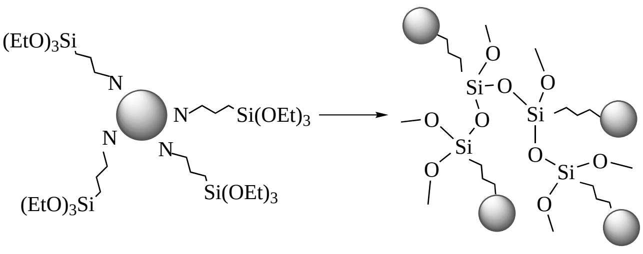
volume fractions greater than 40% and 1%, respectively, were reported.[26]

In a similar approach, titania composites doped with CdSe and CdSe/ZnS NCs were prepared.[32] Here the NCs were mixed with titanium tetrabutoxide in a 2:1 THF/ethanol solvent system, and volume fractions as high as 13% were reported in films that were spin-coated from the sol solutions. While QYs for the CdSe/ZnS-titania sols remained near 10%, smaller values were reported for CdSe NCs that were not initially overcoated with ZnS. In addition, the samples were not very stable, as the PL intensity was observed to decrease in the films almost immediately following processing.

The surface chemistry of the as-synthesized NCs has been exploited in order to develop methods for anchoring the semiconductor NCs directly to the sol–gel network. The approaches investigated are analogous to methods discussed in Section 2 with respect to organically modified gels, with one major exception – the colloidal NC, and not just the starting metal salt, is directly tethered to the metal-oxide network:



(5)

As an example, APTES-functionalized CdSe NCs were synthesized such that the triethoxysilane functionality was found of the periphery of the NCs.[33] Hydrolysis and condensation reactions of this moiety led to an extended metal-oxide network. Following thermal curing up to 350 °C, films with thicknesses near 10 μm were obtained. Comparison of this method to direct growth routes to CdSe-doped silica films suggests that the APTES-functionalized CdSe NC approach yields materials with better NC monodispersity and higher volume loadings (nearly 5%) than the alternative. The results indicate that doping silica composites with colloidal NCs has the advantage of using size-selective precipitation techniques to further improve the monodispersity of the NC sample.

Similarly, CdS NCs capped with mercaptopropyltrimethoxysilane (MPTMS) were added to alcoholic solutions of TEOS or TMOS and subsequently incorporated into silica matrices.[34] Pb and Hg-based NCs have also been synthesized with MPTMS as the capping agent, and the role of the pendant siloxy groups is again to anchor the NCs to the silica, silica-titania, or zirconia networks.[35–37] Zirconia films doped with PbS NCs were prepared with refractive indices up to 1.53 and a third-order susceptibility value of 1.3×10^{-7} esu.[37] Higher refractive index silica-titania sol–gel films doped with PbS (n = 1.63) were also fabricated.[36]

Hydroxy moieties have been explored as alternatives to siloxy groups for attaching the NCs to the sol–gel framework. In one example, the surface capping groups of high quality CdSe and CdSe/ZnS NCs were exchanged for tris(hydroxypropyl)phosphine ligands.[38] The resulting NCs have hydroxy groups on their surface, which allow them to be tethered to a sol–gel matrix. Titania is an attractive medium in this example because hydrolysis and condensation reactions do not normally require an acid or base catalyst to ensue, which can sometimes adversely affect the optical properties of the semiconductor NCs. The sols were spin-cast into thin films with a refractive index tunable from 1.61 to 1.82 and a 10–12% NC volume loading. Amplified spontaneous emission (ASE) was observed at liquid nitrogen and room temperatures in these materials, and NC-titania waveguide structures were developed into a distributed feedback laser.[39]

Higher volume loadings in NC-doped titania matrices were achieved with CdSe NCs overcoated with aminohexanol ligands.[40] The resulting nanocomposites exhibited a 20% volume loading of CdSe NCs (Figure 4a), spin-coated films had refractive indices tunable from 1.6 to 2.1, and the NCs could be incorporated into the titania matrix without

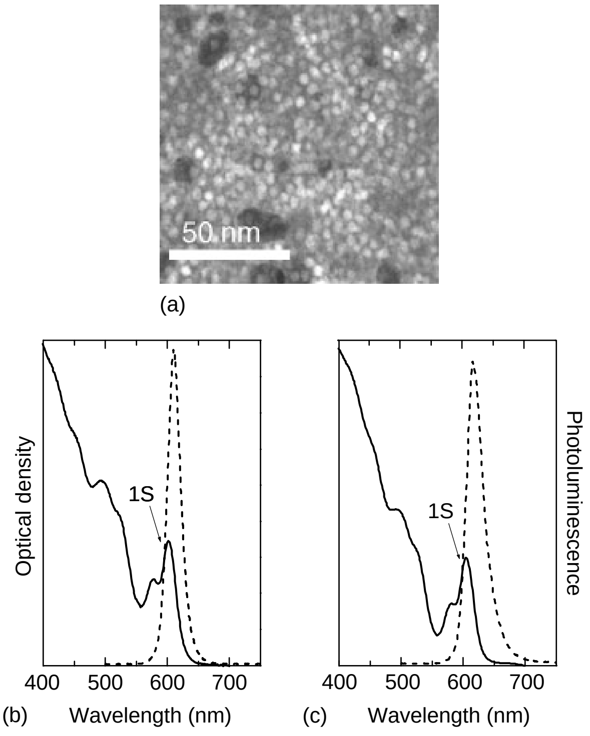


Figure 4 (a) Low-resolution scanning transmission electron microscopy (STEM) image of a thin sol–gel film (1–2 layers) containing 5 nm CdSe NCs. The NCs appear in white, and the dark areas are pores. (b) Linear absorption (solid line) and PL (dashed line) spectra of as-prepared CdSe NCs (r = 2.5 nm) in a hexane solution (the arrow marks the lowest 1S absorption resonance). (c) Absorption and PL spectra of the same NCs after their incorporation into titania

changes in their size or size dispersity (<7%) (Figure 4b and c). In addition, QYs as high as 15% were reported for the CdSe NCs in the titania sols. These waveguide structures demonstrated ASE at liquid nitrogen and room temperatures with optical gain values (100–200 cm^{-1} at room temperature) similar to values obtained for self-assembled films. A third-order nonlinear susceptibility of 1.5×10^{-4} esu was determined, which is comparable to results observed for bulk semiconductors (likely because of the high NC filling factors in the composite) and more than two orders of magnitude greater than $\chi^{(3)}$ values reported for composites prepared via the direct growth method discussed in Section 2. The titania composites prepared from colloidal CdSe NCs show improved photostability with regards to conventional, close-packed films of CdSe NCs and demonstrate consistent performance for several hours under continuous illumination.

While the ligand-exchange approach has been successful in generating functionalities on the NC periphery that allow them to be tethered to the metal-oxide sol–gel network, this exchange causes surface defects, which inevitably lead to a reduction in QY. In order to avoid deteriorating optical properties, new routes have been developed as a means of promoting higher QYs, which are important for light-emitting applications. CdTe NCs capped with thioglycolic acid were synthesized.[41] APTES was used as the sol–gel precursor, and the NCs were anchored to the resulting silica network through the ionic interactions between the COOH groups on the NC periphery and the amino groups of APTES. QYs in excess of 35% were reported, and the optical properties of the gel were stable for at least 6 months.

Polymer-NC adducts have been incorporated into titania and silica matrices via an amphiphilic approach that circumvents the need for ligand exchange.[32] Octylamine-modified poly(acrylic acid) complexes hydrophobically capped NCs as a result of the hydrophobic interactions between the ligands on the NCs and the hydrophobic portion of the amphiphilic polymer (Figure 5). The COOH groups remain on the NC periphery and can serve as the reactive sites through which the NCs are incorporated into the titania matrix. This general approach has been demonstrated for including CdSe and CdSe/ZnS NCs capped with a variety of ligands into titania and silica sol–gel networks. Volume fractions as high as 6% were obtained (these values are necessarily lower than those obtained for the ligand-exchange approach as a result of the added bulk of the polymer) with a refractive index tunable to 1.8 and QYs as high as 47%. ASE was also observed in these composites. This procedure is applicable to a wide variety of NCs and was successfully employed for incorporating PbSe NCs into titania matrices.[42] In this configuration, ASE was demonstrated, for the first time, from colloidal NCs emitting in the near infrared.

4 CONCLUSIONS

Sol–gel processing has been used to successfully encapsulate NCs in transparent host matrices, with the requirements of the resulting composite dictating the precise fabrication routes employed. By simply changing a few basic parameters, the properties of the materials can be easily and abruptly altered. Generally, the approach to these composites broadly diverges into two distinct paths. In

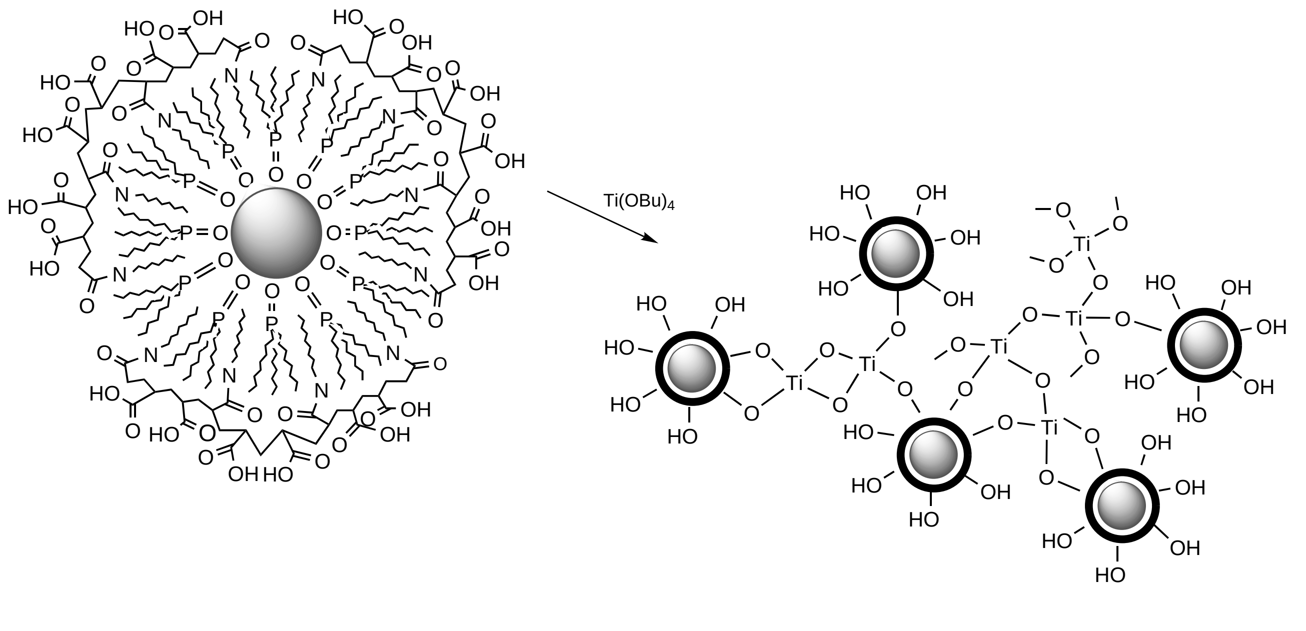

Figure 5 Polymer–NC complex showing an idealized micellar polymer shell (40% octylamine-modified poly(acrylic acid)). Upon addition of the titania precursor, the NC/polymer adducts are linked to each other through the titania network

one strategy, the synthesis of the NCs occurs during the fabrication of the host matrix. This direct growth method has been investigated as an express route to NC-doped glasses that usually involves the addition of metal salts to sol–gel precursors. Subsequent reduction or precipitation of the embedded metal salts, either with gases or other chemical reagents, leads to the formation of the desired NCs. The second approach focuses on a decoupled process in which the synthesis of the colloidal NCs is independent of the fabrication of the composite network. In this way, the size, shape, and composition of the NCs can be tailored for specific applications, promising a precise control over the dopant parameters that is unavailable in the direct growth method.

The flexibility of the methods described enables a variety of important materials properties, including NC volume loading and size dispersity, matrix pore size and chemical composition, and composite refractive index, to be customized by simply varying a few conditions. In addition, sol solutions are highly processible and are essentially unrestricted with regards to geometry, as they can be used to form films or fibers or incorporated into various cavities, where they can assume the shape of their containment vessels. The versatile features of this process provide a whole palette of options from which to choose, allowing for a wide assortment of tailored materials to be prepared while still relying on the same basic methodology for fabrication.

1 INTRODUCTION

The term ‘nanoparticle’ is not properly defined. Roughly, one could say that any particle on the nanometer scale is to be called a nanoparticle. However, this would not express what ‘nanoparticle’ really means. The increasing interest in metal nanoparticles is based on their size-dependent properties placing them between molecules and bulk materials. Therefore, it is not very meaningful to define an exact size range for nanoparticles. Owing to their special properties, metal nanoparticles are contributing decisively to the expanding importance of nanosciences and in consequence of nanotechnology. Thus, the term ‘nanoparticle’ is inevitably linked with the definition of nanoscience and nanotechnology, respectively. What is nanoscience and nanotechnology? Among numerous definitions published in scientific papers as well as in secondary literature, one that has recently been defined seems to be the most comprehensive one and also the most suited one to define the term ‘metal nanoparticle’: *Nanotechnology comprises the emerging applications of nanoscience. Nanoscience is dealing with functional systems based on the use of subunits with specific size-dependent properties of the individual subunits or of a system of those*.[1]

A functional system is best described as a collection of a distinct number of interacting subunits forming a new entity with specific properties. The subunits are hierarchically organized on different levels of complexity, leading to new qualities of the functional system that cannot be achieved by uncontrolled combination of the subunits.

Specific size-dependent properties cover magnetic, mechanic, electronic, optical, thermodynamic, and thermal features as well as the abilities for self-assembly and recognition. The specific size-dependence of these properties becomes evident when they

– no longer follow classical physical laws but rather are described by quantum mechanical ones;
– are dominated by particular interface effects;
– exhibit properties due to a limited number of constituents, since the usual term ‘material’ refers to an almost infinite number of constituents (e.g. atoms, molecules) displaying an averaged statistical behavior.[1]

These three points comprehensively describe the conditions that convey the meaning of ‘nanoparticle’ much better than a simple section of a length scale. They exclude the huge number of oligo- and multinuclear cluster compounds, mainly of organometallic nature, that have become known in the course of the last 2–3 decades. Most of them exhibit typical molecular behavior, that is, they do not follow the rules described before. The term ‘cluster’ will therefore be avoided in the following in order to distinguish these molecular species from those being defined as nanoparticles.

This article on the synthesis of metal nanoparticles is divided into two parts. The first one deals mainly with nanoparticles consisting of noble metals, except for a few examples. The second one will describe synthetic strategies to generate magnetic nanoparticles that may also exist in metal combinations. Magnetic nanoparticles are attracting increasing attention owing to their promising properties with respect to novel magnetic devices.

There exists a huge number of synthetic procedures for metal nanoparticles, especially those consisting of noble metals because of the easy reducibility of noble metal salts. To discuss all the syntheses in detail would exceed the scope of this article by far. Rather, synthetic strategies, elucidated with the help of examples, will be discussed in the following.

Usually, syntheses of metal nanoparticles aim at the generation of monodisperse species. This is especially the case in more recent years, since the properties of interest become more expressed the more uniform the particles are. Metal nanoparticles with broad size-distributions have a long history in many technological applications, for instance, in heterogeneous catalysis, and so are not necessarily developed aiming at monodispersity. High-temperature reduction of metal salts on oxidic supports, a general industrial method to generate catalysts, are of course not very well suited to produce monodisperse particles. On the other hand, synthetic approaches to noble metal nanoparticles, traditionally called colloids, with rather narrow size distribution, originate already from Michael Faraday’s time, that is, the mid-nineteenth century.[2] Reduction of tetrachloroaurate $[AuCl_4]^-$ solutions with white phosphorus resulted in the formation of the known deep red solutions of gold nanoparticles (colloids) with surprisingly narrow size distributions. At the beginning of the twentieth century, Zsigmondy carefully studied the physical properties of colloidal solutions (metal sols) on a scientific

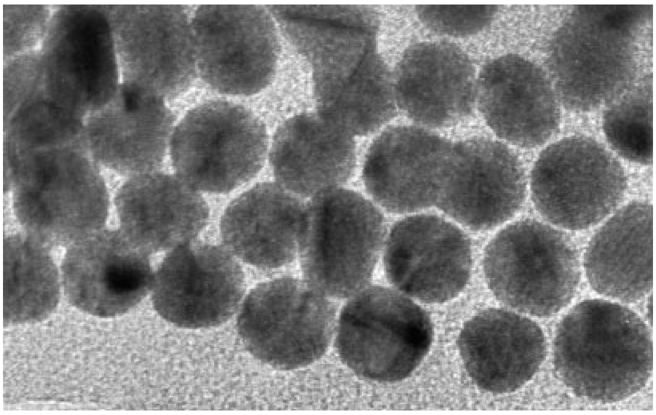

Figure 1 TEM image of 18 nm gold particles synthesized by the Turkevitch method

basis, especially the relation between preparative conditions and particle size using ultramicroscopy.[3] Numerous synthetic procedures have been developed over the years since the very first experiments. Later, Turkevitch *et al.* contributed considerably to synthetic aspects.

The knowledge at the end of the first half of the twentieth century has been summarized by Turkevitch, describing detailed synthesis conditions as well as first electron microscopic investigations.[4,5] He also contributed remarkably to the understanding of nucleation processes, particle growth, and agglomeration mechanisms. Turkevitch's preparative methods are partially used until today. Figure 1 shows a transmission electron microscopic (TEM) image of gold nanoparticles, synthesized by the Turkevitch method.

Nanoparticles in the size range of about 2–100 nm, depending on the experimental conditions and on the metal, became available.

The successful generation of metal nanoparticles is unavoidably linked with successful protection of the particles' surfaces, otherwise spontaneous aggregation with formation of metallic precipitates would happen. For that reason, some general and crucial aspects concerning stabilization of metal nanoparticles will be discussed before the description of synthetic strategies.

2 STABILIZATION OF METAL NANOPARTICLES

Metal nanoparticles are unstable with respect to agglomeration to the bulk. van der Waals forces between the particles attract them to such an extent that metal–metal bond formation occurs. The fact that nanoparticles can be kept in solution is due to either electrostatic or steric stabilization.[6] For instance, the ruby red gold sols, prepared from $[AuCl_4]^-$ and sodium citrate as reducing agent, are stabilized by an electrical double layer formed by adsorbed citrate and chloride ions and the corresponding cations. Thus, Coulombic repulsion between the particles happens, keeping them in solution. Figure 2 elucidates this electrostatic stabilization of metal nanoparticles.

At moderate interparticle distance, a weak minimum in potential energy guarantees stable arrangements of nanoparticles as long as the surface charge is not reduced, for instance, by displacement of adsorbed ions.

The second strategy by which metal nanoparticles can be stabilized is the fixation of molecules by the particles' surface atoms. The protecting molecules may consist of polymers, surfactants, or ligands, as they are known from traditional complex chemistry. The use of polymers is for their amphiphilic nature, that is, they have not only to coordinate to the metal particle, but must simultaneously be solvated by the surrounding fluid. Gelatin, agar, cyclodextrins, cellulose acetate, and cellulose nitrate are used as well as synthetic polymers. Poly(vinylpyrrolidone) (PVP) and poly(vinylalcohol) have turned out to work perfectly in this respect.

Surfactants tend to form micelles and so-called reverse micelles, depending on the solvent. Sphere-like holes are formed either by the hydrophobic tails or the hydrophilic heads of the surfactant molecules. Both are suited perfectly to encapsulating metal nanoparticles.

Small molecules such as phosphines and alkane thiols stabilize metal nanoparticles in a very effective manner. Very stable covalent metal-phosphorus or metal–sulfur bonds lead to such strong ligand shells that in some cases the protected particles can even be isolated in solid state, which can never be done with electrostatically stabilized particles. The chemical nature of the protecting ligand molecules is responsible for the solubility of the particles. Thus, the use of organic solvents has become very useful for several reasons. Figure 3 shows a sketch of the three types of steric stabilizations of metal nanoparticles.

3 SYNTHESES OF NOBLE METAL NANOPARTICLES

Chemical syntheses of metal nanoparticles are all based on the use of appropriate precursor complexes. Depending on the metal, its oxidation state, the desired type of nanoparticle, and so on, the methods applied vary in a wide range. Besides chemical syntheses, there exist also physical approaches. They usually start from bulk metals and use different kinds of energy to transfer them into the atomic state in the gas phase, where the atoms are allowed to condense to nanoparticles. From a preparative point of view, such physical methods are less important, since the resulting particles are bare. As has already been mentioned, unprotected metal nanoparticles cannot exist without aggregation except in the gas phase. That is why gaseous metal nanoparticles have been generated and used

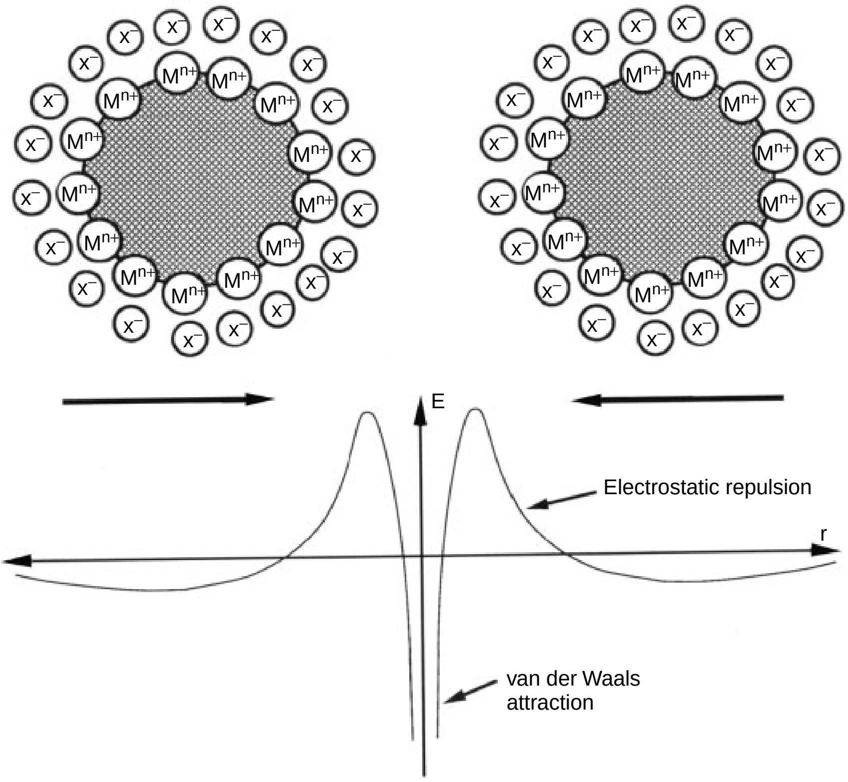

Figure 2 Electrostatic stabilization of metal nanoparticles. Repulsive electrostatic forces outweigh attractive van der Waals forces

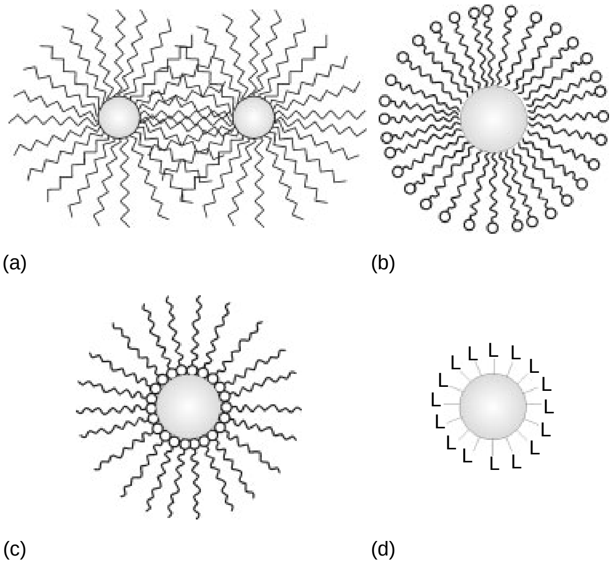

Figure 3 Different types of steric stabilization of metal nanoparticles. (a) polymer molecules on the particles' surface; (b) micelle; (c) inverse micelle; (d) ligand stabilized particle

mainly for spectroscopic investigations, and so on. However, there are some approaches to stabilize naked nanoparticles after their formation by interactions of the gas stream with suited molecules. Therefore, Section 3.1 will briefly deal with some physical methods, before chemical routes will be discussed in somewhat more detail.

3.1 Physical Methods

As already mentioned, the simplest way of generating metal nanoparticles in the gas phase is to produce atoms that are subsequently allowed to coalesce under controlled conditions. This so-called metal–vapour synthesis requires more or less expensive equipment. Numerous modifications of this well established technique have been successfully applied. However, a detailed description of all the devices would exceed the scope of this article. For a summarizing overview, see Reference 7. Some more recent and relevant results shall be mentioned here.

Laser ablation is one of the modern and frequently used methods.[8–12] The disadvantage of broad size distribution could be improved by the so-called 'laser-induced size reduction'. For instance, in the case of gold nanoparticles, their well expressed plasmon resonance around 520 nm can be used to influence the size and shape of the particles.[13–18] Thus, more or less monodisperse gold particles of 1.7 nm and 3.4 nm could be generated with a 532-nm pulsed laser irradiation of gold metal plates in diluted sodium dodecylsulfate solutions.[19]

The solvated metal-atom dispersion (SMAD) technique uses a traditional reactor to generate atoms from bulk gold.[20,21] The gold atoms are then frozen out at 77 K in acetone vapor. After warming up, acetone-stabilized gold nanoparticles are formed that can be further stabilized by dodecanethiol. Gram amounts of gold nanoparticles stabilized in such a manner can be produced. Digestive ripening of thiol stabilized particles in toluene at 120 °C results in 4–4.5 nm species, a remarkable narrow distribution obtained by combination of physical and chemical methods.

In spite of these promising advances based on evaporation methods, wet-chemical methods dominate clearly the field of metal nanoparticle syntheses. The following sections will deal with the most important routes.

3.2 Salt Reduction

Undoubtedly, salt reduction for generating metal nanoparticles is the most widespread chemical method. Aqueous solutions as well as organic solvents can be used to reduce metal salts and metal complexes. In some cases, the organic solvent and the reducing agent can be one and the same, for instance, alcohols. In some cases, even the reducing agent can in addition serve to protect the particles' surface. The so-called 'alcohol reduction process', developed by Hirai and Toshima,[22–28] is a very general process to fabricate metal nanoparticles.

The reduction of metal salts in nonreducing solvents by addition of reducing agents is the oldest and most established procedure for generating metal nanoparticle sols in water. It was especially Turkevitch who developed chemical routes that are still in use today. Sodium citrate is the best-known reducer. $[AuCl_4]^-$ in hot water is reduced to 15–20 nm gold particles.[4] The citrate itself as well as its oxidation products (e.g. acetone dicarboxylate) act, along with Cl^-, as protecting species. Figure 1 shows a selection of as-prepared gold nanoparticles. Besides gold, other noble metal salts, for instance, $[PtCl_4]^{2-}$, can be reduced successfully to metal sols.[29–31] Of course, Turkevitch's citrate is not the only reducing agent being used. Especially Glaunsinger and coworkers[32] have reported on the successful generation of Pt nanoparticles from $[PtCl_4]^{2-}$ and sodium borohydrate, hydroxylamine hydrochloride, dimethylamine borane, hydrazine hydrate, sodium formiate, formaldehyde, or sodium trimethoxyborohydride. Among these various reducing compounds, $[BH_4]^-$ is of paramount importance. Brust *et al.* used $[BH_4]^-$ successfully to fabricate 1–5 nm gold nanoparticles in the presence of alkanethiols.[33,34] Variations of the thiol concentrations allow satisfying control of size.

So-called seeding growth processes starting with 3.5 nm gold particles opened the door to a variety of further particle sizes.[35] Worth mentioning in this connection is the availability of bimetallic core-shell nanoparticles. Beginning with a seed of a distinct metal, a shell of a second metal can then be grown on this seed.[36,37] An example of a perfectly grown bimetallic core-shell particle consisting of a gold core and a palladium shell is shown in Figure 4.

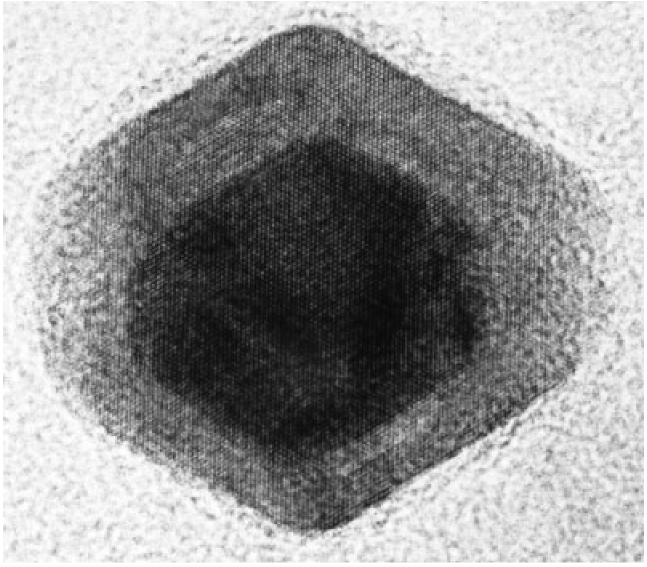

Figure 4 TEM image of a bimetallic core-shell nanoparticle, consisting of a gold core and a palladium shell

Reverse Pd/Au particles or those consisting of other metals become available using this method.

Gold nanoparticles between 10 and 30 nm can be produced by means of $[BH_4]^-$ as reducer and mercaptosuccinic acid as stabilizer. Very well defined sizes, for instance, of 10.2, 10.8, 12.8, 19.4, or 33.6 nm, become available with variation of the $[AuCl_4]^-$: succinic acid ratio.[38]

The number of reducing agents for gold compounds is enormous. In principle, any kind of organic compound having some reducing character can be applied under appropriate conditions to generate gold from a salt. Among those, the so-called 'green chemistry' is going to develop from an academic to a more practical technique.[39,40] Even living species like fungi have been found to transfer gold salts to elemental gold.[41]

Metal nanoparticles stabilized only electrostatically or by weakly binding molecules can be transferred into very stable species by the subsequent exchange of the weak by stronger ligand molecules. This has been successfully done in the case of gold nanoparticles by addition of water-soluble phosphines like $Ph_2PC_6H_4SO_3Na$, $P(C_6H_4SO_3Na)_3$ or by a series of thiols. Au–S bonds are of special strength and so give very well protected particles that can partially even be isolated in solid state, but keep redispersable.[42]

α-Hydrogen containing alcohols are effective reducing agents owing to their oxidizability to the corresponding carbonyl compounds (methanol gives formaldehyde, ethanol forms acetaldehyde, i-propanol gives acetone, etc.).[22–28] As an example, equation (1) describes the formation of rhodium nanoparticles, denoted as Rh(0):

$$RhCl_3 + \frac{3}{2}R_1R_2CHOH \longrightarrow Rh(0) + \frac{3}{2}R_1R_2C{=}O + 3HCl \quad (1)$$

Organosols of palladium nanoparticles become available by the reduction of palladium acetate with various alcohols in the presence of PVP. The boiling points of the alcohols influence the particles size.[43] Long-chain aliphatic alcohols like 1-decanol not only reduce palladium and platinum salts, but act as reasonable stabilizers for the resulting particles.[44] Pd particles in the size range of 1–4 nm can be prepared using C_1–C_5 aliphatic alcohols as solvents and as reducing compounds for palladium acetate, again in the presence of PVP.[45]

Tetraalkylammonium hydrotriorganoborates $[R_4N]^+$ $[BR'_3H]^-$ have become of interest in recent years for generating different metal nanoparticles, especially by numerous contributions of Bönnemann *et al*.[46–50] These salts not only are powerful reducers, but the ammonium cations stabilize the metal particles in a surprisingly good fashion. Equation (2) explains the reaction for $R' = Et$:

$$MX_n + n[R_4N][BEt_3H] \longrightarrow M(0) + n[R_4N]X + nBEt_3 + \frac{n}{2}H_2 \quad (2)$$

$$(X = Cl, Br;\ R = C_6–C_{20};\ M = \text{groups } 6–11 \text{ metals})$$

$[BEt_3H]^-$ not only reduces salts of the more noble metals, but even those of Ti, V, or Nb.[51] Aluminum alkyls have also turned out to act as reducing agents for groups 6–11 metals using halide or acetylacetonate salts.[52,53] Organoaluminum compounds seem to act as stabilizers of the 1–12 nm particles.

Nanoparticles of Ti, Fe, Co, Ni, Pd, Pt, Ag, and Au in preparative amounts became available by electrolytic methods.[54–60] The relevant metal in bulk form is used as anode where atoms from the surface become oxidized, whereas the cathode serves to reduce the cations to atoms and subsequently to nanoparticles. These can be protected, for instance, by tetraalkylammonium salts. A strategic advantage of this technique is the easy influence on the particle size by the current density. Increasing current density results in decreasing particle sizes.

Hydrogen is a reducing agent that has some special advantages. One is the low price, compared with some extraordinary chemical compounds. Without additional stabilizers, syntheses usually end up with only electrostatically stabilized nanoparticles. Hydrosols of Pd, Pt, Rh, and Ir can be yielded from the corresponding hydroxides.[61–65]

Hydrogen is also a successful reducing agent for polyoxoanion-iridium complexes. In rather complex reactions, salts such as $(Bu_4N)_5Na_3[(1,5\text{-COD})IrP_2W_{15}Nb_3O_{62}]$ are reduced in solution, ending up with polyoxoanions-protected nanoparticles containing 300–900 Ir atoms.[51,66,67]

In connection with the reductive element hydrogen, the synthesis of some special nanoparticles will be discussed because they have become known as those following rather discrete analytical composition that cannot be formulated for usual nanoparticles, owing to their size and shape deviations. Moiseev *et al*. reduced palladium acetate in the presence of phenanthroline or bipyridine in aqueous solution to yield nanoparticles of the composition $Pd_{561}L_{\approx 60}(OAc)_{\approx 180}$.[68–73] The number of exactly 561 Pd atoms results from the counting rules for so-called full-shell clusters. (Although the term 'cluster' is generally substituted in this article by 'nanoparticle', in the case of such molecularly precise particles, it will continue to be used.) Full-shell clusters are nanoparticles with hexagonally close-packed atoms, as is the case in most bulk transition metals. A central atom is surrounded by 12 densely packed others, resulting in a 13-atomic one-shell cluster. Two-shell particles consist of 55 and three-shell systems of 147 atoms. Generally, the nth layer consists of $10n^2 + 2$ atoms. Moiseev's 561 atomic Pd particle represents a five-shell cluster. In practice, the number of metal atoms as well as that of ligand molecules may deviate to some extent; however, compared with the usual nanoparticles, full-shell clusters of the above type are strictly monodisperse and deserves to be labelled with a chemical formula. Schmid *et al*. described some more Pd full-shell nanoparticles, namely, $Pd_{561}phen_{36}O_{\approx 200}$, $Pd_{1415}phen_{60}O_{\approx 1100}$, and $Pd_{2057}phen_{84}O_{\approx 1600}$ (phen = phenanthroline), representing another five-shell and a seven- and an eight-shell particle.[74–76] The seven- and the eight-shell clusters are formed simultaneously; however, they can be separated by careful chromatography. The most important tool to determine the exact size of such clusters is high-resolution transmission electron microscopy (HRTEM).

A full-shell cluster of a very special importance is $Au_{55}(PPh_3)_{12}Cl_6$ and some of its derivatives. It is probably the most frequently investigated cluster or nanoparticle owing to its unique electronic properties making it one of the most promising building blocks for future nanoelectronic devices. It can act as a single-electron switch even at room temperature and so follows strictly quantum mechanical rules instead of classical physical laws. It therefore is often called an artificial atom. A prerequisite for technical applications is the easy availability of this quantum dot. Ph_3PAuCl is reduced in benzene or toluene at 60 °C by gaseous diborane.[77,78] B_2H_6 not only reduces Au(I), but furthermore binds excessive PPh_3 as $H_3B\text{-}PPh_3$, an important fact in order to avoid formation of smaller clusters containing higher phosphine yields. The yield of $Au_{55}(PPh_3)_{12}Cl_6$ is about 30%. Bulk gold and larger particles are formed simultaneously. Pure cluster samples can be made by chromatography over Celite. In contrast to the larger gold nanoparticles, $Au_{55}(PPh_3)_{12}Cl_6$ is not red, but forms dark brown microcrystalline powders, best soluble in dichloromethane. Although stable in solid state at room temperature for a long time, the cluster starts decomposing in solution rather quick. This is due to partial dissociation of PPh_3 molecules leading to coalescence processes between clusters and finally to formation of precipitates. On the other hand, the easy dissociation of phosphines in solution can be used to substitute them by stronger ligands, as is usual

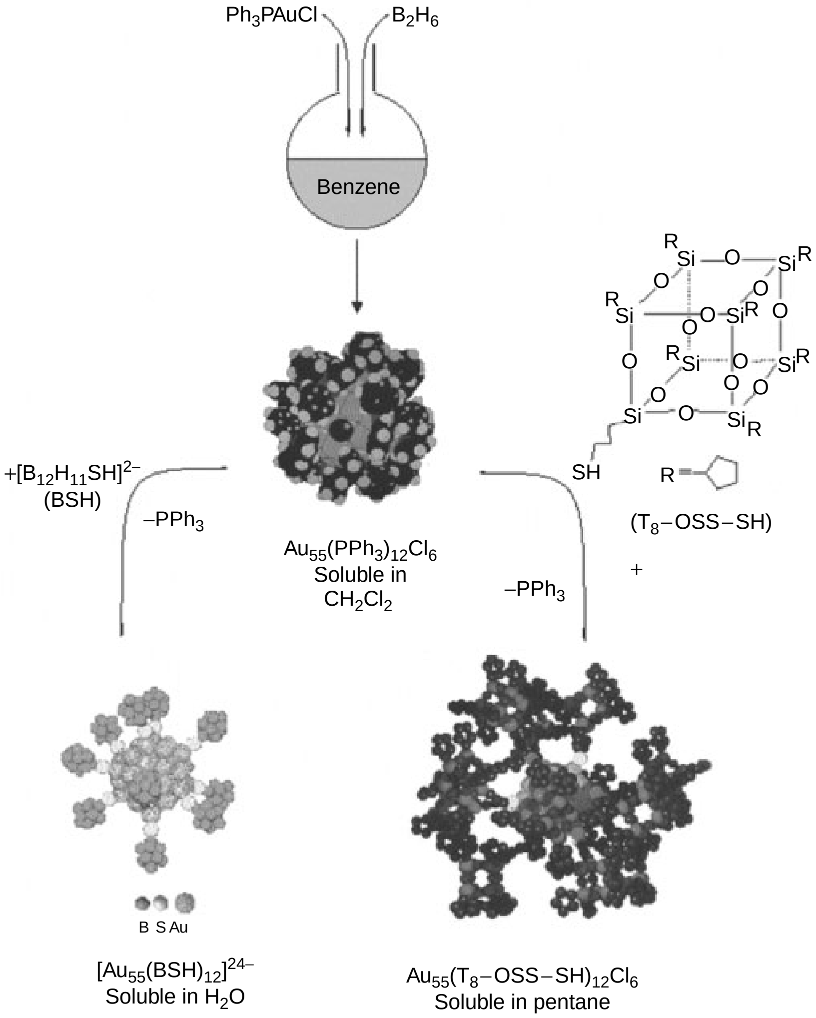

Figure 5 Synthesis of $Au_{55}(PPh_3)_{12}Cl_6$ and some ligand exchange reactions resulting in different solubilities. (Ref. 79. Reproduced by permission of Wiley-VCH)

in complex chemistry. Figure 5 summarizes some of the exchange reactions.

Such ligand exchange reactions lead to cluster derivatives that not only have changed their size, but also their solubility. The solubility of ligand stabilized nanoparticles depends exclusively on the nature of the protecting ligand shell. As can be seen from Figure 5, the solubility changes from dichloromethane for the PPh_3 containing starting compound to totally unpolar solvents like pentane or hexane if the alkyl-substituted silsesquioxane ligand T-OSS-SH is occupying the cluster surface.[80] Even water as solvent becomes possible when using the anionic ligand $[Ph_2C_6H_4SO_3]^-$[81] or $[B_{12}H_{11}SH]^{2-}$, making the Au_{55} cluster 24-fold negatively charged.[82]

The formation of full-shell clusters is a consequence of their thermodynamic stability. The ideal shape of such particles makes them unusually stable species with respect to chemical reactions. Thus, ligand-free Au_{55} clusters cannot be oxidized under oxygen plasma conditions where smaller and larger gold nanoparticles not possessing full-shell character are forming oxides.[83] Corresponding results are obtained from alloying experiments. Indium forms alloys of $AuIn_2$ type with all kinds of gold particles and with bulk gold, but not with Au_{55}.[84]

Some more special routes to metal nanoparticles shell complete this section on salt reductions.

Carbon monoxide/water reduces PtO_2 to nanoparticles based on the water–gas shift reaction providing electrons as is seen from equation (3).[85]

$$CO + H_2O \longrightarrow CO_2 + 2e + H_2 \qquad (3)$$

Alkalides and electrides allow homogenous reduction reactions for various transition metals, even for main group metals in aprotic solvents.[86,87] These reducers consist of alkali metal anions or electrons trapped in crown ethers.

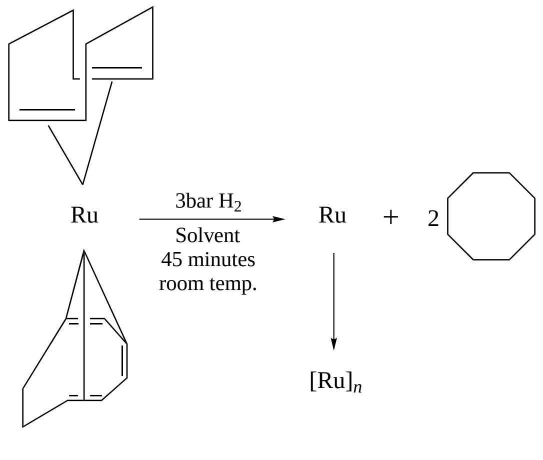
3.3 Thermal Reactions

Thermally unstable metal complexes, particularly organometallic compounds, can be decomposed to liberating metal atoms forming nanoparticles. This widely applicable method is especially applicable for noble metals such as rhodium, iridium, ruthenium, osmium, palladium, and platinum. Particles of those elements in the size range of 1–10 nm are formed by decomposition of polymer-fixed organometallic species.[88–92] High boiling organic solvents are used to decompose complexes like palladium acetate, palladium, and platinum acetylacetonate.[93–98] Mixtures of acetates, for instance, of copper and palladium, are used to produce bimetallic nanoparticles in high boiling solvents. PVP has been used for stabilization.[99] In spite of this easy availability of nanoparticles, it must be stated that thermal decomposition of appropriate precursors often results in rather broad size distributions. This is probably why thermal routes have not been developed to such an extent as salt reduction methods.

3.4 Ligand Removal from Organometallics

A rather novel route to metal nanoparticles of increasing interest and relevance is the soft displacement of ligands from organometallic complexes with zero-valent metal atoms. An elegant way to do this is the decomposition of precursor molecules by CO and H_2.[100–117] A prominent example is the generation of Ru nanoparticles from Ru(COD)(COT) (COD = cyclooctadiene, COT = cyclooctatriene) in solution by hydrogen.[118,119] Scheme 1 elucidates the process.

Depending on the solvent, usually alcohols, the particle size can be astonishingly well controlled. Thus, nanoparticles in the range of about 3 up to more than 80 nm are made from the Ru(CO)(COT) compound at 3 bar of hydrogen at room temperature.



Scheme 1 Formation of Ru nanoparticles by removal of ligands from organometallic complex

Dibenzylideneacetone (dba) complexes of palladium and platinum serve as metal-atom source when they are treated with H_2 or CO under mild conditions.[120]

3.5 Photolysis and Radiolysis

Photolysis of metal compounds is a method of historical dimension as it has been used since the middle of the nineteenth century, when the light-sensitivity of silver salts was used for photographic purposes. Novel research, especially linked with the names Henglein and Belloni, led to a large extended field in the science of nanoparticles. UV-visible irradiation of Au, Ag, and Pt salts in surfactant or polymer solutions end up with nanoparticle formation.[121–136] Compared with hydrogen reduction, photolytic reactions usually give smaller particles with narrower size distribution.[137]

Radiolytic methods in the end result in salt reduction using electrons generated from irradiation with radioactive materials. The radiolysis of aqueous solutions of metal salts is based on formation of solvated electrons reacting with the metal ions or with other solutes to give secondary radicals, which then reduce the metal cations. The use of radioactive tools looks rather unattractive compared with usual chemical procedures; however, it may have advantages in special cases. For instance, radiolysis spontaneously produces many seeds leading to many small particles. Furthermore, radiolysis generates the reducing species in situ and so avoids side reactions of the chemical reducers and their oxidation products. However, all in all, radiolysis does not play a very important role in nanoparticle syntheses compared with other physical and chemical methods.

4 SYNTHESIS OF MAGNETIC NANOPARTICLES

4.1 Miscellaneous Routes

The applications of magnetic nanoparticles are manifold. Single-electron devices, ferrofluids, data storage, and catalyses are just a few examples indicating the importance of nanomagnets. Monodispersity is again a prerequisite in order to guarantee identical properties. Magnetic behavior of nanoparticles depends, except on the chemical composition, on their size and on their crystalline modification. It has been shown that magnetic nanoparticles of similar grain size differ in the magnetic properties when prepared by different methods.[138] Monodisperse magnetic nanoparticles are able to organize themselves to give highly ordered arrangements in two or even in three dimensions, a condition to align the electron spins in a certain direction by an external magnetic field. Sophisticated synthetic procedures are therefore a condition to reach that goal. Protection of magnetic nanoparticles by a shell of appropriate materials is

usually even more important than for noble metal nanoparticles discussed in Section 3 for the easier oxidizability of the less noble magnetic metals. Several chemical and physical routes to magnetic nanoparticles are known. Nanoparticles of Fe, Co, and Ni are frequently generated by the inert gas condensation technique.[139,140] Metal atoms are produced from bulk material at high temperatures into an inert gas, for example, helium. Collisions with gas molecules reduce the kinetic energy of the atoms and allow condensation to nanoparticles. Arc discharges are also used to produce metal atoms that are channelled into a circulating gas mixture of H_2 and Ar. 20–30 nm Fe, Ni, and Fe–Ni alloy particles thus become available. Often, as-prepared nanoparticles are amorphous and partially oxidized, a problem always accompanying synthesis and use of less noble metal nanoparticles.

Among the synthetic methods, the reverse micelle technique shall only briefly be mentioned. It is based on the use of water droplets in an organic phase of a surfactant.[141,142] Metal salts, dissolved in the water droplets, are reduced inside the nanometer-sized water volume, to result in nanoparticles trapped in the micelles. Alloy-like particles as well as bimetallic core-shell particles thus become available. Size distributions up to over 20% have to be put up with this technique.[143] Another disadvantage of the reverse micelle procedure is the lack of crystallinity due to the low synthesis temperature ($<$100 °C) requiring subsequent annealing at 200–300 °C.[144,145] Fe, Co, and Ni form carbonyl compounds that can be decomposed under elimination of gaseous CO and formation of magnetic nanoparticles of these most prominent metals. Decomposition can also be performed by ultrasonic irradiation of metal carbonyl solutions. The advantage of this method is, compared with heat treatment, the formation of acoustic cavitation, that is, formation and collapse of small bubbles within the liquid, resulting in local heats of some thousand K. Atoms and subsequently nanoparticles are formed that can be stabilized if necessary by suited molecules.[146,147] However, sonochemical generation of nanoparticles also yields amorphous and rather polydisperse species.

After these numerous methods, all linked with the one or the other disadvantage, some special routes shall be considered in the following sections, offering formation of monodisperse magnetic nanoparticles.

4.2 Reduction and Thermal Routes to Co and $CoPt_3$ Nanoparticles

High-quality magnetic nanoparticles become available taking routes via thermolysis or reduction of organometallic precursors containing appropriate metal atoms. If the original organic ligands do not act as protectors of the nanoparticles, other stabilizers have to be added during particle formation. Co and $CoPt_3$ nanoparticles will be the focus of this Section since they play an important role with respect to applications. Whereas cobalt nanoparticles can be called the most intensively investigated systems, $CoPt_3$ serves as prominent model for the study of magnetic alloy-like nanoparticles.

Owing to the easy oxidation of cobalt nanoparticles, all syntheses require rigorous exclusion of oxygen. As for other metal nanoparticles, the size distributions of magnetic particles depends on the kinetics of particle nucleation and growth.[148] The so-called ‘hot injection technique’ turned out to give really narrow size distributions. This procedure is based on the rapid injection of a precursor solution into a hot solvent containing the stabilizing molecules. Spontaneous nucleation happens, a prerequisite for uniform nuclei that then grow to nanoparticles by a controlled decrease of temperature.

In the case of less perfect monodispersity, later separation of particles of different size is possible either by differences in solubility or by the size-dependent magnetic interactions of the particles. The larger the particles, the stronger are the magnetic forces between them. This aggregation can be provoked by slow addition of a non-solvent to the particles’ solution. External magnetic fields can also be applied to separate larger from smaller particles with astonishingly good results.[149] Standard deviations below 5% can be reached by this primitive technique. One of the most frequently used organometallic precursors for cobalt nanoparticles is $Co_2(CO)_8$.

As is known, the magnetic properties not only depend on the kind of metal and the grain size, but also remarkably on the crystal modification. Cobalt nanoparticles are known to exist in three different modifications that can selectively be synthesized. Except the hexagonal close-packed (hcp) and the face-centered cubic (fcc) form, also known from bulk cobalt, nanoparticles form a third modification, the metastable ε-Co, which does not exist in the bulk state.[150] Surprisingly, ε-Co is the most frequently observed modification for nanoparticles.[151] Distorted fcc Co nanoparticles are usually generated if $Co_2(CO)_8$, dissolved in diphenylether, is injected into a 200 °C hot mixture of oleic acid and trioctylphosphine (TOP) or tributylphosphine (TBP) in diphenylether, followed by further heating at 200 °C for 15–20 min.[152] Monodisperse ε-Co nanoparticles are formed by reduction of $CoCl_2$ in hot dioctylether (200 °C) by $Li[BEt_3H]$ in the presence of oleic acid and TOP. Changing the amounts of stabilizing TOP varies the particle size from 2 to 6 nm. TBP instead of TOP causes formation of particles of 7–11 nm.[153,154] ε-Co nanoparticles are transferred into perfect hcp-structured particles when annealed at 300 °C.[154] hcp-Nanoparticles can alternatively be generated by reduction of cobalt acetate by 1,2-dodecanediol at 250 °C in diphenylether, again in the presence of oleic acid and TOP.[149,154]

The Co nanoparticles described up to here are more or less spherically shaped. Other geometries are available by selective adsorption of organic surfactants onto specific crystallographic faces, allowing crystal growth only in particular crystallographic direction.[155–157] For instance,

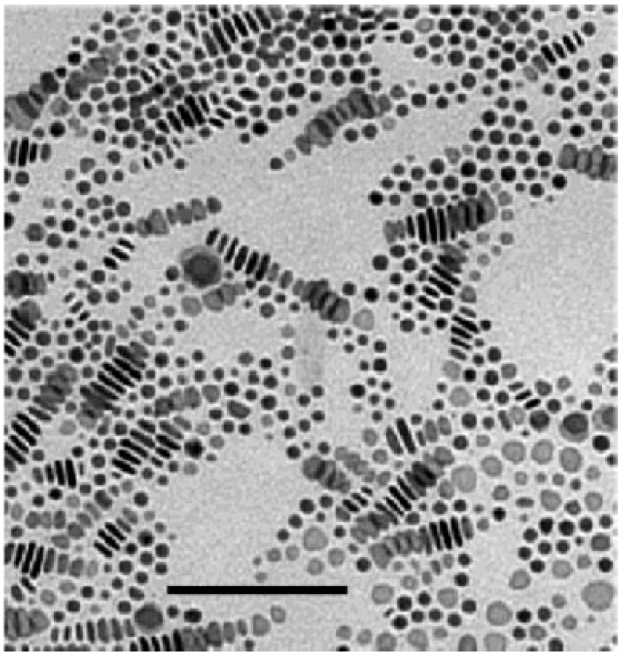


Figure 6 TEM image of partially self-assembled Co nanodisks. Bar = 100 nm. (Reprinted with permission from Ref. 157 © 2002 American Chemical Society)

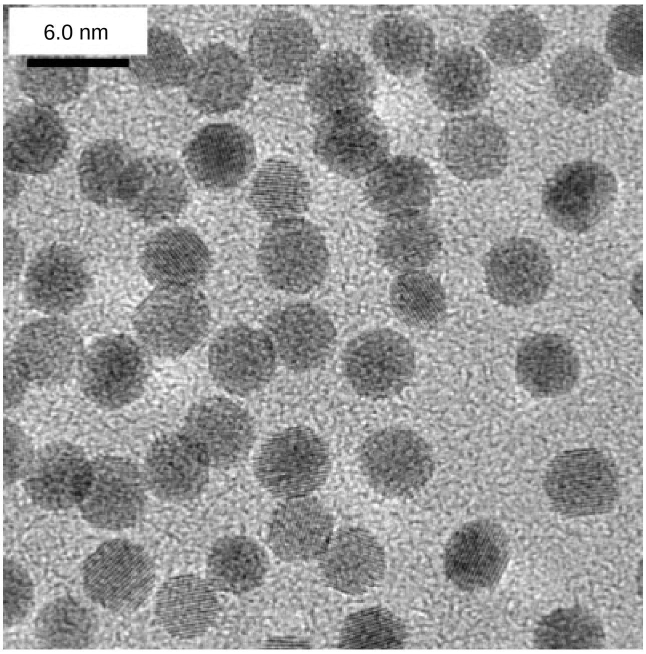

Figure 7 TEM image of $CoPt_3$ annealed nanoparticles. (Reprinted from D.V. Talapin, E.V. Shevchenko, H. Weller in ed. G. Schmid 'Nanoparticles. From Theory to Application', Wiley-VCH, Weinheim 2004, with permission of Wiley-VCH)

thermolysis of $Co_2(CO)_8$ in the presence of octylamine together with trioctylphosphineoxide (TOPO) or oleic acid gives nanodisks of hcp cobalt,[156] as can be seen from Figure 6.

The geometry of the disks can be tailored by the reaction times or variation of the precursor:surfactant ratios. On the other hand, long-term annealing of nanodisks yields spherical nanoparticles of ε-Co. Owing to their ferromagnetic properties, Co nanodisks can arrange to give ribbons consisting of stacked nanodisks.

Nanorods and nanowires of hcp structure become available by thermolysis of the precursor $[Co(\eta^3\text{-}C_8H_{13})(\eta^4\text{-}C_8H_{12})]$ in oleic acid and oleylamine at 3 bar of H_2 pressure.[158] Variations in concentration and nature of stabilizing compounds result in changes of the aspect ratio of the nanorods.[158–164]

$CoPt_3$ nanoparticles earn interest as representatives of alloy-like species. Furthermore, they are less sensitive towards oxygen and so are somewhat easier to be prepared and to be handled. They become available by simultaneous reduction of platinum acetylacetonate and thermal decomposition of $Co_2(CO)_8$. As stabilizing agents, adamantanecarboxylic acid and hexadecylamine (HAD) are used.[165] Practically, the hot injection technique is applied. The recipient vessel contains the platinum salt, dissolved in 1,2-hexadecanediol, and the stabilizers, whereas $Co_2(CO)_8$ in 1,2-dichlorobenzene is injected into the hot stock solution. In order to obtain well crystallized nanoparticles, annealing of the reaction mixture at 275–285 °C for about an hour is necessary. The crystallinity can be checked by TEM and XRD. Figure 7 shows a TEM image of $CoPt_3$ nanoparticles, indicating excellent crystallinity.

As in all cases of nanoparticle synthesis, controlling of particle size and distribution is the most important challenge. Like for monometallic nanoparticles, growth control can be tuned by nucleation and growth rates. Fast nucleation results in smaller particles, slow nucleation gives larger particles owing to the limited number of nuclei that grow as long as monomer is available.[148] The reaction temperature is the most important instrument to control the balance between nucleation and growth rates. Again, the concentration of the stabilizing compounds is an additional possibility to influence the particle size. As was shown for Co,[149] $CoPt_3$,[148] and Ni,[149] increasing concentrations of stabilizers result in decreasing particle sizes.

4.3 Other Magnetic Nanoparticles

Approximately 6 nm iron nanoparticles are formed if $Fe(CO)_5$ is thermally decomposed in the presence of oleic acid and TBP.[149] Their structure is bcc, like that of bulk iron. 2 nm Fe particles are generated if the decomposition of $Fe(CO)_5$ is performed in TOP at 320–340 °C.[157] They can be used to form rod-shaped species of 11–27 nm length by heating in pyridine in the presence of didodecyldimethylammonium bromide.[166]

Spherical nickel nanoparticles of 12–13 nm in diameter can be obtained by reduction of various nickel salts by polyalcohols in the presence of appropriate stabilizers such as

TBP or tributylamine (TBA).[149] Stabilizing molecules with longer alkyl chains like in trioctylamine (TOA) reduces the particle size to 8–10 nm.

Monodisperse 4 nm Ni particles are formed if nickel acetylacetonate is reduced by Et_2AlH in diethyl ether in the presence of PPh_3. As protecting shell on the particles' surface, PPh is observed, not the original PPh_3.[167] The PPh units are formed by hydrogen generated from the alane during the reduction process.

Iron–platinum alloy nanoparticles are very promising candidates for future data storage systems.[168] They become available by simultaneous reduction of platinum acetylacetonate and the decomposition of $Fe(CO)_5$ in oleic acid and oleyl amine.[169] The composition of Fe_xPt_{1-x} can be varied between $x = 0.48$ and $x = 0.7$. The particles exhibit disordered fcc structure. They are superparamagnetic at room temperature. Annealing at 550–600 °C transforms the fcc structure into a face-centered tetragonal (fct) one. These have been shown to be suited for storage devices owing to their room temperature coercivity.[169] The exact transition temperature depends on the stoichiometry.

Corresponding synthetic approaches are known for FePd[170] and MnPt[171] nanoparticles. Core-shell type bimetallic nanoparticles are also known.[172,173] They have to be prepared stepwise, starting with the generation of the core seed, which is then covered by a shell of the second metal as was already described above for nonmagnetic systems. For instance, reduction of platinum salts in the presence of cobalt nanoparticles gives air-stable CoPt nanoparticles with Co cores. AgCo nanoparticles are formed if $Co_2(CO)_8$ is decomposed in the presence of silver salts.[173]

5 SUMMARY

The generation of noble metal as well as of non-noble metal nanoparticles has meanwhile reached an enormous multiplicity. Apart from several somewhat sophisticated methods, most of the working and therefore frequently applied routes are based on traditional routes. First of all, it is the reduction of metal salts that brought big success. Decomposition of appropriate precursor molecules and complexes turned out to be another very successful way to metal nanoparticles. Different kinds of energies are available to evolve metal atoms from molecular compounds, forming nanoparticles in subsequent growth processes. Thus, it can be stated that chemistry offers enormous varieties of bottom-up techniques for generating metal nanoparticles. This fact opens doors for applications on numerous fields. These reach from using metal nanoparticles as quantum dots in single-electron switches and transistors up to the enormous potential of magnetic particles in storage systems. After a long period of inactivity after Ostwald's seminal works in the early nineteenth century, there was a second great development, mainly initiated by Turkevitch's pathbreaking preparative works from 1950 on, making metal nanoparticles meanwhile one of the pillars of modern nanoscience and nanotechnology.

1 INTRODUCTION

The reasons for organizing metal nanoparticles in three (3D), two (2D), or in one dimension(s) (1D) are to be seen in the most attractive properties of those particles, namely, their size-dependent electronic behavior. In an ordered form, preferably in 2D, such particles are promising candidates as building blocks in future nanoelectronic devices. For instance, storage systems might contain metal nanoparticles of appropriate size as quantum dots working as single electron switches/transistors or as nanomagnets. Both possibilities look realistic since it was shown that Single Electron Tunneling (SET) processes can be realized at room temperature for metal particles in the 1–2 nm region and that nanoparticles of magnetic metals or of suited alloys can act as magnet storage units. Before describing principles of organization, the reasons for these unique properties shall briefly be discussed.

If a metal particle, independent of the element, is reduced in one, two, or in all three dimensions to such an extent that the mobility of the electrons is decisively restricted, one speaks of size quantization because the electrons no longer follow the laws of classical physics based on the statistics of an infinite assembly of atoms in three dimensions, but rather obey quantum mechanical rules as they are used to describe atoms or molecules. Figure 1 illustrates the formal transition from 3D to a 0D state, represented by a so-called quantum dot with three-dimensional quantum confinement.[1]

As can be seen, the density of electronic wave functions in a 3D system (I) changes in z-direction if the number of atoms is reduced to a few layers (II). Corresponding changes occur if restrictions happen in y (III) and x (IV) direction with the consequence of formation of discrete energy levels in z, y, and finally in all three directions. Situation IV corresponds principally with that in an atom. That is why quantum dots are often also called ‘artificial atoms’. In a more qualitative way, the transition from 3D to 0D can be illustrated as is done in Figure 2.[2]

A discrete molecule, for instance, consisting of 4 atoms, exhibits sharp energy levels (a), usually called bonding and antibonding molecular orbitals. Increasing the number of atoms to an up to here unknown value leads to a broadening of the energy levels (b) and is finally ending up in the well known band structure characterizing bulk metals (c). Following the process in the opposite direction, the question arises, how small a metal particle has to become to allow observation of an energy splitting indicating the existence of a quantum dot. In principle, there is a simple answer: if the diameter of the particle corresponds with the de Broglie wavelength of the electron. However, this wavelength is not a constant, but varies with the energetic conditions. So, the answer can only be given by the experiment.

From numerous experiments to get information on the electronic ‘inner life’ of metal nanoparticles only a few, but decisive ones shell be mentioned, explaining why predominantly the nanocluster compound $Au_{55}(PPh_3)_{12}Cl_6$ is in the focus of interest with respect to future applications. This precisely defined nanoparticle consists of a nucleus of 55 gold atoms in a hexagonal close-packed manner as is the case in bulk gold. It belongs to the special class of so-called full-shell clusters where a central atom is surrounded by a first shell of 12 atoms, resulting in the one-shell Au_{13} cluster. 42 atoms can be arranged on the first shell resulting in 55 atoms, and so on. Generally, the nth shell contains $10n^2 + 2$ atoms.

2 SOME PROPERTIES OF INDIVIDUAL METAL NANOPARTICLES

Full-shell clusters possess an unusual stable configuration, as has recently been demonstrated.[3] A series of smaller and larger gold nanoparticles have been oxidized in an oxygen plasma, demonstrated by X-ray photoelectron spectroscopy (XPS) spectra, except Au_{55}. Its oxidation would end up in a degradation of the full-shell constitution what obviously does not happen. A similar series of various gold nanoparticles has been alloyed with indium to $AuIn_2$ phases, but not Au_{55}.[4] The reasons for this surprising behavior are probably the same as in case of oxidation.

In one of several fundamental experiments, it has been demonstrated that Au_{55} in its ligand protected form behaves electronically like a metal in the ‘embryonic state’. Gold particles of 15 nm, 1.4 nm (Au_{55}) and 0.7 nm (Au_{13}) have been irradiated by femtosecond laser pulses, generating excited electrons.[5] Observation of the relaxation behavior is very

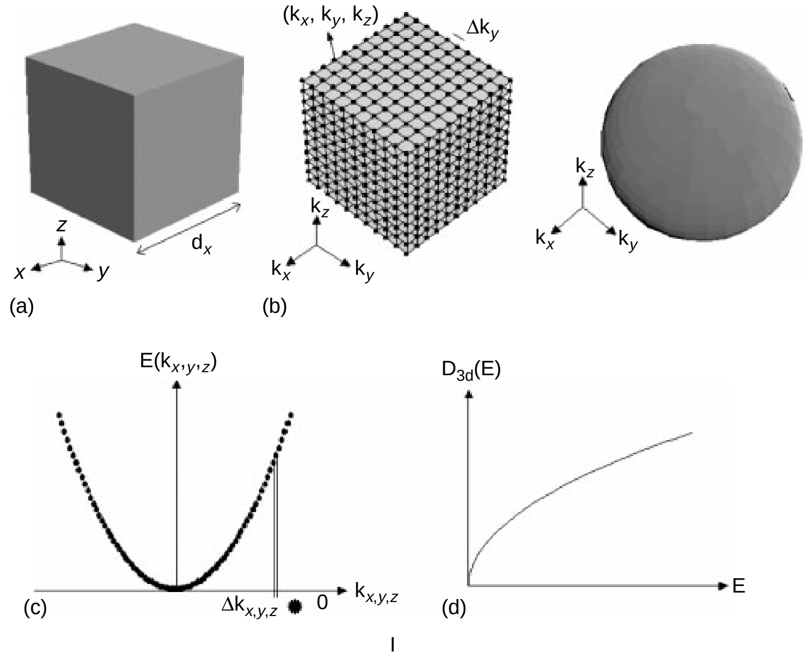

Figure 1 (I) Electronic behavior in a 3D system, infinitely extended in x, y, and z directions (a). The electronic states are symbolized by dots k_x, k_y, k_z (b). In a bulk particle the spacing $\Delta k_{x,y,z}$ between individual electronic states is so small that a quasi-continuous situation arises. The energy of the freely mobile electrons varies in the square of the wavenumber, resulting in the parabola (c). The density of states D_{3d} in a 3D system (d). The allowed energies are quasi-continuous. Their density varies with the square route of the energy $E^{1/2}$. (II) In a 2D system the extension in z-direction is limited to a few atomic layers. $\Delta k_{x,y}$ is still very small, but Δk_z is increased so that discrete values n_1, n_2 ... exist (c), resulting in a so-called stair-case (d). (III) Situation in the 1D case. Only Δk_x is still small, whereas Δk_y and Δk_z are discrete, ending up in a density of states situation where each of the hyperbolas (d) corresponds to an individual k_y, k_z – state. (IV) In a zero-dimensional state (0D) of the extension of the de Broglie wavelength only discrete energy levels result (d). (Ref. 1. Reproduced by permission of Wiley-VCH)

much instructive. The relaxation time is controlled by two opposite effects: the electron-phonon coupling in the particle and the electronic collision rate on the particle's surface. As can be seen from Figure 3, the relaxation time in case of Au_{55} is much faster than for the 15 nm species because of a reduced electron-phonon coupling and an increased collision rate on the surface.

However, the relaxation behavior of Au_{13} is very much different. It behaves like a typical molecule without any freely mobile electrons so that collisions on the particle's surface cannot happen. $Au_{55}(PPh_3)_{12}Cl_6$ can therefore be considered as being positioned exactly at the borderline between bulk and molecule.

This interpretation agrees perfectly with results originating from Scanning Tunneling Spectroscopy (STS) investigations. An experimental setup as sketched in Figure 4 is used to study the current (I)-voltage (U) behavior of individual nanoparticles.

A single ligand protected particle is trapped between an Scanning Tunneling Microscopy (STM) tip and a conductive substrate. In case of having quantum size behavior, tunnelling of single electrons trough the insulating ligand shall into the cluster core should happen at an appropriate voltage. The presence of that electron blocks the transition of a next one until a voltage is reached overcoming this so-called Coulomb blockade (CB). In case of having a particle with bulk character, linear I-U behavior can be expected (Ohm behavior). However, SET can only be observed if the electrostatic energy $e^2/2C$ is very large compared with the thermal energy k_BT of the electron, in order to avoid uncontrolled thermal electron transitions. So, SET can indeed be observed in rather large particles if the temperature is low enough. A 15 nm Pd particle has been demonstrated to behave bulk-like at 295 K, but exhibits quantum size properties at 4.2 K.[6] However, $Au_{55}(PPh_3)_{12}Cl_6$ is small enough to reduce the capacity C to such an extent that $e^2/2C$ becomes large enough to allow SET at room temperature.[7] The corresponding Coulomb blockade is shown in Figure 5.

This is probably one of the most important results with respect to applications of metal nanoparticles in future electronic nanodevices: it impressively demonstrates $Au_{55}(PPh_3)_{12}Cl_6$ to work as single electron switch at room temperature. From this knowledge, a series of consequences are following with respect to future electronic applications of this quantum dot.

It should be mentioned that corresponding investigations of slightly larger particles, for instance, of a Pt_{309} four-shell cluster with a 1.8 nm metal core, clearly indicated

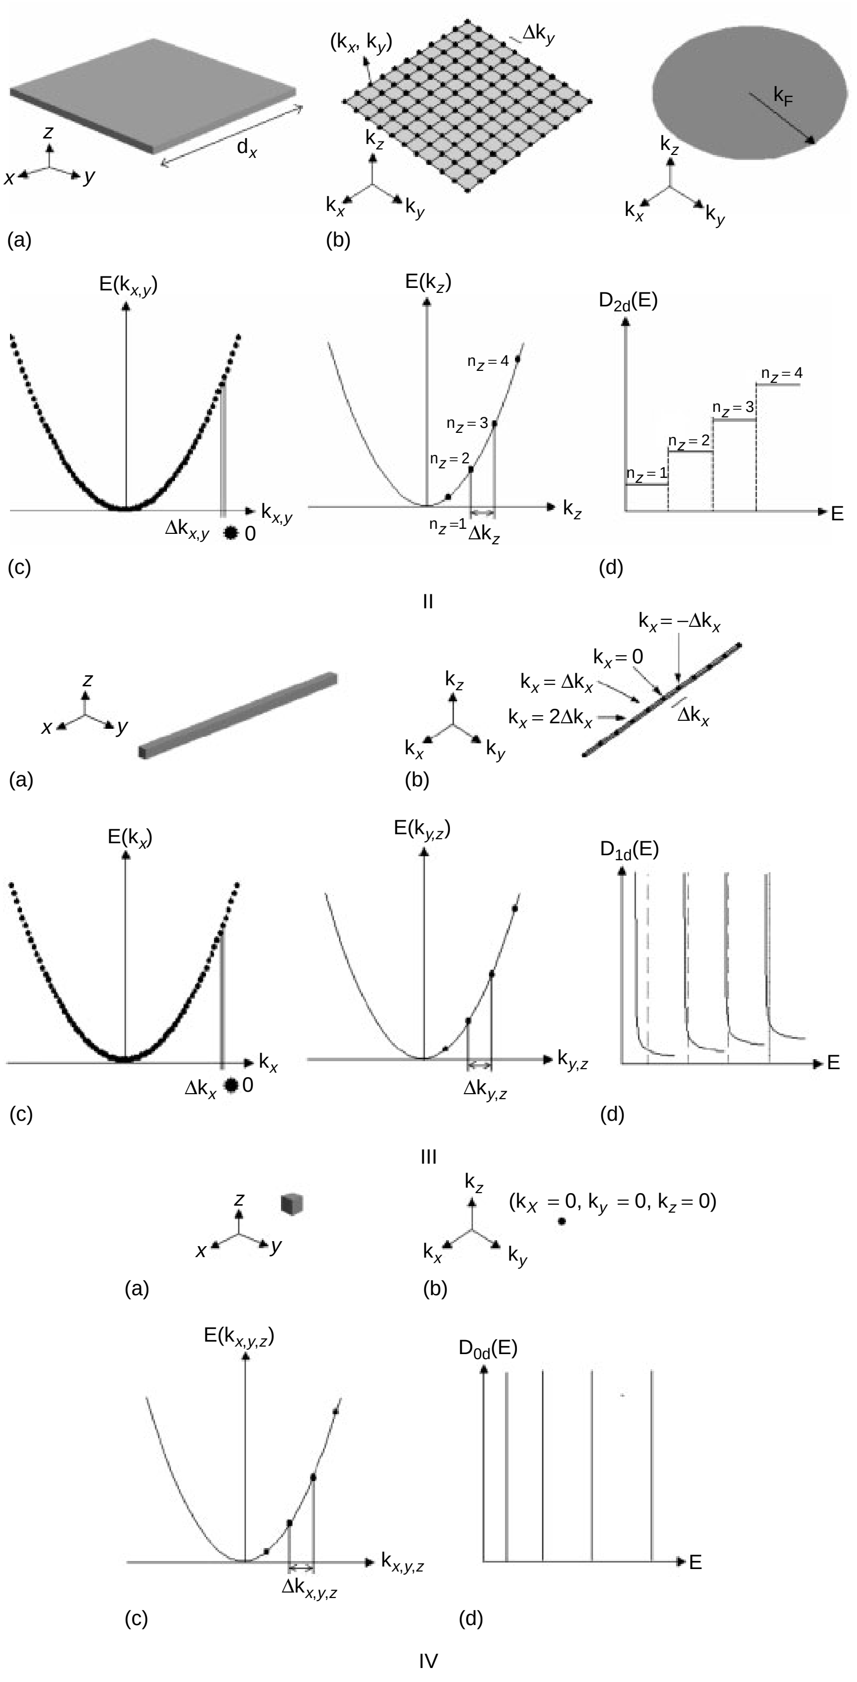

Figure 1 cont’d

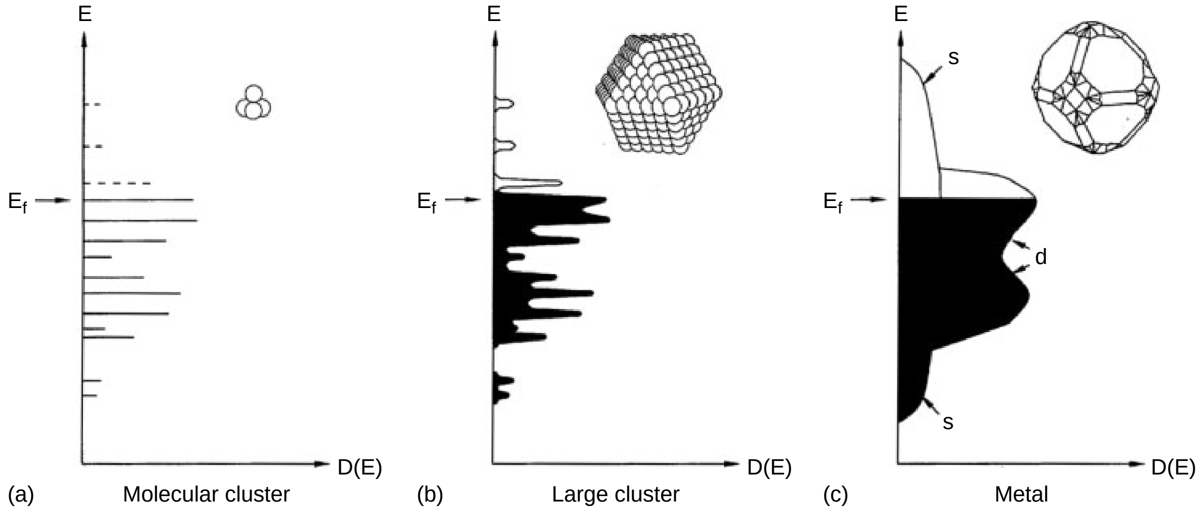

Figure 2 Simplified explanation of transition from a small molecule (a) via a nanoparticle (b) to the bulk (c) with respect to the electronic situation. Between states a and c there is a situation to be expected with broadened electronic levels (b)

bulk behavior at room temperature so that the discussion of electronic properties of even larger particles in this connection seems not necessary.

Magnetism is a result of moving charges. Magnetic properties arise mainly from moving electrons (orbital and spin motion). Since the electronic structure of a magnetic nanoparticle is characteristically dependent on the particle's size, monodispersity of the particles is therefore a condition to yield trustful results. Magnetic nanoparticles can be understood as single-domain magnets. The properties of individual particles can only be studied if they are separated from each other, for instance, in solution at low concentration.[8] Magnetic nanoparticles can exhibit unexpected properties. So, not only nanoparticulated iron, cobalt, or nickel, the only three metals that are ferromagnetic in the bulk state, are of interest, but, for instance, very small rhodium particles[9] that can be ferromagnetic as well as ferro- and ferrimagnetic alloy-like particles of manganese, chromium, cobalt, or platinum.[10] Monodisperse magnetic particles are able to organize themselves to build up highly ordered 2D and even 3D architectures. It can be expected that monodisperse magnetic nanoparticles can reach magnetic recording densities between 100 Gb/in^2 and 1 Tb/in^2.[11] Spin-dependent tunneling electron transport has been demonstrated in organized Co nanoparticles.[12] Unique magnetoresistive properties have been observed for magnetic nanoparticles embedded in matrices of nonmagnetic metals or dielectrics.[13–17] So-called ferrofluids develop rapidly to applicable materials.[18–23] These are magnetic nanoparticles having a shell of protecting molecules making them not only soluble in appropriate solvents, but prevent coagulation. In addition, a ligand shell can affect the magnetic properties.[24–26]

3 ORGANIZATION IN THREE DIMENSIONS

3D organization of metal nanoparticles is easy to be reached compared with 2D or even 1D, since nature tends to organize itself three-, but not two- or one-dimensionally. The most convenient way to get 3D assemblies of metal nanoparticles is to let them crystallize. Usually crystallization happens with identical molecules or with oppositely charged ions. Surprisingly, nanoparticles can form 3D crystals even if they are not identical in size and shape; however, it is obvious that deviations should be as small as possible.

So-called superlattices of 5 nm alkylthiolate protected silver particles having truncated octahedral shapes as well as thiol-stabilized 5–6 nm gold particles can be obtained from solution.[27–30] Fractional crystallization is a very usual method to separate chemical compounds from other compounds and impurities. Mixtures of thiolate stabilized gold nanoparticles between 1.5 and 3.5 nm could successfully be fractioned into real monodisperse species containing 140, 225, 314, and 459 atoms.[31] 2D assemblies have also become available of these fcc-structured nanoparticles. The decisive criterion to successfully fraction and crystallize metal nanoparticles is to protect them perfectly by strongly bound ligand molecules in order to avoid coalescence.

With respect to the mentioned conditions for nanoparticles, crystallization of the well defined nanocluster $Au_{55}(PPh_3)_{12}Cl_6$ and some of its derivatives are ideal candidates to form crystals. Indeed, $Au_{55}(PPh_3)_{12}Cl_6$ crystallizes spontaneously from dichloromethane solution as perfect, but small microcrystals. Macroscopic crystals, growing over longer periods of time, could not yet been gained owing to the continuous decomposition of the particles in solution. The reason for this decomposition must be traced back to the mobility of the ligand molecules, linked with partial dissociation. The

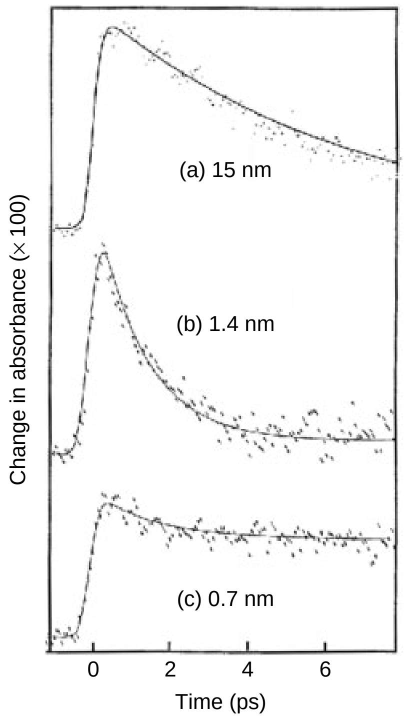

Figure 3 Electronic relaxation behavior of gold nanoparticles of different size after excitation with femtosecond laser pulses. The 1.4 nm particles (Au_{55}) represent a transition between bulk and molecule. (Reprinted from Ref. 5. © 1997, with permission of Elsevier)

high mobility of the PPh_3 ligands has been demonstrated by NMR experiments long time ago.[32] The loss of ligand molecules in solution provokes coalescence processes ending up in precipitates of agglomerated particles and sometimes even of gold mirrors. On the contrary, solid cluster samples are stable over long periods of time.

3D Au_{55} assemblies can also be generated, linking the particles by spacer molecules. This was done in order to vary the particle–particle distances aiming at systems with different conductivity properties. Two different types of spacers can be used: molecules that link the nanoparticles via contacts between ligand shell and spacer molecule and those that directly combine the metal nuclei via covalent bonds. Table 1 informs about the different ways to vary the distances. Except using spacers, variations of the ligand shells can also give samples of interest wherein the particles simply touch each other (Type I).

Type II consists of Au_{55} particles with a ligand shell consisting of sulfonated triphenylphosphine. The presence of SO_3H functions allows ionic interactions with diamines. Dithiols finally give type III systems. Here, part of the original PPh_3 molecules is substituted by thiol functions combining the metal particles directly via covalent bonds and not only by contact or by ionic interactions like in type II systems.

The electrical properties of such different 3D systems are quite interesting, since they show characteristic differences. They have been studied by dc and ac complex impedance measurements.[33,34] At temperatures several tens of Kelvin below room temperature, the temperature dependence of both conductivities follows the Arrhenius relation

$$\sigma(\mathrm{T}) = \sigma_o + \exp\frac{-E_A}{k_B T}$$
$$(E_A = \text{activation energy},\ k_B T = \text{thermal energy}) \qquad (1)$$

This behavior indicates hopping transport of individual charges between nearest neighboring particles (Nearest Neighbor Hopping). With decreasing measuring temperature, E_A becomes temperature dependent and so the conductivity follows the Variable Range Hopping (VRH) defined by Mott,[35] indicating a thermally activated stochastic multiple site hopping process, whereas at high temperatures around room temperature, nearest neighbor-hopping dominates.[36] This nearest neighbor-hopping around room temperature leads to the question if the charging energy of such metal nanoparticles can chemically be changed by varying the particle–particle distance as indicated in Table 1. Figure 6 summarizes the experimental results.

As long as the distance between the gold nanoparticles is based on noncovalent effects (type I and type II) an almost linear increase of activation energy in dependence of the particle spacing d can be observed.[37] This can be understood by a decrease of the junction capacitance scaling with 1/d. However, in case of covalent spacing (type III) with molecules having π-electrons, electrons use molecular orbitals for transport between the metal centres, resulting in characteristic energy drops, depending on the electronic structure of the spacer molecules and their respective length. These results remind the classical description of outer-sphere and inner-sphere mechanisms[38,39] of redox processes in aqueous systems.

3D assemblies of magnetic nanoparticles are formed if solutions of the corresponding particles are slowly reduced in volume or by careful destabilization of a solution by letting slowly diffuse a nonsolvent into the solution to get an oversaturation. Such procedures are in principle well known as crystallisation techniques also for nonmagnetic particles. 3D assemblies of up to several micrometers of cobalt,[40–43] nickel,[41] FePt,[44] or $CoPt_3$[45] have been generated by one of these traditional routes.

A method that can exclusively be applied for magnetic nanoparticles is the use of an external magnetic field that should not be too strong, otherwise glassy materials can be formed instead of 3D superstructures. The direction of the applied field influences the shape and structure of the resulting crystals.[41,46,47] For instance, a field applied in the plane of a substrate results in spindle-like aggregates of Co nanoparticles with their long axes aligned along the external magnetic field,[41,48] whereas $CoPt_3$ nanoparticles have been

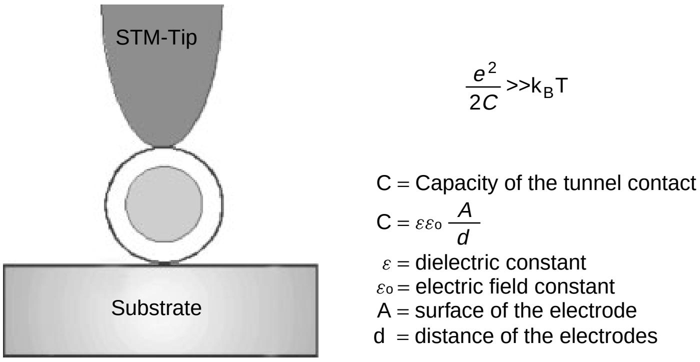

Figure 4 Sketch of an experimental setup to measure SET from a tip to a substrate and the conditions necessary to observe it

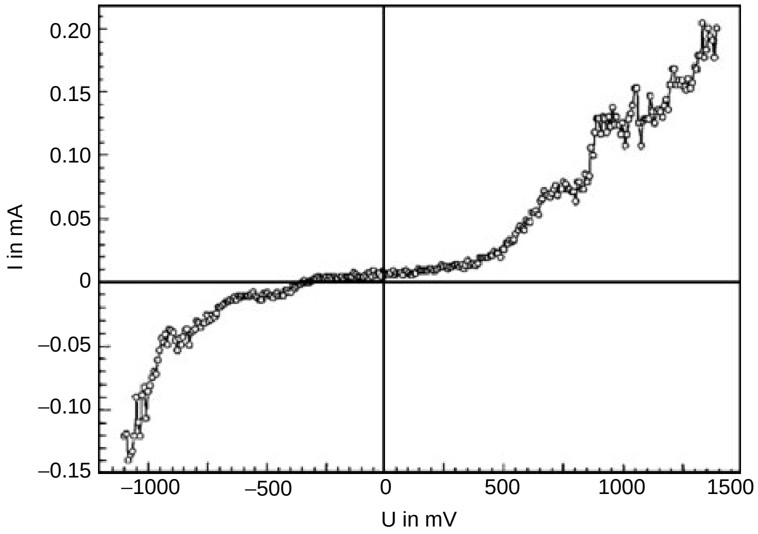

Figure 5 Current (I) voltage (U) characteristic of an individual $Au_{55}(PPh_3)_{12}Cl_6$ clusters at room temperature showing a well expressed Coulomb blockade between about −500 and +500 mV. (Ref. 7. Reproduced by permission of Springer Verlag)

ordered in parallel stripes if the field is directed parallel to the substrate. Needles of 4 nm $CoPt_3$ particles of up to 100 µm in length and 0.1–2 µm in diameter are formed in a magnetic field of 0.9 T applied perpendicularly to a substrate.[46]

There is still a lack of systematic investigations and also some contradictory results indicate that extended research is necessary to routinely generate superstructures of uniform magnetic nanoparticles.

4 TWO- AND ONE-DIMENSIONAL ASSEMBLIES OF METAL NANOPARTICLES

Compared with 3D organizations and with some respect also with 1D arrangements, ordered monolayers (2D) earn by far most interest owing to their potential applicability in future storage systems based on nanoparticulated building blocks. Like in case of 3D structures, identical size and shape of the nanoparticles help to start self-assembly processes; however, deviations from both properties are tolerated if they are not too large. 2D superlattices can even be generated if two very different species, each of distinct size, are combined. Generally, formation of 2D structures can be divided into processes where classical self-assembly is the dominating driving force, others that are called ‘guided self-assembly’ and finally formation of ‘aimed structures’ that are the most promising developments with respect to applications in nanoelectronics. Guided self-assembly of 2D structures is based on weak interactions between the particles and between the particles and appropriate surfaces, respectively. The various possibilities will be discussed in the following.

Self-assembled monolayers (SAMs) of organic molecules are known since decades. Self-organized metal nanoparticles have been observed for the first time only about 10 years ago.

Table 1 Noncovalently (I, II) and covalently (III) linked Au_{55} clusters with cluster–cluster distances and activation energies

Noncovalently linked			
Linking system	Type	Distance nm	E_a (eV)
	Ia	0.7	1.6
	IIa	1.9	2.0
	IIb	2.8	2.3
	Ib	3.1	2.6
	IIIa	1.1	0.095

(cont'd overleaf)

Schiffrin *et al.* generated SAMs of 8 nm gold particles at the phase boundary of a liquid–liquid system using dithiols to cross-link the particles.[49,50] From the same group, bimodal monolayers of AB_2 and AB type became known using silver and gold nanoparticles of different size[51,52] as is indicated in Figure 7.

For instance, ligand protected 8 nm Au and 5 nm Ag particles form perfect bimodal 2D arrays of the AB_2 type. Magnetic $CoPt_3$ nanoparticles of different size (4.5 and 2.6 nm) even form AB_5 structures,[53] whereas identical species spontaneously arrange to ordered monolayers when spread on a substrate, followed by slow evaporation of the solvent.[45,54] Depending on the experimental conditions, double and triplelayers are obtained that practically still can be considered to be two-dimensional.

Numerous examples of ordered 2D structures, especially of thiol-stabilized silver and gold nanoparticles, have become known in the course of the last few years.[27,31] They usually form spontaneously on Transmission Electron Microscopy (TEM) grids or other surfaces from solution and will not be

Table 1 cont'd

Covalently linked

discussed quantitatively. A decisive experimental prerequisite if ordered SAMs are formed or not is the hydrophobicity or hydrophilicity of the corresponding surface that has to fit to the nature of the solvent where the nanoparticles are dissolved in. On the one hand, particles that deposit from solution on a substrate must be freely mobile in order to organize themselves, usually in a dense packed manner. On the other hand, there should be some attraction between the particles and the substrate's surface, since otherwise there is no reason why to deposit from solution and in order to make the monolayers stable enough to survive drying or eventually transport to another surface. An illustrative example showing

this sensitive interplay between particles in solution and surfaces is the 2D organization of $Au_{55}(PPh_3)_{12}Cl_6$ clusters. Dissolved in dichloromethane, they can be distributed on a water surface forming a thin film as is usually applied in Langmuir–Blodgett techniques. With proceeding evaporation the Au_{55} clusters organize with formation of small islands that are stable enough to be transferred to TEM grids for imaging, as can be seen from Figure 8.[55]

Partial overlap comes from the transfer process from the water surface onto the grid. Rather large extended ordered monolayers are formed if a thin film of appropriate polymer molecules is generated at the phase boundary between water and dichloromethane in advance.[56] Poly(vinylpyrrolidone) (PVP) or poly(*p*-phenyleneethynylene) (PPE) derivatives turned out to give best results. The reason for the formation of such largely extended 2D arrays is to be seen in weak interactions between the phenyl groups of the PPh_3 ligands and the chemically related polymers. Therefore, it can be understood that an alkyl terminated polymer film consisting of poly(methylmethacrylate) (PMMA) does not support formation of 2D films of comparable quality. Figure 9 shows a TEM image of a part of a perfectly ordered monolayer of $Au_{55}(PPh_3)_{12}Cl_6$ particles in a hexagonal arrangement, generated on a film of PPE at the phase boundary of water and dichloromethane.

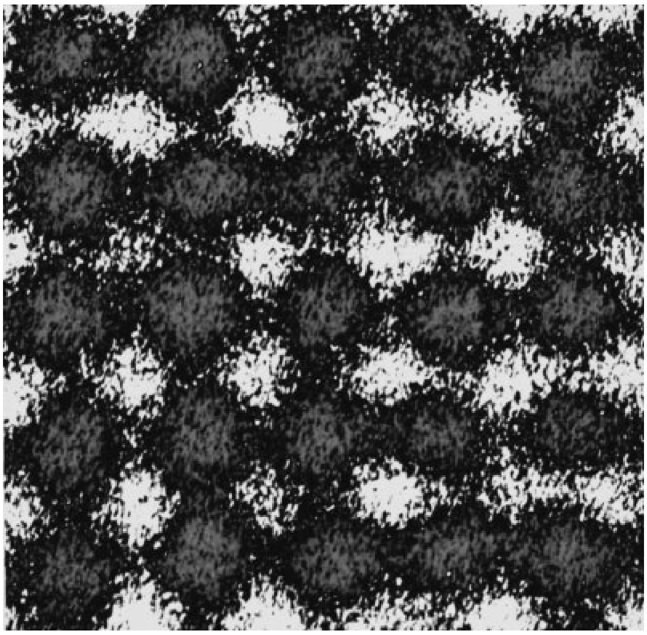

Figure 10 Cutout of orthogonally ordered Au_{55} clusters

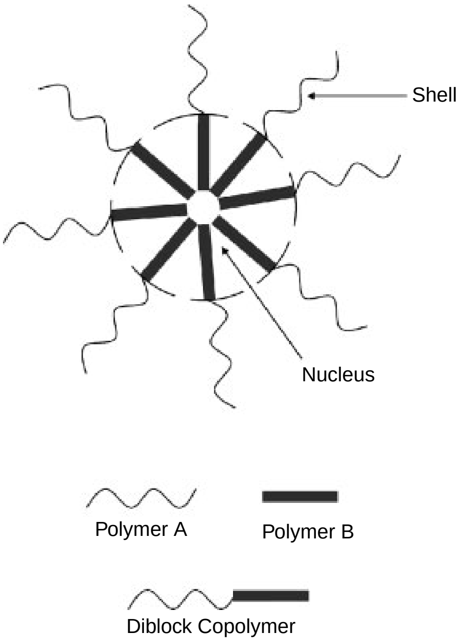

Figure 11 Sketch of the formation of micelles of diblock copolymers

The interaction between the nanoparticles and the polymer film is strong enough to survive the transfer onto a TEM grid. Simple square structured 2D organizations can also be found. If a hexagonal or a square architecture is generated may simply depend on the very first contacts between a few particles, serving as crystallization seeds. Figure 10 shows a small cutout of a monolayer with square-packed Au_{55} particles.[57]

Guided self-assembled monolayers are those where self-assembly is supported by means of experimental conditions that enforce the nanoparticles into distinct positions. Langmuir–Blodgett (LB) technique is one of the methods to organize molecules and also nanoparticles on a large scale. It is based on the spreading of solutions of the corresponding particles, dissolved in a suited organic solvent, on a water surface with subsequent compression of the thin film on the water surface. However, as it turned out, larger areas of nanoparticles generated by LB are usually not well ordered, but contain mostly randomly oriented nanoparticles. For some applications such monolayers may be suited, however, not with respect to the use of nanoparticles as individual species in nanoelectronics. Smaller areas with ordered metal nanoparticles could, however, be generated; for instance, alkanethiolate stabilized 3–5 nm gold metal particles[58] as well as ligand protected Au_{55} clusters.[59] Improvements were reached using amphiphilic particles and repeated compression resulting in areas of $0.25\,\mu m \times 0.35\,\mu m$.[60]

A guided self-assembly of gold nanoparticles succeeded also on patterned GaAs surfaces.[61] Structured Be-doped GaAs surfaces were first decorated with a monolayer of xylyl dithiol molecules. A uniform monolayer of dodecanethiol stabilized 5 nm Au particles, generated by spreading a hexane solution on a convex water surface (to be considered as a special kind of LB), is then transferred to the GaAs surface by gentle contacting this surface with the monolayer. It can be assumed that xylyl dithiols partially substitute dodecanethiol ligands. A remarkable development in making ordered metal nanoparticles arrangements is based on the use of so-called diblock copolymers. Polymer A and polymer B are first combined to the block copolymer A-B, which then forms micelles. Figure 11 illustrates the micelle formation.

Like other micelles, they represent perfect ‘nano reaction vessels’ that can be used to generate metal nanoparticles inside. The decisive point is that with the transfer onto smooth surfaces thin coherent films of ordered micelles become available.[62–68] Examples for A-B diblock copolymers are poly(styrene)-poly(ethylene oxide) or poly(styrene)-poly(2-vinylpyridine). Formation of metal nanoparticles inside of the micelles starts with loading of the hollow spheres with the corresponding metal salt, followed by the reduction step. For instance, gold nanoparticles are made from $HAuCl_4$ or $LiAuCl_4$. The tetrachloroaurates penetrate into the micelles in nonpolar solvents. Ultrasound supports the diffusion process. Subsequent reduction with hydrazine or $[BH_4]^-$ leads to gold nanoparticles. Usually, several nanoparticles are formed in each micelle in a first step. These can then be transferred into single particles by annealing. Gold particles of 2.5, 4, 6, or 12 nm have so been obtained. Figure 12 shows TEM images of ordered 2D gold nanoparticles of different size.

Except gold, several other metal nanoparticles, also those of less noble metals, could be prepared, for instance, of silver, palladium, and cobalt, as well as sulfidic species like CdS or PbS.[69]

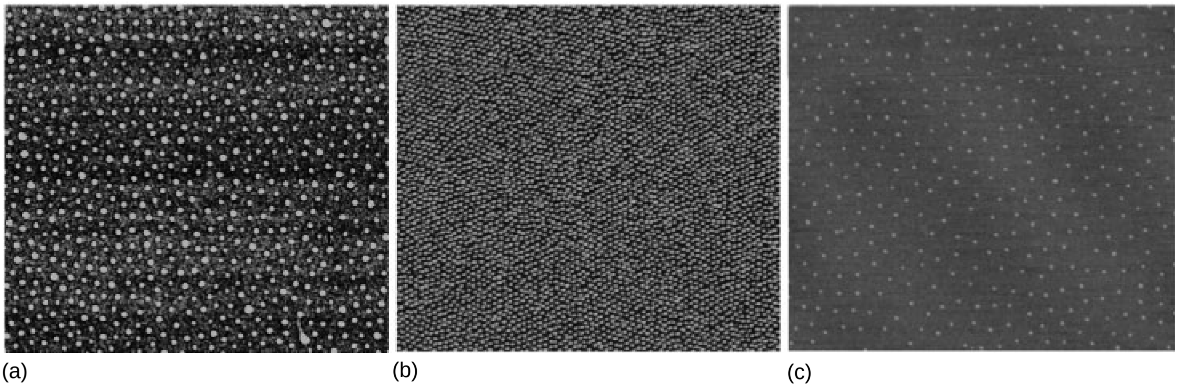

Figure 12 TEM images of gold nanoparticles of different size prepared in diblock copolymer micelles. (a) 6 nm, (b) 4 nm, (c) 2.5 nm. (Reprinted from G. Schmid, D.V. Talapin, E.V. Shevchenko in ed. G. Schmid Nanoparticles. From Theory to Application, Wiley-VCH, Weinheim 2004, with permission from Wiley-VCH)

The real value of this diblock copolymer technique is to be seen in the possibility to remove the organic matter without destroying the organization.[70–72] Ordered micellar films on glass or mica can be treated by an oxygen plasma leading to bare metal nanoparticles without loss of the original order. The metal particles are strongly fixed to the surfaces and cannot be removed by rinsing or even by rubbing with soft tissues. Furthermore, particle size, interparticle distances and herewith particle density can be varied by the composition of the micelles, the amount of metal salt, and so on. The use of diblock copolymers of different molecular weights determines decisively the interparticle distances. 1 nm Au particles with 140 nm distance from each other or 12 nm particles of 80 nm distance are available likewise.[70]

Ordered assemblies of gold nanoparticles generated by this micelle technique seem to become of importance on the rapidly developing field of nanobiotechnology. Regularly arranged spots of gold serve as anker places for biomaterials, as has impressively been demonstrated by Spatz *et al.*[73–75]

Finally, the so-called S-layers should be mentioned. They consist of 2D protein organizations, naturally formed as the outermost cell surface layer (S-layer) of prokaryotic organisms.[76] At liquid-surface interfaces of various lipid films or solid substrates such systems can form nanoporous monolayers that can be used for generating ordered arrays of, for example, 4–5 nm Au[77] or 1.9 nm Pt particles from salts.[78]

The 2D structures discussed up to here were all formed by self-assembly of particles or by self-assembly guided with the help of preformed surfaces, spheres, and so on. However, the highest goal of depositing metal nanoparticles on substrates is to create **aimed structures**, that is, those that are not influenced or even determined by any kind of a natural process, but instead are resulting in completely artificial architectures.

After having studied numerous templates for generating 1D assemblies of nonmagnetic metal nanoparticles, for instance, polymers,[79,80] nanopores[81–84] and even DNA,[85–87] it turned out that these approaches not really resulted in practicably applicable 1D systems. Therefore, they will not be discussed further. However, there are several other developments becoming visible that promise much better success with respect to aimed structures. They offer indeed chances to realize any kind of artificial architecture so that 2D or 1D structures can be designed likewise or combined with each other so that differentiation between both makes no longer sense from a technical point of view.

The so-called dip-pen nanolithography is one of these promising novel techniques. It has been developed by Ch. Mirkin *et al.* and is based on the use of Atomic Force Microscopy (AFM) tips to deposit functionalized molecules on appropriate surfaces.[88,89] The molecules are first deposited in solid state on the tip. The transport to the surface happens by means of the water meniscus between the tip and the surface that is present in air of usual humidity. Gold surfaces are preferably used to deposit thiol molecules forming strong Au–S bonds. The places were thiol molecules are deposited simply depend on the software moving the AFM tip on the surface. Figure 13 explains in a simplified manner the process.

Mirkin *et al.* used this method to even write down part of the famous lecture of R. Feynman given in 1960, predicting the future development of nanotechnology.[90]

Deposition of metal nanoparticles on molecularly patterned surfaces requires further functions. For instance, in case of using 16-thiohexadecanoic acid positively charged nanoparticles can be deposited at these positions. An impressive pattern of gold nanoparticles of two different sizes has been generated following several steps, elucidated in Figure 14.

Two interpenetrating orthogonal structures made of gold nanoparticles of different size can be generated following several steps: a first patterning of a gold surface is performed again with 16-thiohexadecanoic acid molecules. Unpatterned areas are then passivated with 1-octadecanethiol. The alkylamine-modified oligonucleotide *a* ($TCTCAACTCGTAA_{10}$) can then be deposited exclusively on the positions exhibiting carboxylic functions. The second

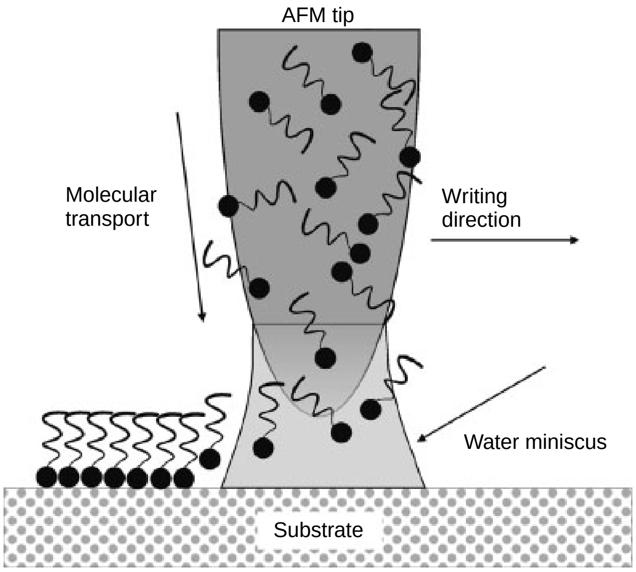

Figure 13 Dip-pen nanolithography. Sketch of the transport of molecules from the tip to a surface

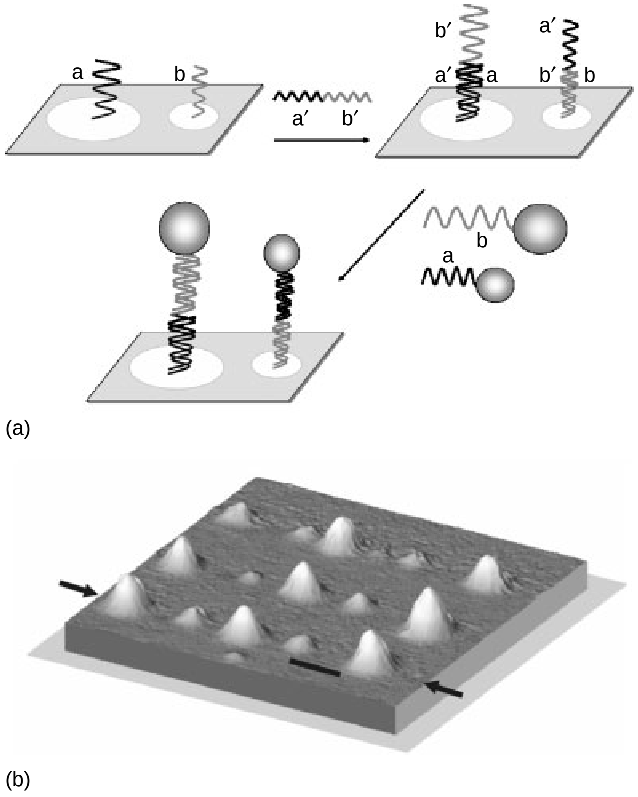

Figure 14 Formal illustration of the formation of a pattern of different gold nanoparticles via complementary oligonucleotides (a). (b): AFM image of an as-prepared arrangement

orthogonal structure is realized by replacing 1-octadecanethiol molecules by further 16-thiohexadecanoic acid molecules via the AFM tip at the relevant positions followed by derivatizing these places by another alkylamine-modified oligonucleotide *b* (A_{10}CGCATTCAGGAT). The as-prepared *ab*-modified surface is then combined with the complimentary *a′b′*-oligonucleotide. 13 and 30 nm gold nanoparticles, substituted with *a* and *b* oligonucleotides complete the structure. The impressive result is shown in 14b. No doubt that such structures earn highest interest in the field of future nanoelectronic devices.

A second developing technique also uses AFM tips to nanopattern surfaces. J. Sagiv uses conductive AFM tips to oxidize CH_3 end groups of (SAMs) to COOH functions by emitting electrical pulses.[91,92] Herewith, chemical information is written into an inert 'methyl-surface'. Again, only the software moving the tip over the surface decides where to inscribe the information. However, similar like in the former case, there are further chemical steps necessary to finally end up with 2D or 1D patterns of metal particles. The chemical modifications used in this case are explained in Scheme 1.

The carboxylic groups are derivatized by alkene terminated silanes, followed by the photolytic addition of H_2S to the C=C double bond. Successive treatment with BH_3·THF is necessary to reopen S–S bonds that could have partially been formed during thiolization. In the last step gold nanoparticles can be attached to all positions with SH functions. Larger particles[92] can be used as well as the small Au_{55} clusters, here as the water-soluble derivative $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$.[91] In Figure 15, Picasso's dove of peace, drawn from negatively charged 2–6 nm gold nanoparticles fixed at ammonium functions, is shown,[92] whereas Figure 16 shows a pattern

of orthogonally positioned Au_{55} particles.[91] However, as can be recognized from the magnified part, each dot still consists of 3–4 clusters, but not of one. The reason for this is simply the quality of the AFM tip used for this experiment leading to too much extended functionalized areas.

With an improved AFM tip ideal one-dimensional wires of individual particles become available and as can also be seen from Figure 17, even individual Au_{55} particles are positioned in predefined intrawire gaps.[91]

This impressive example indicates possible routes to aimed structures of quantum dots that can be applied in future storage systems.

Magnetic metal nanoparticles tend to self-assemble not only for reasons known from nonmagnetic species, namely, van der Waals forces, but especially owing to their intrinsic magnetic nature. Solutions of 4.8 nm $CoPt_3$ particles, spread onto a substrate, organize spontaneously when the solvent is evaporated.[45,54] Higher concentrations of the solutions easily result in formation of double and triple layers as is indicated in Figure 18.[45]

The morphology of the self-assembled structures is strongly influenced by the shape of the individual nanoparticles.[93–95] Faceted and cubic nanoparticles organize in such a way that they all are oriented in the same direction. Such superstructures are promising candidates for generating materials of high magnetic anisotropy owing to the aligning of the axes of magnetization of the individual particles. This is especially valid for $CoPt_3$ particles for their high magnetic anisotropy.[96] Figure 19 shows a TEM image of self-assembled cubic $CoPt_3$ nanoparticles.

Starting from $Co(\eta_3\text{-}C_8H_{13})(\eta_4\text{-}C_8H_{12})$, which is decomposed in anisole at 150 °C in the presence of hexadecylamine and stearic acid under 3 bar of hydrogen pressure, spheric Co

nanoparticles are formed that can be transferred to perfectly looking nanorods by successive aging.[97] These Co nanorods perfectly align as is seen from Figure 20.

Such organizations can be expected to exhibit high magnetic anisotropy and coercitivity, but have not yet been studied in this direction.

In contrast to nonmagnetic nanoparticles, 1D organization of magnetic nanoparticles is quite usual owing to their magnetic dipolar interactions. A magnetic single-domain nanoparticle of radius r has a magnetic dipole moment $\mu = 4\pi r^3 M_S/3$ (M_S = saturation magnetization of bulk). The dipole–dipole interaction between two contacting magnetic particles is proportional to $\mu^2/\sigma^3 \propto r^6/\sigma^3$ with σ = effective hard sphere diameter (magnetic core diameter and thickness of surfactant layer).[98] Anisotropic aggregation of magnetic nanoparticles are the consequence of those forces. Self-assembly of magnetic nanoparticles to flexible 1D chains

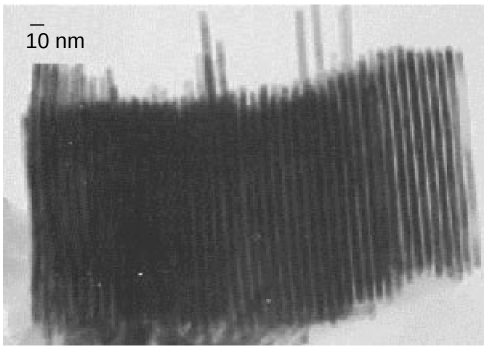

Figure 20 TEM image of cobalt nanorods. (Reprinted from G. Schmid, D.V. Talapin, E.V. Shevchenko in ed. G. Schmid Nanoparticles. From Theory to Application, Wiley-VCH, Weinheim 2004, with permission from Wiley-VCH)

has already been predicted in 1970 in order to minimize magnetostatic energy.[99] Figure 21 gives an impression of possible structure originating from such magnetic interactions.

Superparamagnetic nanoparticles can form chains even at zero field as has been demonstrated by simulations[100,101] and by experiment in a dispersion of iron nanoparticles at zero field.[102] Ring formation happens by unpaired dipoles at the ends of chains and have also been observed with 27 nm cobalt particles.[103] External magnetic fields can by applied in order to orient flexible chains in one direction enabling formation of superstructures.

Magnetic nanoparticles can be quasi or fully 1D organized by outer magnetic fields. Increasing magnetic fields lead

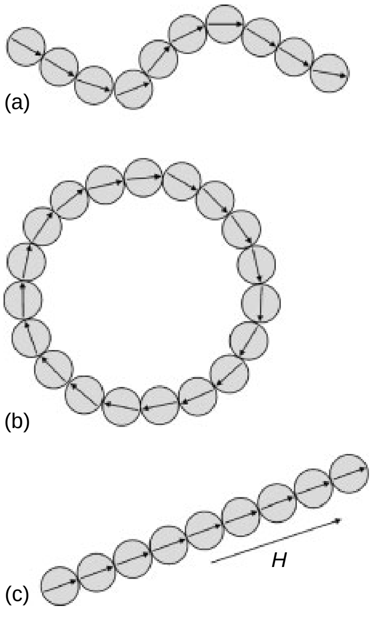

Figure 21 Various forms of chains of magnetic nanoparticles with head-to-tail organized paired dipoles

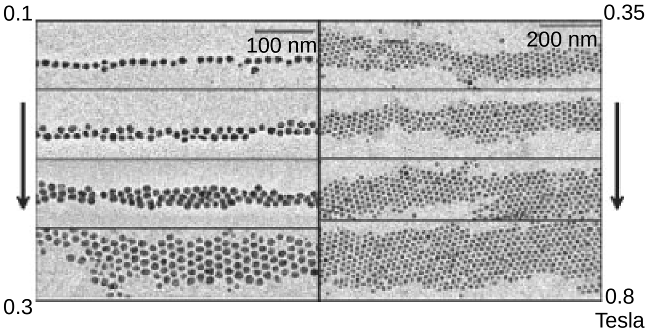

Figure 22 TEM images of 1 D formation of cobalt nanoparticles in dependence of the applied magnetic field. (Reprinted from Ref. 48. © 2002, with permission of Elsevier)

to increasing widths of the lines, as has been shown by using cobalt nanoparticles.[48] Figure 22 shows TEM images of organized Co nanoparticles in dependence of the applied magnetic field.

The progressive alignment is explained by the attractive chain–chain interactions.

5 SUMMARY

Summarizing the status quo of organization of metal nanoparticles, it can be stated that there exist several very promising procedures to especially generate 2D and also 1D arrangements. However, it has also to be recognized that we are still far from having techniques to routinely fabricate 2D and 1D structures. The final challenge to generate artificial instead of self-assembled structures seems indeed possible as is shown by the dip-pen lithography and the nanoelectrical surface patterning. Both allow construction of any kind of pattern of metal nanoparticles. Even if we would succeed in making aimed nanostructures routinely, there is still a long way to get working systems. These require techniques to individually address the quantum dots from outside. First steps to solve also these problems have been made; however, presently it is still too early to discuss them.

1 INTRODUCTION

Carbon is the fundamental building block for life on earth. The ability of carbon to form covalent bonds with diverse elements is unique without which the basis for life would be impossible. There are more than 10 million carbon-compounds known so far and many of them are pivotal to sustain the cycle of life. Covalent bond formation between the carbon atoms with sp^2 or sp^3 hybridization in a two- or three-dimensional array produces different allotropes. Graphite and diamond are the two best-known examples with distinct chemical, physical, and mechanical properties. Another carbon allotrope, exhibiting a closed carbon cage-like structure, known as fullerene was recently discovered during laser-vaporization of graphite (Figure 1).[1] Fullerene (C_{60}) is a highly symmetrical and truncated iscosahedral molecule consisting of 60 carbons and resembling a soccer ball. Several larger fullerenes with a higher number of carbons were found in high yields along with C_{60} in arc-vaporization of graphite.[2,3] The formation of cage-like carbon structures with a positive curvature from planar fragments of hexagonal graphite lattice requires inclusion of a specific number of pentagons. According to Euler's principle of least action, the perfect closure of hexagonal lattices into fullerenes geometrically requires 12 pentagons.

The research on the chemistry of carbons has been rejuvenated by the discovery of fullerenes.[1–4] Although scientists have continued developing the chemistry of fullerenes, the formation and the stability of fullerenes induced speculation to yet another new carbon nanostructure of an elongated fullerene-like structure, with larger number of hexagons and closed through the incorporation of pentagons. It was Sumio Iijima, at the NEC Corporation Fundamental Research Laboratory, who first discovered the formation of needle-like carbon nanotubes on the surface of a graphite electrode in an electric arc-discharge experiment in 1991.[5] High-resolution transmission electron microscopy (HRTEM) images of the needles showed a unique arrangement of hexagonally packed graphene sheets, rolled into a number of coaxial cylindrical shells (Figure 2). Interestingly, these tubes had fullerene-like caps at the ends. These tubes have been named multiwalled carbon nanotubes (MWNTs). In 1992, Ebbesen and Ajayan achieved production of MWNTs in gram quantities using an arc-discharge method.[6] Single-walled carbon nanotubes (SWNTs) were synthesized in 1993 by Sumio Iijima[7] and Donald Bethune[8] using iron- or cobalt-catalyzed arc-discharge processes. Rick Smalley and coworkers produced bulk quantities of SWNTs using a laser-vaporization of graphite, in the presence of a nickel–cobalt mixture catalyst at 1200 °C.[9,10]

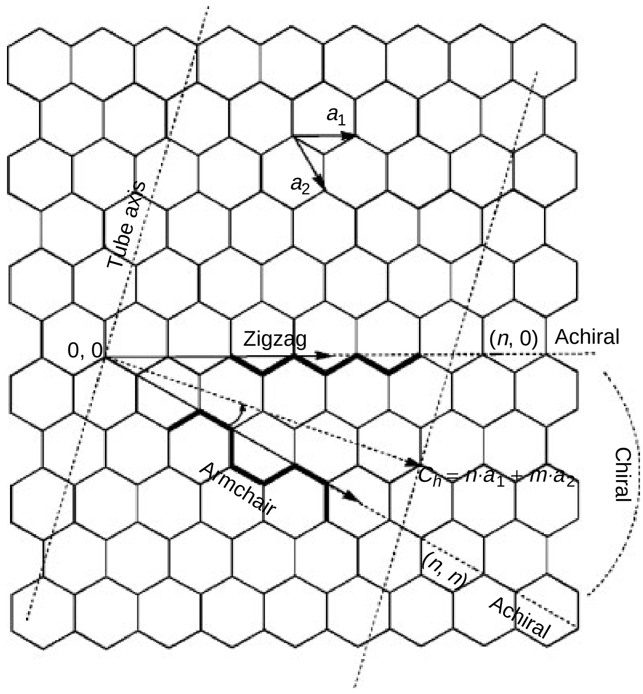

Figure 3 Illustration of chiral vector $C_h = n{\cdot}a_1 + m{\cdot}a_2$ using 2D graphene sheet with lattice vectors a_1 and a_2 and with limiting achiral cases of zigzag (n, 0) and armchair (n, n) configuration

Carbon nanotubes, with one-dimensional 'honeycomb' sp^2 carbon structure, exhibit exotic electrical, optical, and mechanical properties. Defect-free carbon nanotubes are considered as prototype one-dimensional (1D) solid quantum wires. This article focuses on some of the fundamental developments in the area of synthesis, characterization, and modification of carbon nanotubes.

2 STRUCTURAL CLASSIFICATION

2.1 Achiral and Chiral Tubes

Different types of carbon nanotubes arise from the unique arrangement of the honeycomb hexagonal carbon lattice upon a cylindrical coordinate. The orientation of the honeycomb lattice with respect to the tube axis determines the chirality of the carbon nanotubes. The carbon nanotubes can be simply envisaged as folding a graphite sheet into a cylinder, with a perfect matching of the open edges to form a seamless shell. The folding of graphite can be expressed in terms of a chiral vector, $C_h = n{\cdot}a_1 + m{\cdot}a_2$ that connects two longitudinally equivalent sites specified by a pair of integers (n, m) (Figure 3).[11–14] Here, a_1 and a_2 are the unit vectors of the hexagonal lattice of the graphene sheet and n and m are the integers specifying the chiral vector.

There are different types of folding that can generate distinct structures depending on the specificity of the pair of integers n, m with respect to zigzag or armchair directions. The zigzag direction can be drawn from a carbon atom (0, 0) on the cylinder axis to the other side passing through similar carbon atoms of each hexagon (Figure 3). The armchair direction can be drawn from the same carbon and passing through each hexagon dividing them into two equal halves. The chiral vector starts from the same carbon atom on one side of the separation line in the cylinder axis to another carbon intersection on the other side closest to the armchair line. The chiral angle, θ, is the angle between the chiral vector (C_h) and the zigzag direction. If the chiral vector lies on the zigzag direction ($\theta = 0$), then it is called a zigzag nanotube with the vector $m = 0$ (n, 0) and if $\theta = 30°$, then it is called an armchair nanotube with the vector $n = m$ (n, n). These are two limiting cases called achiral nanotubes since they have a mirror plane. Nanotubes characterized by all other angles between 0° and 30° are chiral, with specific vectors ($n \neq m \neq 0$). The different properties of carbon nanotubes arise from the variation in chiral angles and diameters. Atomically resolved images of SWNTs by scanning tunneling microscopy (STM) show clearly the honeycomb hexagonal lattice and orientation of different types of tubes (Figure 4).[15]

2.2 Metallic and Semiconducting tubes

The properties of carbon nanotubes, in general, are strongly dependent on the orientation of their honeycomb lattice with respect to the tube axis.[11,13–15,17] The electronic band structure calculations show that the vectors (n, m) determine the conductance and other properties of carbon nanotubes.[18,19] It is known that the two dimensional graphite's valence and conductance bands touch and degenerate at six points (K_f) of the graphene layer, which define the corners of the first Brilluion zone (Figure 5a). For a one-dimensional (1D) tube generated by rolling a 2D graphite sheet, the periodic boundary condition imposed by C_h determines the allowed 1D subbands for the tubes. The conductance of nanotubes depends on how the graphene valence and conduction bands pass through their degeneration points with respect to C_h. The tubes become metallic when the subbands of the tubes depending on the vectors pass through the graphene's degeneration points. The quantized subbands of a zigzag tube (9, 0) touch the degeneration points unlike in a tube (10, 0) (Figure 5b and c). Those tubes whose subbands are not passing through degeneration points are called semiconducting nanotubes. The zigzag (n, 0) and chiral (n, m) nanotubes can be either metallic or semiconducting depending on their pair of vectors. It is known that the zigzag (n, 0) or chiral (n, m) SWNTs are metallic if the value $(n - m)/3$ becomes an integer and all other tubes are semiconducting. However, armchair (n, n) nanotubes are metallic as their subbands remain on the graphene's degeneration points.

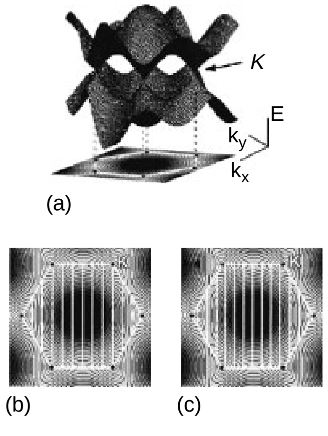

Figure 5 (a) Degeneration points (K) of a graphene's valence and conductance (π/π^*) bands in its three-dimensional projection. Black dots in the corners of white hexagon are the graphene K points. (b) The allowed 1D subbands passing through K for a metallic tube (9, 0). (c) The quantized 1D subbands deviating K for a semiconducting tube (10, 0). 3 SYNTHETIC TECHNIQUES

The synthesis of carbon nanotubes was first shown using an arc-discharge method.[5,7,8] The carbon nanotubes are generally synthesized by vaporization and condensation of carbon at high temperature in the presence or absence of a catalyst. The plume of carbon vapors reacts and rapidly assembles to form a tubular sp^2 network of various types. The synthesis can be classified, based on the source of carbon feedstock and the method of vaporization, into the following three basic techniques; 1) arc-discharge, 2) laser-vaporization, and 3) chemical vapor deposition (CVD). All of these techniques produce SWNTs or MWNTs under appropriate experimental conditions. Attempts have been made to optimize various factors influencing the growth processes to provide certain degree of control in the synthesis. However, the growth mechanism is very complex and not yet understood to the full extent needed to fine-tune these techniques to obtain selectively a particular type of carbon nanotubes. The task yet remains to produce exclusively semiconducting or metallic carbon nanotubes with uniform length and diameter distributions.

3.1 Arc-discharge Technique

The carbon arc-discharge method, also used for the mass production of C_{60}, under appropriate condition produces carbon nanotubes.[5,6] An arc is generated by applying a high dc/ac voltage between two graphite electrodes, placed end-to-end separated at 1 mm distance in a closed vessel under an inert atmosphere. Iijima accidentally discovered graphitic carbon needles deposited on the negative-end of the carbon electrode in arc-discharge evaporation of carbon at 100 torr argon pressure.[5] The analysis of the needles using transmission electron microscopy (TEM) showed graphite structure of lattices along the needle axis. The carbon needles exhibited the same number of lattice fringes from both sides of the needle with diameters of 4–30 nm and lengths up to

1 µm. The seamless and tubular carbon nanotubes consisted of several graphite sheets (Figure 2).

Under optimal conditions, the arc-discharge technique produces a large amount of MWNTs. It was found that increasing the pressure of inert gas during the arc-discharge increases the formation of tubes.[6] Later, the production of SWNTs was accomplished by using a small amount of iron as catalyst under an atmosphere of methane. The presence of metal catalyst in the vapor phase during arc-discharge favors selective growth of SWNTs against MWNTs. Metal catalyst mixed with graphite powder is filled into a drilled hole of the graphite electrode to selectively grow SWNTs. In the arc-discharge technique, the SWNTs are produced with an average diameter of 1 nm in large quantities.[7] The nature of the catalyst present in the arc-discharge technique controls the formation of SWNTs. The presence of cobalt in the absence of hydrogen also produces SWNTs along with fullerenes in the arc-discharge technique.[8] Several other bimetallic mixture catalysts such as Ni–Co, Co–Y, and Ni–Y in certain atomic percentages have been shown to be active in producing SWNTs with varying efficiency. For example, the mixture of 1 at.% of Y and 4.2 at.% of Ni under a helium atmosphere produced SWNTs in large scale (Figure 6a).[20] The electron diffraction pattern of the carbon nanotubes shows a slightly larger interlayer distance (0.344 ± 0.001 nm) than those found in bulk graphite (Figure 6b).[21]

The thermal conductivity and diffusion coefficient of the inert gas in the arc-discharge method have profound effects on the diameter of SWNTs. It was shown that an argon atmosphere produces smaller diameter SWNTs compared to helium and the average diameter of the tubes decreases $\sim$0.2 nm per 10% increase of argon in the argon–helium ratio.[22] In situ observation of HRTEM of the growth process reveals that the micrographenes and disordered layers form at early stage and subsequently rearrange into highly ordered graphitic layer.[23] The growth occurs first by rapid formation of rod-like carbon, which slowly undergoes graphitization of its wall leaving a cavity inside.[24]

The arc-discharge technique has been used to produce both high quality MWNTs and SWNTs. The MWNTs have also been produced using an electric current passing between graphite electrodes in molten LiCl at 600 °C.[25,26] The MWNTs consisting of 5 to 20 concentric layers are produced at an optimum current (1–5 A) from the eroded surface of the graphite electrode and get dispersed in the LiCl melt. Only amorphous carbon was generated at a very low and a very high current, indicating the formation of carbon nanotubes is controlled by the kinetics of the diffusion of carbon. Arc-discharge of the graphite electrodes under liquid nitrogen also produces a highly crystalline MWNTs.[27] Simply annealing the carbon face of hexagonal silicon carbide (SiC) under vacuum without a metal catalyst produces carbon nanotubes.[28–30] However, the silicon face of the SiC gives only graphite-like structures. The MWNTs perpendicular to the surface have been grown when the carbon face of SiC is annealed at high temperature. When the annealing is done at temperatures above 1500 °C, the carbon face of the SiC forms ordered SWNTs with preferred atomic orientation of the surface morphology.[30]

The quality of carbon nanotubes depends on various parameters such as the nature and the concentration of metal catalyst, the kind of inert gas and its pressure, the applied voltage, and, most importantly, the vessel geometry.[20,22,31,32] Adjusting the anode to cathode distance, rotating one of the electrodes, or subjecting the arc under a strong magnetic field have significant effects on the quality of MWNTs.[33,34]

Several catalysts have been used, and it has been learned that catalysts are technique specific (i.e. not all of the catalysts that work well in CVD method produce SWNTs in arc-discharge method). Under optimum conditions, the arc-discharge technique produces carbon nanotubes with diameters in the range of 0.3–1.4 nm. A very small diameter carbon nanotube has been found in the innermost shells of MWNTs in the arc-discharge method.[35–37] The use of hydrogen instead of helium in the absence of metals produced confined carbon nanotubes inside MWNTs with diameters of 0.3 and 0.4 nm (Figure 7a).[35,36] The presence of hydrogen atoms plays an important role in the formation of a small diameter tube. According to the density functional calculation, a tube with a diameter of 0.3 nm is probably an armchair (2, 2) with C_{12} end caps and would have severe steric distortion in the sp^2 bonds.[35] A smaller diameter carbon nanotube of 0.4 nm has been found inside MWNTs using a graphite anode filled with cobalt metal.[37] A type of one-dimensional carbon nanowire made of carbon atoms covalently connected with double bonds or alternatively connected with single and double bonds has also been found inside a MWNT produced by hydrogen arc-discharge (Figure 7b).[38]

A slight change in operating conditions leads to the formation CNTs with entirely different morphology in the arc-discharge technique. Using Ni/Y catalyst, selectively double-walled carbon nanotubes (DWNTs) can be produced at 1250 °C. However, the same catalyst system produces SWNTs at slightly lower temperatures. The Ni/Co catalyst also produces DWNTs over a wide temperature range from 1000 to 1400 °C.[39] A metal mixture catalyst consisting of Ni, Co, and Fe with elemental S selectively produces DWNTs in argon and H_2 (1:1 v/v) atmosphere.[40] The carbon nanotubes produced by the arc-discharge technique have several by-products as impurities such as fullerenes, graphitic carbons, enclosed metal nanoparticles, and amorphous carbon.[41] Special purification procedures have to be used to get pure carbon nanotubes.

3.2 Laser-ablation Technique

Smalley and coworkers at Rich University developed a new method for the synthesis of SWNTs using a laser impingement technique in 1995.[9] A laser was used to vaporize a graphite composite containing ∼1 at.% transition metal in an oven filled with inert gas at 1200 °C.[9,42–44] In laser ablation, the target graphite surface absorbs the laser energy and raises its temperature to ∼3000–4000 °C bringing the carbon and metal to a plume of vapors. Subsequent condensation of vapors and the chemisorption of metal atoms result in the formation of a fullerene precursor that nucleates the growth of graphitic sp^2 carbon network around the metal clusters.[9,45,46] The chemisorbed metal clusters migrate to the dangling bonds at the edges of the fullerene precursor preventing its closure (or termination). The carbon vapors quickly react with fullerene coordinated with metal and extend the growth. Insertion of new carbon linkages between the carbon edges and the metal particle occurs rapidly at high temperature leading to the formation of SWNTs. The yield of SWNTs increases with increasing the oven temperatures up to 1200 °C. A single metal or bimetal catalyst can be used in the synthesis in the laser-ablation technique. Continuous irradiation of graphite/bimetallic target (Ni:Y/2:0.5 at.%) using a 250 WCO_2 laser operated at 1074 nm produces SWNTs with average diameters of 1.4 nm (Figure 8).[47]

Recently, the mechanism of the growth process was probed by in situ imaging of the carbon/nickel/cobalt plume using Rayleigh scattering over different time and temperatures.[46] The results revealed that the metal evaporation occurs upon irradiation of the target and the plume stays in the vapor phase, which slowly grows nonuniformly for about 100 μs. At around 200 μs, the carbon vapor starts condensing and clustering well before the metal atoms condense. The size of carbon cluster is around 20 nm at 1100 °C. The nucleation of SWNTs growth occurs by condensation of all atoms and molecules into clusters and nanoparticles in 2 ms at the plume

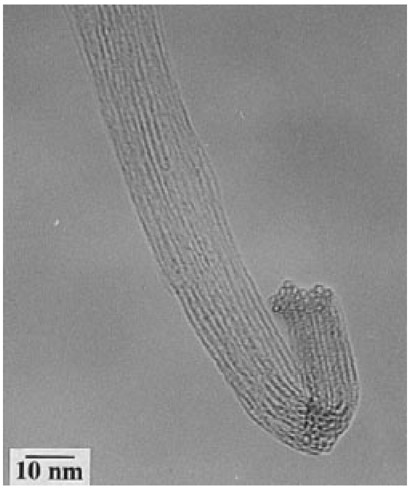

Figure 8 TEM of SWNTs bundle synthesized using Ni:Y (2:0.5 at.%) catalyst. (Reprinted from Ref. 47. © 1998, with permission from Elsevier)

temperature of ∼1400 °C just above the metal/C eutectic temperature (Figure 9).

The laser ablation of the graphite target produces high quality SWNTs with narrow size distribution in high yields. Among various catalysts studied, Ni, Co, and the mixture of Co/Ni and Ni/Y have produced higher yields of SWNTs.[45,47] A pulsed Nd:YAG laser beam has been used at 532 and 1064 nm to irradiate graphite-metal composites in many studies.[9,45,46,48,49] High efficiency laser-vaporization methods such as ultrafast pulses from a free electron laser and continuous wave laser have been used to grow SWNTs.[45,47] It was found that the growth and the nucleation of SWNTs are affected by the temperature and the laser-beam intensity respectively.[45] There is a direct correlation between the diameter and the low-frequency radial breathing modes of SWNTs in Raman spectroscopy. By optimizing the power of the laser pulse as well as the temperature, it is possible to obtain a certain degree of control over the diameter of SWNTs (Figure 10).[48,50] A single laser-beam pulse has also been used to produce SWNTs under specific conditions.[49]

Several factors affect the growth of SWNTs in the laser-ablation technique.[51,52] Extensive studies on the development of the laser-vaporization technique have optimized the process conditions such as laser parameters,[45,49] composition of graphite and metal,[45,47,52] carrier gas, pressure,[51] and temperature.[48,50] Through these studies, a significant understanding of the SWNT's growth and propagation under laser-vaporization condition is achieved.[42,43,46,53,54]

3.3 Chemical Vapor Deposition technique

A catalytic decomposition of carbon feedstock under a controlled environment at high temperature (>900 °C) produces carbon nanotubes. The CVD technique is one of the widely used techniques for the synthesis of both MWNTs and SWNTs. A hydrocarbon feedstock is used as the carbon source that is catalytically decomposed to form reactive carbon vapors. Ethylene and acetylene are used as carbon feedstocks at 550–750 °C in many CVD techniques. There are many different metals that can be used as catalysts to produce

MWNTs. However, only a few specific metal catalysts produce SWNTs in the CVD method.[7,55] The most effective catalysts used in the CVD method are iron, nickel, and cobalt. These metals have an ability to decompose hydrocarbons or other carbon sources to form metastable carbides at high temperature through a rapid diffusion mechanism. It has been proposed that the carbon vapors first deposit hemispherically on the exposed surface of the catalyst. A fast diffusion and deposition of carbon atoms occur around and below the bisecting diameter of the catalyst and the carbon atoms assemble into graphitic layers with an interlayer spacing of graphite. The deposition of carbon takes place in and around the hemisphere except for a small portion at the apex of the hemisphere leading to a hollow core while growing into carbon nanotubes. In the process, the catalyst particle is lifted upward, probably owing to a fast condensation of carbons at the bottom of the catalyst hemisphere. This leads to the formation of a cylindrical tube whose open-end carries a chemisorbed metal particle. Subsequently, a tubular growth occurs through the insertion of new carbons at the interface between the catalyst and the tube edge. This process is called a 'tip-growth' mechanism.[56–58] In some cases, the metal particles remain attached to the surface of the substrate and the carbon diffusion and deposition occur at the upper hemisphere of the metal particles. The carbon nanotube grows upward from the metal particles and this type of growth is called a 'root-growth' (extrusion) mechanism (Figure 11).[58–60] In situ observation of the state of the metal particle during the growth process is found to be fluidic and in some cases the upward pulling force of the carbon nanotube layers elongates and breaks the metal nanoparticles into two portions. One portion remains at the substrate surface and the other portion is active in the growth process.[56] The composition of chemicals that are used in the CVD technique is very important, as it has profound

influence on the diffusion property of pyrolyzed carbon and its condensation.

3.3.1 HiPco Process

The formation of single- or multiwalled tubes depends primarily on the size and the nature of the catalyst. When the size of the catalyst becomes smaller comparable to C_{60}, it nucleates the growth of SWNTs. The Boudard reaction of catalytic disproportionation of CO into elemental carbon and CO_2 is well known and it has been used for the synthesis of SWNTs. It was found that a preformed iron cluster induces disproportionation of carbon monoxide at high pressure at 1200 °C and produces SWNTs in good yield.[55] This process of high-pressure disproportionation of CO at a high temperature to produce SWNTs is called the 'HiPco' process. Nanosized iron, molybdenum, and mixture of Ni/Co (1:1) were used as preformed catalysts in HiPco process. The gas-phase catalytic growth produces smaller diameters SWNTs (~0.7–1.1 nm) with a metal particle cap. The diameter of the tubes correlated very well with the diameter of the metal particles. The growth of SWNTs stops only when the metal cluster size reaches a size that favors formation of a carbon shell around the cluster. The mechanism of growth was named 'yarmulke' or 'tip-nucleation' growth. One of the advantages of CO feedstock is that it decomposes in the vapor state at an optimum rate at 1200 °C. At this high temperature, the chances of formation of defects in the sp^2 network are minimized owing to annealing.

3.3.2 Hydrocarbons as Feedstock

Different types of hydrocarbons could be used in catalytic decomposition to produce SWNTs. It was shown that benzene could be used as a feedstock in the presence of a small amount thiophene as the catalyst precursor at 1200 °C.[61] High quality SWNTs with diameters ranging from 1.3 to 5 nm have been synthesized using methane in the presence of supported Fe_2O_3 at 1000 °C.[62] In the case of the production of MWNTs in the presence of a catalyst, a higher operating temperature significantly enhances the pyrolysis rate compared to the tube's growth rate leading to amorphous carbon deposition. However, the rate of decomposition of hydrocarbons could be controlled with an appropriate reactor design to minimize the amorphous carbon formation.

Long MWNTs of ~2 mm lengths have been produced in the presence of iron/silica nanoparticles as catalyst using pyrolysis of acetylene at 600 °C.[63] Similarly, the SWNTs with large diameters in the range of 2–5.2 nm were prepared using benzene as feedstock with ferrocene as catalyst and thiophene as growth promoter.[64] The size of the catalyst and the nature of carbon feedstock have significant influence on the growth process. The catalyst size is closely related to the diameters of the CNTs formed in the CVD technique similar to the other techniques.[58–60] Nanoclusters consisting of Fe and Mo atoms with ~1.3 nm in sizes produce SWNTs of similar diameter with narrow size distribution.[65] Synthesis of helically twisted MWNTs has been accomplished on a quartz plate by pyrolysis of $Fe(CO)_5$ and pyridine at 900–1100 °C under a flow of argon and hydrogen.[66] It is believed that a concomitant insertion of pentagon and heptagon pairs into the hexagonal sheet occurs during the growth that leads to a helical twisting.

It is possible to grow selectively DWNTs using molybdenum or by controlling the concentration of ferrocene in the decomposition of methane.[67,68] The mechanism associated with the selective growth of DWNTs by the CVD method is not well understood. A large amount of DWNTs was produced by pyrolysis of C_2H_4 at 900–1100 °C using iron in the presence of sulfur.[69] It was also noticed that the presence of sulfur is critical in promoting growth of DWNTs and the process gave only SWNTs in the absence of sulfur. This indicates that the chemical composition and the rate of pyrolysis are the important parameters that can be tuned to have certain control on the process. The diameters of DWNTs vary from ~1 to 2.9 nm and the inner diameters from 0.4 to 2.0 nm. The DWNTs produced by the CVD method had varying inner layer spacing between 0.34 and 0.41 nm.[68]

Synthesis of MWNTs on a polymeric substrate at atmospheric pressure has been shown using microwave irradiation.[51] Enhanced selective heating of the catalyst particles occurs under microwave irradiation owing to the dielectric specific heating. This raises the temperature of the catalyst very high without raising the temperature of the substrate polymer. Polycarbonate and Teflon® have been used as substrates to produce MWNTs in the presence of cobalt with acetylene (C_2H_4) and hydrogen sulfide (H_2S) mixed gas as carbon feedstock.[70] One of the problems of the CVD process is that the carbon nanotubes have higher defect density compared to the arc- or laser- techniques. Low

operating temperatures of the CVD process do not provide necessary thermal energy sufficient to anneal the nanotubes to form a perfect sp^2 network structure. However, the simplicity of the process makes it viable for a large-scale production of carbon nanotubes.

3.3.3 Aligned Carbon Nanotubes

One of the advantages of the CVD method is that well-aligned SWNTs and MWNTs perpendicular to the substrate could be grown from many substrates.[71,72] The specificity of the process is unique as the tubes grow only from the catalyst deposited regions of the substrate. The SWNTs have been grown from patterned silicon wafers using iron as the catalyst and methane as the feedstock at 1000 °C. The iron catalyzed methane decomposition produces pure SWNTs without any amorphous carbon coating for up to 10 min. However, a slow self-pyrolysis of methane produces amorphous carbon coating on the tubes if the process is continued over a period of time.[71] The end of SWNTs is closed and contains no catalyst, which indicates carbon nanotubes are formed by a 'root-growth' mechanism. When ethylene gas is used instead of methane, a regular array of MWNTs oriented perpendicular to the substrate is produced.[73]

A template assisted synthesis of MWNTs in an anoidic aluminum oxide (AAO) on metal surfaces has been shown to produce aligned MWNTs.[74] Well-aligned MWNTs have been grown perpendicular to the substrate from a quartz plate and it has been noticed that the length of the tube increases with time during synthesis. The tubes have a small amount of amorphous carbon deposited on the surface owing to a low temperature and a long reaction time.[75] By controlling the catalyst particle size and its patterned deposition, it is possible to grow MWNTs in a patterned orientation from the substrate (Figure 12). Aligned MWNTs have been grown on a quartz substrate and filled with polymer to form a nanotube membrane and used for transport studies.[76] Nickel catalyst deposited on a glass substrate in the presence of acetylene at 660 °C has been used for the production of MWNTs with diameters from 20 to 400 nm and lengths from 0.1 to 50 μm.[72,77] The MWNTs with a bamboo-like structure aligned perpendicular to nickel coated silicon substrate have been produced in the hot-filament CVD method using C_2H_4/NH_3 gas source at 600–800 °C.[56] Aligned CNTs have been grown in a pattern as 'crop circles' using iron(II) phthalocyanine at 1000 °C.[78]

Region-specific growth of CNTs has been achieved on a photolithographically patterned quartz surface or micro-molded surface with a micrometer resolution (Figure 13a).[79–81] The nanotubes can be grown in different directions perpendicular and tilted to the substrate simultaneously from a geometrically tailored catalyst deposited surface.[82] Multidirectional growth of MWNTs is achieved from a patterned SiO_2 template on silicon surface using xylene/ferrocene vapor at 800 °C (Figure 13b).[82,83] Aligned carbon nanotubes have been grown on a partially masked surface by pyrolysis of iron(II) phthalocyanine. Recently, a selective growth of semiconducting SWNTs was achieved by a plasma enhanced CVD method using Fe/CH_4 system on a SiO_2/Si wafer surface at 600 °C.[84]

The driving force for the growth of aligned carbon nanotubes is the presence of van der Waals interactions between the growing nanotubes.

3.3.4 Hydrothermal Synthesis

Hydrothermal pyrolysis is another approach used for the synthesis of MWNTs.[85,86] The MWNTs have been synthesized using amorphous carbon and water in an autoclave at 800 °C under 100 MPa. The MWNTs with diameters of 10–50 nm with graphitic nanoparticles were obtained in hydrothermal pyrolysis. The formation of CNTs in the absence of a metal catalyst under hydrothermal conditions involves rearrangement of bonds of amorphous carbon.[85] A simple procedure has been used to produce MWNTs by tipping a red-hot graphite rod into water at 0 °C.[87] The water turned black and particles slowly segregated, which were identified as MWNTs. It was explained that the temperature difference between inner and outer layers of the graphite rod while tipping into water produces necessary energy to crimp the graphitic layers and fuse the edges through covalent linkages in the presence of water. The actual mechanism of the formation of MWNTs by this procedure is not well understood. Nevertheless, the MWNTs produced by this method have defect-free lattices.

The hydrothermal synthesis of MWNTs can also be carried out in the presence of metal catalyst and other hydrocarbons as carbon feedstock. Nickel and high-density polyethylene or polyethylene glycol have been used as catalyst and carbon feedstock respectively to form MWNTs in the presence of water at 800 °C under 100 MPa.[86] The growth occurs in a high-density fluid phase and produces a large diameter MWNTs (50–150 nm). The process also produces some of the tubes partially filled with fluid in side the capped MWNTs. The presence of trapped fluid inside the cavity of MWNTs indicates a high perfection of the graphene layer.

4 DIFFERENT TYPES OF CARBON NANOTUBES

Topologically different types of carbon nanotubes can be synthesized using appropriate reagents and conditions. A structural deformation of a carbon nanotube leading to cross-linking, ring closing, and junction formation can also be accomplished using post chemical or physical treatment.[88–90] It is possible to weld the SWNTs at a desired location using electron beam irradiation at elevated temperatures.[88] A controlled irradiation at the cross section of two individual SWNTs can transform the junction geometry into ‘X’, ‘Y’, and ‘T’ shapes through welding depending on the point of irradiation (Figure 14A). The dynamic simulation studies indicate that the junction linkage occurs with the formation of seven or eight-membered carbon rings. However, the actual welded junctions are not showing such perfect rings and have defective atomic arrangements at the junctions. It is also possible to produce branched carbon nanotubes through the CVD process using appropriate precursor reagents. The pyrolysis of nickelocene along with thiophene at 1000 °C produces branched MWNTs with multiple ‘Y’ junctions (Figure 14B).[91] The MWNTs containing ‘Y’ junctions have been synthesized in a catalytic thermal decomposition process.[92] However, the mechanism of formation of branching during the synthesis is not well understood.

The formation of junctions in carbon nanotubes is important for use in electronic application. The SWNTs have been shown to react with silicon and transition metals and form metal carbide nanorods and nanoparticles at high temperature under high vacuum.[93] A heterojunction interface with metal carbide at the tips of SWNTs is possible. Silicon and metal substrates such as Ti and Nb have been used with SWNTs to form long SiC, TiC, and NbC nanorods respectively. A small number of SWNTs with partial reaction are found to have connected to SiC nanorods (Figure 15). The formation of such a carbide heterojunctions in carbon nanotubes with

the properties of semiconducting or metallic is very important in the development of nanoelectronic devices.

Carbon nanobulbs have been formed in a process similar to the conventional 'glass' blowing.[89] Blowing carbon nanotubes requires a sudden formation of gas that should generate a sufficient pressure difference between the inside and outside of a closed tube. One of the synthetic procedures for MWNTs involves explosive decomposition of picric acid in the presence of nickel formate generating a high temperature (~1200 K) with a high pressure (~40 MPa). This gives a required pressure difference between the inside and outside of the tubes during the growth process until the end is capped by

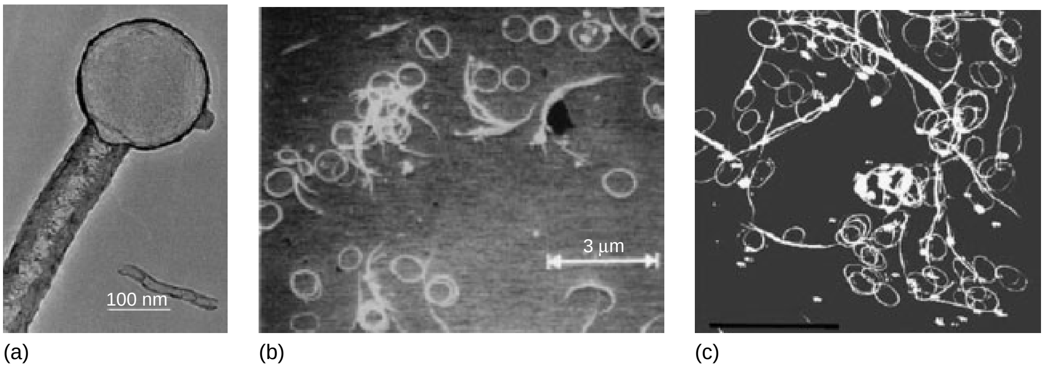

Figure 16 (a) TEM image of carbon bulb formed from tube blowing. The wall thickness is 25 nm for the parent tube and 9 nm for the blown blub. the termination. The end capping produces a temperature difference and the tubes expand in volume owing to the pressure difference into spherical bulbs at the tips as well as along the tube axis (Figure 16a). Up to 30% bulb formation has been reported.[89]

The carbon nanotubes are well known for their high flexural rigidity.[95] They can be mechanically or chemically forced to form nanorings and nanocoils.[90,94] A small percentage of rings of SWNTs with diameters ranging from 300 to 500 nm and rope widths of 5–15 nm have been found in some cases of laser-grown material.[96] It has been proposed that the rings are formed through ‘intramolecular-growth’ termination during the laser ablation. However, the formation of such rings is very low (0.1–1%). The ring formation of SWNTs occurs even under ultrasonication in a post treatment when long SWNTs are dispersed in a solvent and sonicated for 1–3 h at 40–50 °C. It is believed that a bubble formation during sonication around the hydrophobic nanotube forces the nanotube mechanically to bend at the bubble-liquid interface.[94] The ring formation occurs through van der Waals stabilization as the bubbles collapse leaving cavitation (Figure 16b). It is difficult to ascertain whether these rings are closed loops or open-ended coils. The acid and the hydroxyl groups generated during shortening or oxidative procedures are concentrated at the open ends of the SWNTs and they can be intramolecularly reacted to form rings.[90] The intramolecular ring closer of the oxidized SWNTs dispersed in N, N-dimethylformamide (DMF) using esterification in the presence of dicyclohexylcarbodiimide (DCC) produces a large amount of rings at room temperature (Figure 16c). This process shows the ability of SWNTs to bend and under go chemical reaction, intramolecularly, in solution like a semiflexible polymer. Theoretical studies show that the stability of SWNT rings is very high and the ring dissociation occurs only at high temperature.[97]

5 PURIFICATION OF CARBON NANOTUBES

The purity of carbon nanotubes mainly depends on the techniques used for the production. Unfortunately, none of the techniques, even after extensive optimization, produces pure carbon nanotubes that can be used directly for applications. In general, *as-synthesized* CNTs contain variable amounts of amorphous carbon, graphitic, and carbon coated metal nanoparticles, smaller fullerenes, and metal catalysts. The CNTs synthesized in the absence of metal catalyst contain largely amorphous and graphitic carbon impurities. The impurities vary widely in the range of 10–70% depending on the experimental conditions as well as the technique used for the synthesis. Several strategies have been developed for the purification of CNTs. Impurities are removed by subjecting CNTs to an appropriate repetitive dry or wet oxidation.[98–101] The amorphous carbon and the residual catalyst materials are removed first by oxidation with HNO_3, air-oxidation at high temperature, and subsequently the metal oxides are removed by dissolution in mineral acid.

It is difficult to remove the impurities by oxidation procedures without affecting the pristine CNTs since the carbon nanotubes and the impurities have only slight differences in their reactivity towards oxidation. The oxidative purification procedures are known to introduce defects, chemical functionality, doping, opening of caps, and shortening of lengths, and so on. Hence, the conditions for oxidation should be carefully chosen in order to minimize the damage to pristine CNTs. The reactivity of SWNTs varies depending on the diameter. The tubes with smaller diameters have higher reactivity then the larger ones. As different methods produce SWNTs with different average diameters, it is important to choose an appropriate oxidation procedure. The amount of impurity also differs from batch-to-batch since a slight variation in the experimental condition affects the growth significantly. Depending on the method

of production and the level of impurities, the sequences of oxidation steps should be optimized for efficient purification of the carbon nanotubes.

5.1 Nitric Acid Reflux and Length Reduction

The SWNTs with larger diameters especially laser produced ones can be purified with the nitric acid reflux method. *As-prepared* SWNTs are treated with 3 M HNO_3 solution and refluxed for 48 h to remove a substantial amount of impurities.[101–106] The acid partially attacks the robust SWNTs network through intercalation of nanotube ropes and removes a considerable amount of exposed metal and nontubular carbons. The tubes are then thoroughly washed with water and dried. Further purification can be accomplished by treating the SWNTs in a mixture of sulfuric acid and nitric acid (3:1 v/v) at 70 °C for a short time followed by treating with a 4:1 (v/v) mixture of sulfuric acid and hydrogen peroxide (30%). This treatment shortens the SWNTs into smaller lengths (Figure 17). A longer duration in such a strong oxidizing agent is not advisable as it affects the sidewalls of SWNTs and cuts the tubes severely.[101,102,104,107–110]

The SWNTs have also been cut into smaller lengths using a simple grinding procedure with cyclodextrin.[111] The SWNTs composite mixed with cyclodextrin forms a colloidal suspension in water under sonication (10 min) and the TEM analysis shows that 70% of the nanotubes in the suspension have reduced in lengths between 100 and 600 nm from an average of 4 µm. Other reagents such as octadecylamine (ODA) when ground with SWNTs do not give a good dispersion. It is believed that the cyclodextrin is adsorbed noncovalently on the surface of SWNTs and the soft cutting occurs through mechanical force.

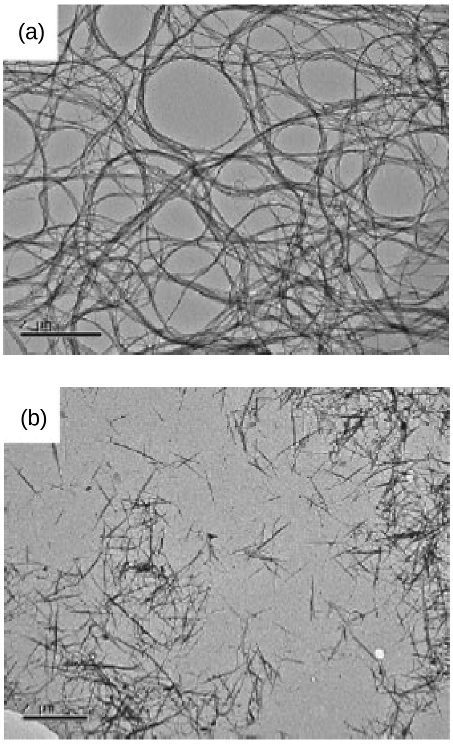

Figure 17 TEM images of (a) purified SWNTs and (b) after H_2SO_4/HNO_3 treatment (scale bar 2 µm). (Ref. 110. Reproduced by permission of Wiley-VCH)

5.2 Air-oxidation and Acid Treatment

One of the purification procedures involves air-oxidation followed by washing with HCl to remove metals. Metal nanoparticles that are covered with carbon coating are difficult to dissolve in an acid treatment. In order to break-up the carbon coating, air-oxidation is usually done at an optimal temperature for a specific duration. The presence of metal impurities enhances the oxidization of CNTs at higher temperatures and, hence, the oxidation is done by a step-by-step manner.[100,112,113] In this procedure, the sample is heated first in air at a moderate temperature ($T_1 \sim 225-300\,°C$) for a certain duration (t_1)

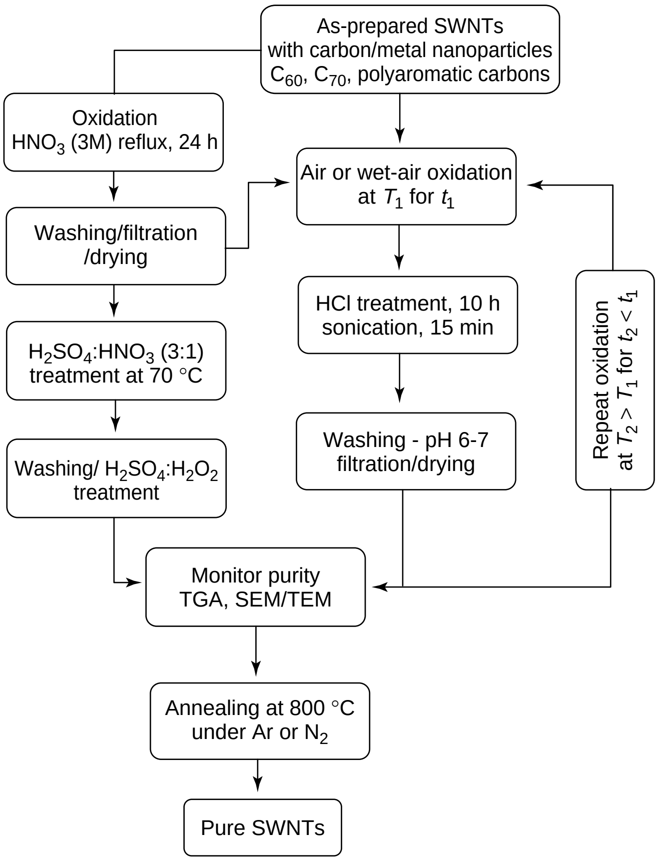

Figure 18 Schematic of the steps involved in different methods of oxidative purification of SWNTs. Oxidation is done at a particular temperature (T_1) for a certain period of time (t_1). Both the T_1 and t_1 are required to be determined for every sample batch with prior knowledge of decomposition rate using TGA

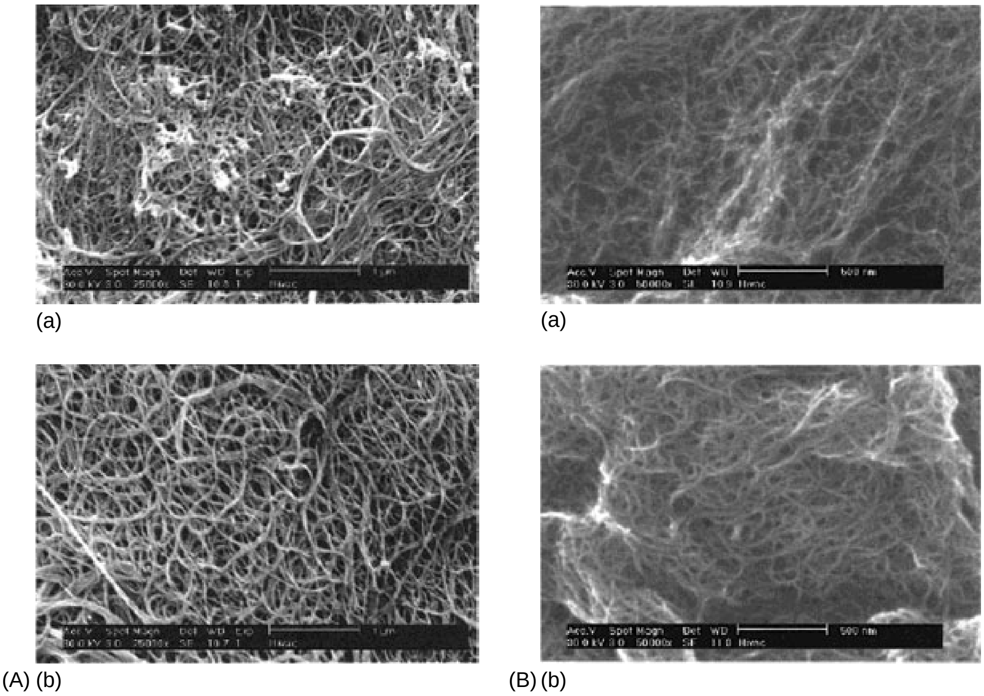

Figure 19 SEM images of purified SWNTs. (A) Laser-grown SWNTs subjected to two stage air oxidative purification (scale bar 1 μm); (a) before purification and (b) after purification. (Reprinted with permission from Ref. 109. © 2001 American Chemical Society)

and subsequently treated with HCl to remove dissolved metals and then washed with water to clean the CNTs.[99,109] The temperature (T_1) and the duration (t_1) are dependent on the amount of impurity present in the sample. On the basis of the decomposition rate of the carbon nanotubes, T and t can be estimated. The oxidation can be repeated at a slightly higher temperature ($T_2 > T_1$) for a shorter t_2 ($t_2 < t_1$). After every oxidation steps, the sample is treated with HCl to remove the metal oxides by dissolution and washing with water to neutral pH. The advantage of the step-by-step oxidation procedure is that it incrementally removes catalyst and improves the purification efficiency (Figures 18 and 19). The purification efficiency of every oxidation step can be monitored using thermogravimetric anaylsis (TGA), Raman and Near-IR spectroscopy, and SEM/TEM imaging. The oxidation and the cleaning steps are repeated until desired purity is achieved. The CNTs are finally annealed at a high temperature under vacuum or inert gas to get purified carbon nanotubes.

The SWNTs produced from the HiPco process exhibit a smaller average diameter and, hence, a mild wet-air oxidation is done to avoid damages to the tubes. The oxidation of SWNTs in the presence of wet-air is found to selectively oxidize the nontubular carbon impurities without affecting the small diameter tubes.[100,112] In this procedure, the oxidation is done in the presence of air saturated with water vapor at 225 °C for 24 h. This is followed by sonication for ~15 min or stirring 10–15 h in concentrated HCl. The tubes are washed with water and dried thoroughly. The TGA of purified tubes shows a considerable reduction in metal content and other impurities. The wet-air oxidation is continued in multiple steps at higher temperatures (325 °C for 1–2 h and 425 °C for 1 h) to remove catalysts and other nontubular impurities. The sample must undergo HCl treatment and water washing after each oxidation procedure. The purified carbon nanotubes are obtained after annealing in argon or under vacuum at 800 °C for 1 h.

The oxidation of CNTs has been done using microwave (2.5 GHz, 150 W) treatment at 500 °C.[114] Irradiation by microwaves raises the local temperature of the metal catalysts significantly and ruptures the carbon layer around the catalytic nanoparticles. Then, the exposed metal is removed by refluxing in 4 M HCl for 6 h. It has been reported that the amorphous carbon and the metal caps could be removed from aligned MWNTs using the radio frequency glow-discharge plasma etching technique.[98]

5.3 Sonication and Filtration

Ultrasonication has been used for the purification of CNTs.[115] The low-molecular weight impurities are removed from carbon nanotube dispersion in methanol by filtration under a continuous sonication. The carbon nanotubes are

kept in dispersion in methanol through sonication during the filtration. Methanol is continuously supplied during the filtration to maintain a constant filtration volume and the filtered SWNTs are washed with H_2SO_4 to remove the residual metals. A microfiltration technique has also been used to separate C_{60}, C_{70}, and other polyaromatic carbons from the SWNTs dispersion in CS_2.[116] The chemical modification of SWNTs affects the solubility parameters of nontubular carbon impurities significantly. Nontubular carbon species in the 'as-prepared' SWNTs can be extracted in tetrahydrofuran (THF) and filtered using 0.2 μm Teflon® membrane after a simple fluorination procedure.[112]

5.4 Chromatographic Separation

The size of impurities such as fullerenes, metal nanoparticles, and polyaromatic carbons are much smaller than the carbon nanotubes. Such impurities can be separated using size exclusion chromatography (SEC).[105,117] The carbon nanotubes are first dispersed in organic solvent either by functionalization or using surfactants. The dispersed SWNTs in organic solvents at low concentration can be used to separate the impurities by SEC techniques.[105,118] The conventional styrene-divinylbenzene crosslinked column materials are used for the separation. The ODA functionalized SWNTs in THF can be separated into pure functionalized SWNTs, other nanoparticles, and amorphous carbon at different retention times. A similar procedure has been used to separate different lengths of zwitterion-functionalized SWNTs using SEC.[119]

5.5 Generation of Carboxylic Acid Functionality

The carbon nanotubes can be functionalized with carboxylic acid groups using several wet-oxidation procedures.[106–108,120–122] The carbon nanotubes undergo severe acid itching when subjected to oxidizing conditions such as refluxing with nitric acid, sonication in a mixture of sulfuric and nitric acids at moderate temperature, or treating with piranha solution (sulfuric acid-hydrogen peroxide). Acid treatment opens the caps and removes considerable amount of amorphous and nontubular carbons along with intense cutting of the tubes leading to a reduction in length distribution.[106,107,120,121] The open ends of the carbon nanotubes with reactive dangling carbons transform into an indefinite number of oxygenated functionalities under oxidative condition. The oxidative purification of carbon nanotubes generally introduces a large concentration of carboxylic acid groups at the ends of the tubes and also at the defective surfaces along the tube with a small amount of other functionalities such as anhydride, alcohol, quinines, and esters. The carbon nanotubes with smaller diameter are more reactive and get oxidized more readily. This leaves more defects generated all along the surface in smaller diameter tubes than larger diameter tubes. Hence the distribution of functional groups in the carbon nanotubes varies widely with length and diameter.

6 PROPERTIES OF CARBON NANOTUBES

6.1 Optical Properties

The properties of carbon nantotubes are strongly dependent on their symmetry and diameter.[13] The carbon nanotubes are considered as a one-dimensional quantum-wire, and the influence of the quantum-size effect on the physical properties is significant. Raman scattering of the crystalline ropes of SWNTs shows several vibration modes, which are dependent on the diameter of the carbon nanotubes.[123] The Raman spectrum of SWNTs have several radical breathing vibration modes (RBM) around 180 cm^{-1}, minor disorder-induced band (D-band) at around 1200–1400 cm^{-1}, and the first-order tangential vibration modes (G-band) between 1500 and 1600 cm^{-1} along with the second order mode at 2700 cm^{-1}.[13] The G-band corresponds to the stretching and bending vibrational movements of the C–C bond in the plane towards the tube axis and D-band corresponds to similar vibrational movements in the plane towards and away from the center of the hexagons. A typical Raman spectrum of the randomly oriented SWNTs at different excitation frequency is shown in Figure 20(a). Experimentally observed frequencies correlate very well with the theoretically calculated ones using the C–C force constant.[124] Raman frequency increases with decreasing diameter especially in the low-frequency region ($\omega \leq 500\,cm^{-1}$).[125] The vibration frequency and its intensity towards the low-frequency modes change with increasing laser wavelength. The electronic density state (DOS) calculation using the tight-binding model shows that the energy difference between the valance (v_1) and the conduction band (c_1), decreases with increasing diameter (Figure 20b). The optical symmetric transitions occur between the lowest subbands (mirror image spikes) in semiconducting and metallic tubes (v_1 to c_1 and v_2 to c_2, etc.).

The tangential modes of SWNTs show a distinct band broadening and shift to lower frequencies at a critically narrow range of laser energies (1.7 eV $\leq E_{laser} \leq$ 2.2 eV).[126] This anomalous behavior is attributed to the presence of metallic nanotubes, which have a similar range of energy separation ($E_{11} = E_{c1} - E_{v1}$) in the one-dimensional density of electronic states. The differences in DOS for metallic and semiconducting SWNTs cause a distinct change in the tangential vibrational modes for Stokes and anti-Stokes Raman spectra.[127] The G-band frequencies determined for 62 isolated SWNTs show that they can be classified into two intense bands depending on the structure of the tubes.[128] The peak at 1591 cm^{-1} is found to be independent on diameter. The peaks at 1554–1575 cm^{-1} are dependent on diameter and shift to lower frequencies for both metallic and semiconducting tubes.

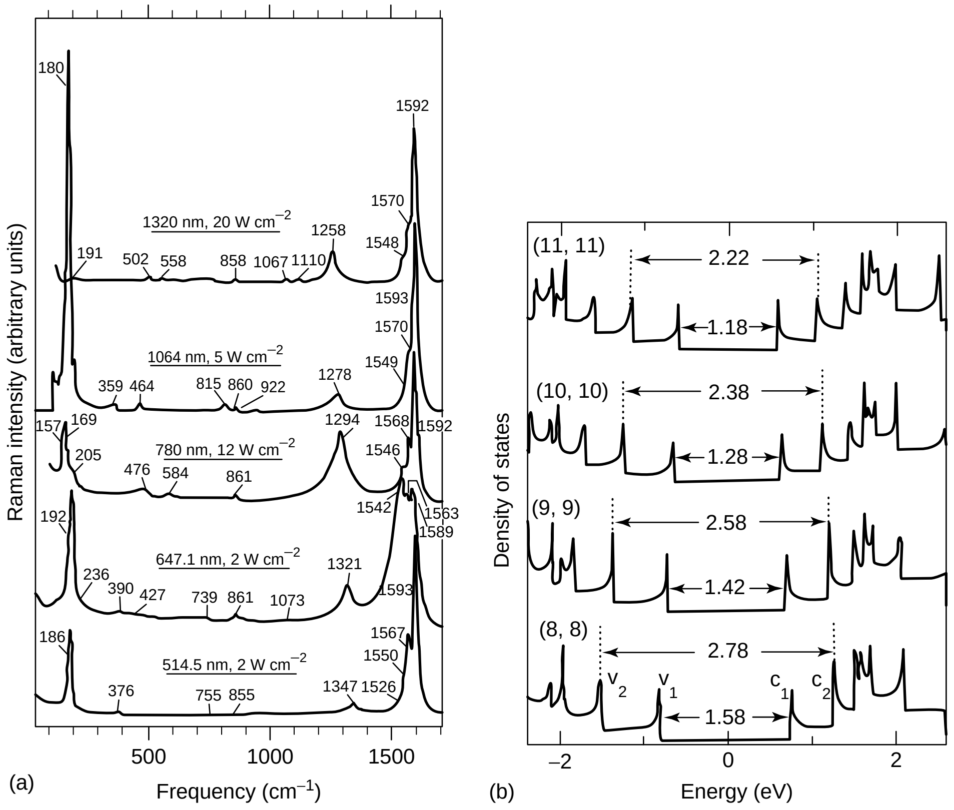

Figure 20 (a) Raman spectra of SWNTs excited at different laser frequencies and (b) Electronic density of states (DOS) calculated with the tight-binding model for the (8,8), (9,9), (10,10) and (11,11) arm chair nanotubes. Dresselhaus, *Science*, 1997, **275**, 187. © 1997 AAAS)

Unlike the SWNTs, the MWNTs do not show such well-defined vibrational frequencies owing to their larger diameter and broader distribution. The tangential vibrational and disorder mode for the MWNTs are very broad. The radical breathing modes of MWNTs in the region between 100 and 600 cm^{-1} are originating from the inner most tubes. Low-frequency RBM has been used to determine the diameter of the innermost tubes in MWNTs that agrees well with the high-resolution TEM results.[129] Raman scattering studies of DWNTs have shown that the RBM frequencies of the outer tube are not strongly influenced by the presence of an inner tube.[130] The tangential mode frequencies of the outer ($d \sim 1.3–1.6$ nm) and inner ($d \sim 0.6–0.9$ nm) semiconducting tubes are appearing distinctly at ~1590–1594 cm^{-1} and ~1584–1587 cm^{-1} respectively. The down field shift of the tangential mode frequencies of the inner tube is attributed to a wall-curvature.

The radical breathing, in-plane graphitic G-band and disorder-induced D-band frequencies of SWNTs have been found to be dependent on temperature. A linear decrease in frequency with respect to increasing temperature has been identified.[131] The temperature-dependent ω_D band for semiconducting tubes at 1565 cm^{-1} is ~−0.0226 $cm^{-1}\,K^{-1}$. However, experimental and molecular dynamic simulation studies have shown that the thermal expansion of the individual SWNTs in radical directions is extremely small and thus will have a minor effect in the frequencies of ω_{RBM} at various temperatures. The main reason for the dependence of ω_{RBM} is the temperature induced softening of the intratubular C–C bond strength and the intertubular van der Waals interactions.

It is known that the radical breathing mode has an inverse relation with respect to diameter $d = A/\omega_{RBM}$ where 'A' is a constant that can be obtained by theoretical models. A mean value of 'A' from many models appears to be 234 nm cm^{-1}. This correlation is consistent with the experimentally determined semiconducting tube diameter distribution.[132] The van dar Waals intertubular interaction between the individual tubes in a bundle also shifts RBM further to ~14 cm^{-1}. Hence, the actual diameter is given by; $d = (A/\omega_{RBM}) + 14\,cm^{-1}$.

6.2 Absorption Spectroscopy

One-dimensionality of the carbon nanotubes transforms the DOS into several sharp van Hove singularities with distinct energy gaps. The energy differences in the electronic transition (E_{11}, E_{22}, etc.) of conduction and valence bands

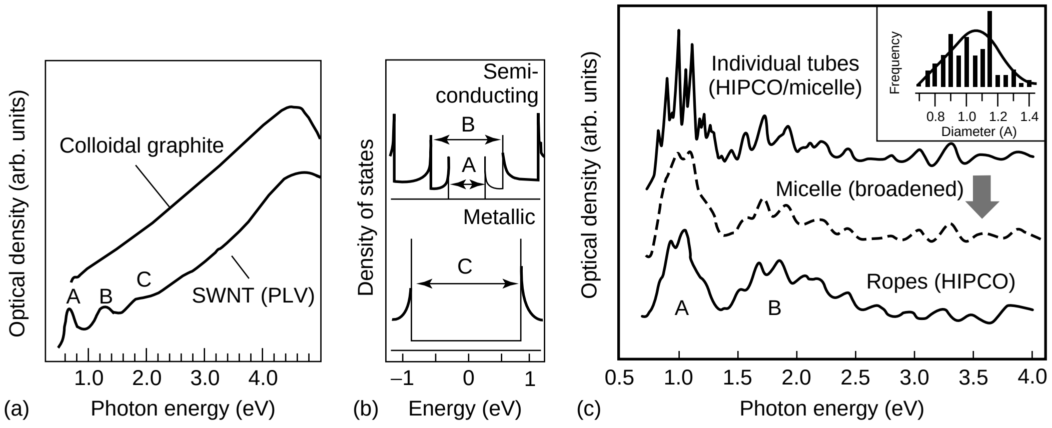

Figure 21 UV−vis-NIR spectra of different SWNTs. (a) Spectrum of SWNTs ropes produced by laser ablation in comparison with the colloidal graphite. (b) Symmetric transitions (DOS) between lowest subbands in the semiconducting (A, B) and the metallic (C) tubes. (c) HiPco samples in suspended sodium dodecyl sulfate (SDS) micelles. are dependent on the diameter, and the chirality of the carbon nanotubes. The existence of interband transitions between DOS singularities for various types of carbon nanotubes can be characterized using optical absorption spectroscopy. A typical optical absorption spectrum of SWNTs shows three broad peaks at energies between 0.65 and 2 eV that agree well with the theoretical calculations (Figure 21).[133–137] The peaks at ∼0.68−0.8 eV (1823−1549 nm) and ∼1.2−1.5 eV (1033−826 nm) (A and B) are related to interband transitions between the first and second subbands of semiconducting tubes and a peak at ∼1.8−2 eV (688−620 nm) is a second subband transition of metallic tubes (C) (Figure 21).

As the electronic transitions depend on the diameters of the carbon nanotubes, a smaller diameter SWNTs produced by the HiPco process (average $d \sim 1$ nm) shows fine structural details in the transition peaks. Any change in the electronic properties of the carbon nanotubes is reflected in these absorption peaks. The carbon nanotubes dopped with organic or inorganic materials have significant change in the electronic transition states. Doping SWNTs with electron acceptor (Br_2 or I_2) or donor (K, Cs) molecules makes the absorption peaks disappear owing to either electron depletion or addition of specific bands in the semiconducting or metallic tubes.[138]

It has been observed that the SWNTs suspended in a micellar solution exhibit a well-defined optical spectrum and show a bright photoluminescence in the near infrared region (Figure 22).[139] The individual SWNT suspended in air at room temperature also shows a bright photoluminescence.[140] The emission spectrum of the semiconducting SWNTs correlates well with the absorption spectrum in a micellar solution. The intensity of emission decreases dramatically when the isolated nanotubes start aggregating in a destabilized micellar solution. The decrease in the emission is attributed to the quenching of electrons by the metallic nanotubes when

bundling occurs with the adjacent semiconducting tubes. On the basis of the lifetime and the quantum yield of luminescence, the photoluminescence has been characterized as fluorescence.[139]

6.3 Electrical and Thermal Properties

Electrical conductivity of the carbon nanotubes shows a quantized property of an extremely thin one-dimensional wire. As predicted by theory, the conductance of carbon nanotubes is found to be ballistic. The advantage in

ballistic conductance is that the dissipation of heat energy is nearly absent during conduction.[141,142] The experiment carried out using MWNTs as a tip of a scanning probe microscope contacting a liquid metal to establish electrical contact shows a quantum conductance ($G_0 = 2e^2/h$ $\sim$12.9 kilo ohms^{-1}) without any heat dissipation.[143] The resistance of an individual SWNT and ropes of SWNTs decreases with the temperature and reaches superconductivity below 1 K.[75]

The electrical conductance of carbon nanotubes is sensitive to the chemical environment of the tubes. A large difference in the electrical conductance is observed for the carbon nanotubes in the presence of air and oxygen atmosphere.[144] It is possible to tune the electrical conductance of carbon nantubes reversibly using adsorbent gas molecules. The carbon nanotubes were also used to increase the conductance of a conjugated polymer for the development of electroluminescence polymer-nanocomposites.[145]

Thermal and thermal storage properties are very important and they determine the limitation of any applications such as molecular electronics, and conducting polymer composites, and so on. The carbon nanotubes have a higher specific heat and a higher thermal conductivity than any other known materials.[146–148] It is known that the heat transport in carbon nanotubes occurs through phonons.[149,150] The electronic and phonon spectra of carbon nanotubes are quantized owing to their smaller diameter. Low-energy phonons have a pronounce effect on the mechanical properties and thermal conductivity of carbon nanotubes. Similar to the one-dimensional electronic spectra of SWNTs, the low-energy phonon spectra also show a one-dimensional behavior.

The SWNTs have a larger specific heat at low temperature that follows a quadratic function (Figure 23a). The specific heat of the MWNTs determined in the temperature ranges from $1 < T < 200$ K is somewhat similar to that of the graphite. At temperatures, $>$50 K, the relationship between the specific heat and the temperature is linear up to 300 K. Thermal conductivity of SWNTs decreases gradually with decreasing temperature from 350 to 40 K, and the decrement is linear at $<$30 K up to zero K. The temperature-dependent thermal conductivity of SWNTs is very different from the graphite exhibiting a marked decrease of K with increasing temperature $>\sim$150 K (Figure 23b). However, it has been shown that the thermal conductivity of a single nanotube is comparable to that of diamond or in-plane graphite.[150] The thermal conductivity of MWNTs is independent of the tube length and smaller than diamond and in-plane graphite by a factor of 9 and 7.5 respectively.

6.4 X-ray Diffraction of Carbon Nanotubes

X-ray diffraction is used to characterize the structural parameters such as diameter distribution, intertube distances,

and in-plane reflections of carbon nanotubes.[21,151,152] The powder X-ray diffraction plotted as a function of the wave vector θ is defined by $(4\pi\, Sin\theta)/\lambda$, where 2θ is the scattering angle and λ is the wavelength. A typical diffraction pattern for MWNTs plotted as a function of 2θ shows several Bragg peaks.[153] On the basis of the hexagonal graphite structure, the peaks can be indexed with (00*l*) and (*hk0*) relating to interplane layer stacking and in-plane reciprocal reflections respectively. The X-ray diffraction of MWNTs from 10 to 100°/2θ shows peaks for the layer stacking (00*l*) and reciprocal spacing (*hk0*). A strong Bragg peak centered around 26.1° in 2θ (3.4 Å) corresponds to the interlayer spacing (d_{002}) within the MWNTs. A similar diffraction pattern is observed for the SWNTs produced by the laser and the arc-discharge techniques indicating a unique growth mechanism involved in both of these techniques (Figure 24).

The interlayer distance between the coaxial tubes are slightly larger in MWNTs than in graphite and the determined mean value of the interlayer spacing is around 0.344 ± 0.0001 nm.[21,152,154–156] The electron diffraction pattern of the carbon nanotubes also confirms a slightly larger interlayer spacing.[21] The X-ray diffraction data show that the MWNTs have a nonuniform distribution of inner tube diameters. A high-resolution TEM image of the carbon nanotube shows that the d_{002} increases from 0.34 to 0.39 nm with decreasing inner tube diameter (Figure 25).[157] An empirical relation exists between the inner tube diameter and the layer spacing as given

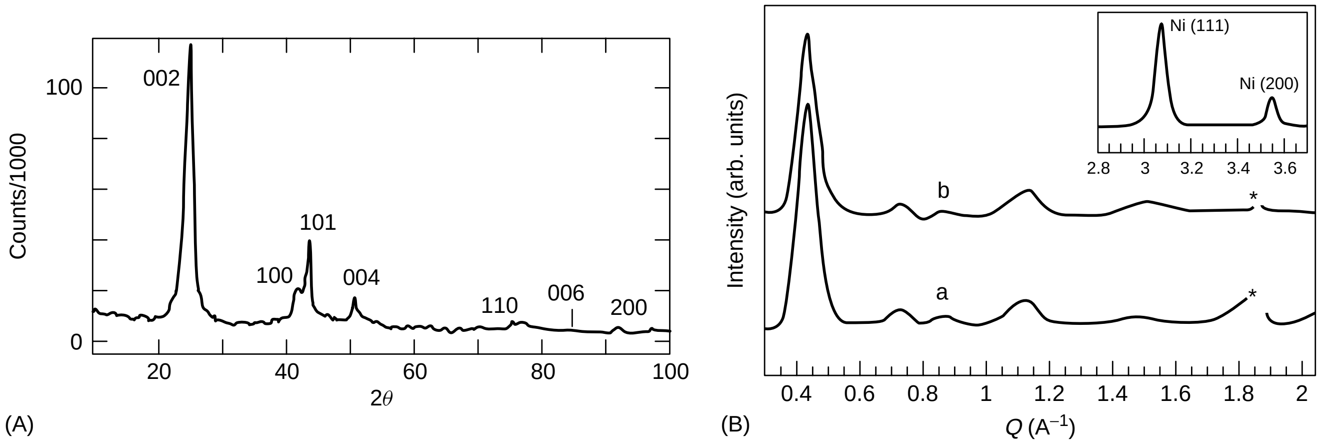

Figure 24 High-resolution X-ray diffraction of (A) MWNTs. (Ref. 153. Reproduced by permission of Wiley-VCH) and (B) SWNTs produced by (a) arc-discharge and (b) laser-ablation techniques. Figure 25 (a) The interlayer spacing (d_{002}) measurement using HRTEM images of MWNTs. (b) Relationship of d_{002} versus inner tube diameter for three different nanotubes; (○) 7 layer tube with $D_{\min} = 1.7$ nm, (•) 41 layer tube with $D_{\min} = 2.6$ nm, (□) 6 layer tube with $D_{\min} = 3.5$ nm. (Reprinted with permission from C.-H. Kiang, M. Endo, P.M. Ajayan, G. Dresselhaus, and M.S. Dresselhaus, *Phys. Rev. Lett.*, 1998, **81**, 1869. © 1998 by the American Physical Society)

below:

$$d_{002} = 0.344 + 0.1e^{-D/2} \text{ for } D \geq 0, \quad (1)$$

where D is the inner tube diameter and d_{002} is the interlayer spacing and all the units are expressed in nm. It has been found that the interlayer spacing decreases exponentially and approaches 0.344 nm asymptotically at around $D \sim 10$ nm. The interlayer spacing in the MWNTs is strongly dependent on the intrinsic structure and on the basis of the method of production. The MWNTs produced in a H_2 atmosphere has a temperature-dependent shift of d_{002} reflection indicating the interlayers have varying thermal-expansion-coefficient along the radical direction of the MWNTs.[158]

The alignment of SWNTs can be determined in macroscopic quantities using a low θ X-ray diffraction pattern. A detailed study of the low θ X-ray diffraction on pellets of SWNTs (prepared by applying pressure of ~10 k bars) shows that the tubes axis are aligned in the plane of the pellets within an out-of-plane spread angle of ~4°.[151] The orientation and the degree of alignment of MWNTs in a stretched polymer composite material have been determined using the X-ray diffraction.[155]

6.5 Mechanical Properties

The structural perfection and the one-dimensional topology of the carbon nanotubes have predicted that they are the strongest material with high mechanical strength.[159–161] The carbon nanotubes with their high aspect ratio and low density are expected to be suited for the development of enhanced lightweight ultrastrong nanocomposites. Although theoretical calculations show that the Young's modulus of carbon nanotubes can reach up to 5.5 TPa,[159,160] various experimental results suggest that it is in the range of 1.2 to 1.8 TPa.[162–164] The experimentally determined Young's modulus for 27 individual SWNTs ($d \sim 1$–1.5 nm) using the room temperature vibrations method in a TEM has shown an average $\langle Y \rangle = 1.25$ Tpa, which is lower than a previous measurement using the thermal vibrations (1.8 ± 0.9 TPa) method. Nevertheless, the carbon nanotubes are the strongest known material with exceptional elongation and highest tensile strength around 100 GPa. It should be mentioned here that high strength steel has much lower Young's modulus and tensile strength of 200 GPa and 1–2 GPa respectively.

Atomic force microscopy (AFM) has been used to determine the bending force of suspended MWNTs pinned at one-end to a molybdenum disulfide surface.[95] The MWNTs with diameters from 26 to 76 nm show an average Young's modulus of 1.28 ± 0.59 TPa. The determined Young's modulus has no dependence on the diameter of MWNTs. The bending strength calculated for the MWNTs is around 28.5 GPa. Recently, a direct tensile-loading experiment using individual MWNT mounted between two opposing AFM tips that can be stress-loaded inside a scanning electron microscopy (SEM) has shown that the maximum Young's modulus and tensile strength are 950 and 63 GPa respectively (Figure 26 and 27b).[165] The mechanical response of 15 SWNTs ropes under tensile load using a similar experimental technique showed an average Young's modulus of 1.0 TPa (Figure 27a).

The SWNTs under a hydrostatic pressure can undergo shape transitions gradually from a circle to an oval and to a peanut with a specific geometric constant.[166] The carbon nanotubes can undergo large deformations and can accommodate external forces without irreversible atomic rearrangements. The resilience of carbon nanotubes is remarkable as they can form kinks under compression and bending, ribbons under torsion, and are able to reversibly restore their original shape once the applied force is relieved. The presence of wear-free low interwall friction forces has been shown in MWNTs.[167] It has been also observed that a coalescence of SWNTs into MWNTs occurs at high temperatures (2200–2400 °C).[168] The molecular dynamic simulation indicates that this kind of transformation occurs through a 'patching and tearing' mechanism.

6.6 Alignment of Carbon Nanotubes

The carbon nanotubes are difficult to align or assemble owing to their broad size distribution along with overwhelming van der Waals interactions. The alignment and the control of the alignment process are important to realize the potential use of carbon nanotubes in applications such as conducting wires, electrodes, and nanocomposites. The carbon nanotubes have been aligned during synthesis in the CVD method.[169] The carbon nanotubes can also be aligned either in suspended or dispersed states.[110,170,171]

Ruoff, *Science*, 2000, **287**, 637. © 2000 AAAS)

The SWNTs have been assembled into long macroscopic fibers and ribbons using a surfactant-dispersed nanotubes solution injected into a polymer solution with a continuous evaporation of solvent and recondensing the nanotubes in the flow of polymer solution to form an aligned fiber.[172] This procedure has been modified to produce SWNTs-polymer fibers composed of 60% SWNTs and 40% polymer exhibiting 1.8 GPa tensile strength similar to spider silk.[93] The SWNTs dispersed solution is injected into the center of a cylindrical pipe in which polyvinyl alcohol coagulation solution flows continuously. Upon contact with the coagulant, the SWNT solution collapses into a nanotube fiber associated with polyvinyl alcohol.[173] The SWNTs dispersed in water have been assembled in an electrode into a submicrometer diameter fibrils with lengths up to 1 cm under asymmetric electric field.[171] The individual tubes in such fibril bundles are aligned along the direction of the fibril axis. A continuous process of drawing carbon nanotubes into yarn by simply pulling a free-standing carbon nanotube array has been shown to produce 30 cm long yarns with 100 μm wide.[174] Similar to the Langmir-Blodgett film, the SWNTs suspended in solution can be used to form an aligned film on a substrate. A strong van der Waals interaction between the individual tubes at a critical concentration induces a self-assembly process at the air-liquid-substrate interface leading to the formation of an aligned SWNTs film on the substrate.[110] The alignment of SWNTs has been shown to occur in polymer composite under the influence of a magnetic field.[175]

6.7 Filling of Carbon Nanotubes

A large free volume is available inside the carbon nanotubes, which has been filled with various metals and gases. The filled carbon nanotubes have different physical and chemical properties that can be tailored to a specific application. The filling has been done using wet-chemistry in solution as well as in the molten state in the presence of chemical reagents.[120,176–179] The purification procedures such as acid treatment or refluxing in HNO_3 open the end caps and also fill partially (<20%) the inner volume of the carbon nanotubes. The presence of metal salts during acid reflux fills the tubes along with acid. The acid treated carbon nanotubes can also be filled in a post treatment with metal salts by using sonication.[120] The carbon nanotubes filled with metal salt are subjected to calcination to obtain the corresponding metal oxide filled carbon nanotubes.

Various metal oxides and metals from d-block and f-block transition metals have been used to fill partially the carbon nanotubes.[120,179] Metal salts such as KI, KCl, UCl_4, $CuCl_2$, $ZrCl_4$, $AuCl_3$, $AgNO_3$, $Pd(NO_3)_2$, $Cd(NO_3)_2$, CdO, and so on, have been used to fill the carbon nanotubes. Acid treated SWNTs have been filled using molten $AgNO_3$ at high temperature with filling efficiencies up to 3% (Figure 28A).[177] The filling occurs through a capillary action especially in a larger diameter tubes ($d \sim\geq 5$ nm). The filling of spherical or nonspherical organic gaseous molecules have been shown to diffuse through the interiors of carbon nanotubes.[178] Hydrothermally synthesized MWNTs are found to have an inner cavity partially filled with a dense aqueous fluid indicating that the filling can also occur during the formation of carbon nanotubes (Figure 28B).[180] The SWNTs filled with potassium iodide at a high temperature (~680 °C) show the metal salt trapped inside behaves distinctly.[181] The van der Waals force inside the tube surface have been found to affect the coordination of the surface atoms in the crystals of KI. This is supported by the fact that the filled KI inside the tubes had a distinct lattice spacing compared to normal KI.

7 SURFACE MODIFICATION OF CARBON NANOTUBES

The presence of an enhanced van der Waals interaction between individual carbon nanotubes makes them difficult to disperse and dissolve in an organic medium. The influence of van der Waals interaction with a high surface area and aspect ratio forces the carbon nanotubes to exist in an agglomerated bundle. Several potential applications of the carbon nanotubes require using them as an isolated material or integrated with other materials. Surface modification of the carbon nanotubes through chemical functionalization with organic substances is one of the strategies to break the overwhelming van der Waals interactions and use them either individually or disperse them homogeneously in a particular medium in many applications.

The problem associated with organic reactions of carbon nanotubes is the formation of multiple products with a different degree of functionality that renders functionalized carbon nanotubes with differing degree of solubility characteristics. There are basically three different types of distribution in the carbon nanotubes: 1) length, 2) diameter, and 3) functionality (Figure 29). It is very difficult to control the efficiency and the specificity of organic reactions in a heterogeneous reaction with respect to the placement of a functional group and the degree of functionalization.

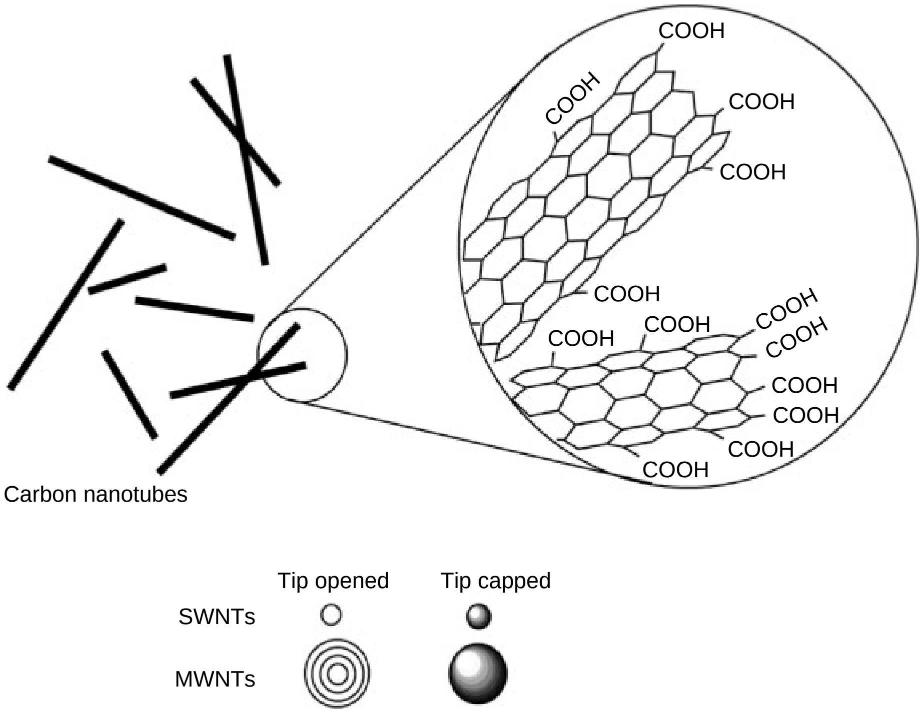

Figure 29 Distribution of the carbon nanotubes with their length, diameter, and functional groups

Moreover, some of the carbon nanotube's tips are either capped with a catalyst or opened. The amount of particular type of tubes present in a given sample also varies significantly depending on the method of production and, hence, every organic reaction performed with the carbon nanotubes would have, in principle, a multiple distribution of products.

The covalent attachment of organic moieties on carbon nanotubes would change the surface chemistry and help assembling them on a variety of substrates for electronic applications. The surface modified carbon nanotubes can be oriented conveniently in solution and in solid matrices. Controlled attachment of a specific functionality on the carbon nanotubes is essential in developing sensing nanodevices for biomedical and other applications. The surface modified carbon nanotubes can be used as nanofibers in novel ultrahigh-strength polymer composites that would have a low interfacial energy and a good load transfer efficiency. It is believed that the exotic mechanical and electrical properties of the carbon nanotubes will enhance the performance of polymer-carbon nanotube composites. Incorporation of carbon nanotubes in a polymer would produce electrically conductive composites with improved antistatic, electrostatic dissipation, electromagnetic interference shielding, and electroactive capabilities. Hence, the surface modification of carbon nanotubes through chemical reactions is very important to improve interaction with other materials and to realize the unique potentials of carbon nanotubes in many applications. Several strategies have been used for the functionalization of carbon nanotubes through post chemical reactions and noncovalent intermolecular weak-interactions $(\pi - \pi)$.[122,182–199]

7.1 Covalent Functionalization

The chemical modification through covalent functionalization of the carbon nanotubes can be classified broadly into two categories (Figure 30).[200] One of the methods involves the use of carboxylic acid groups that are formed in the carbon nanotubes during the purification processes. Another method involves a direct reaction with the sp^2 carbon network of the carbon nanotubes. The advantage of the covalent functionalization is that the surface modified carbon nanotubes are easily dispersible in organic/aqueous medium. However, the stability of the dispersion is highly dependent on the extent of modification. The attachment of organic moieties at the ends and at the surfaces even at a low concentration has improved significantly the dispersion of the carbon nanotubes in organic solvents.[200]

7.1.1 Reaction with Carboxylic Acid Groups

Various oxidative processes used for the purification of carbon nanotubes such as refluxing in acid, sonication in sulfuric and nitric acid (3:1) solution, and treatment with

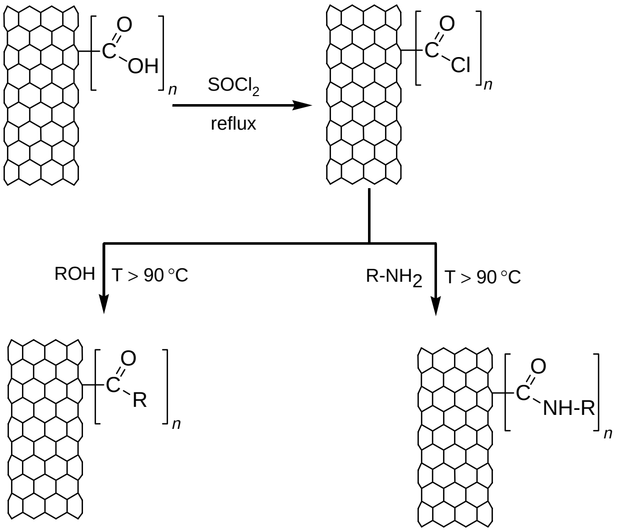

Figure 30 Use of carboxylic acid groups in postesterification and amidation reactions. The precursor acid functionality is distributed around the tubes and concentrated at the open ends. For clarity, one substitution with '*n*' multiples is illustrated

sulfuric acid and hydrogen peroxide solution introduce defects in the carbon nanotubes accompanied by the removal of amorphous and graphitic carbon.[41,120,122,201,202] Depending on the extent of oxidation, the carbon nanotubes are itched and shortened leaving the ends with large defects in the sp^2 network. The terminal carbons of the defective surface are converted into carboxylic acid groups along with small amounts of other oxygenated functionalities such as anhydride, quinine, alcohol, and ester. The carboxylic acid groups can also be introduced onto the carbon nanotubes using ozone treatment.[203,204] The amount of acid groups introduced during the purification steps varies between 1 and 5 mol% with respect to the total carbon depending on the procedure used for the purification. A high concentration of carboxylic acid groups is located at the open ends of the carbon nanotubes. The carbon nanotube bound carboxylic acids have been extensively used in amidation or esterification reactions with amine or hydroxyl containing organic molecules (Figure 31).

Haddon and coworkers have demonstrated the use of carboxylic acid groups of the SWNTs for attaching ODA.[122] The acid groups on the SWNTs are first converted in to acid chloride by refluxing with thionylchloride in the presence of a small amount of dimethylformamide at 70 °C for 24 h. The tubes are then reacted with excess ODA at 100 °C for 96 h to produce soluble surface modified SWNTs. The UV–vis spectrum of the soluble SWNTs shows a featureless absorption decreasing from 250 to 900 nm. The FT-IR spectrum showed a shift of carbonyl frequency of acid (1710 cm^{-1}, – COOH) to amide (1663 cm^{-1}, – CONH) indicating the presence of an octadecyl moiety on the SWNTs. Using a similar approach, the MWNTs have been solubilized and used for composite preparation.[205] A detailed end-group and defect analysis of

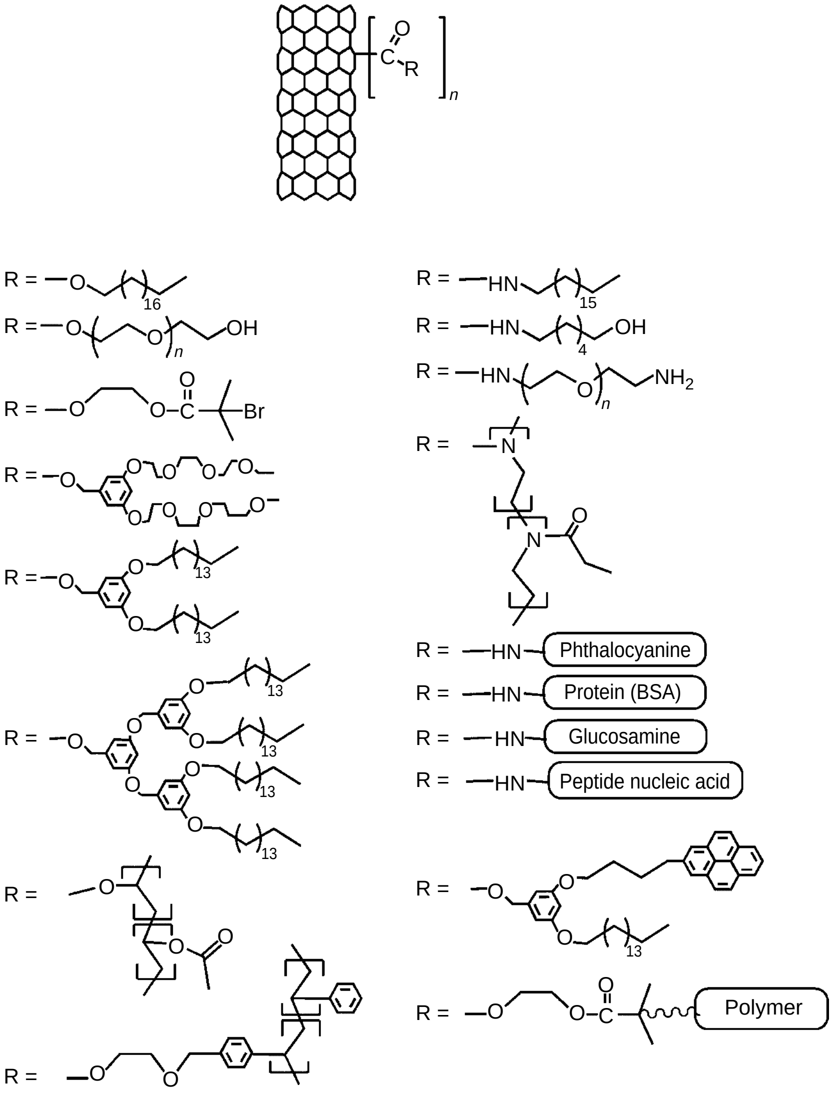

Figure 31 Representative reaction products obtained in the covalent functionalization of the carbon nanotubes. The precursor acid functionality is distributed all around the tubes and concentrated at the open ends (~1–3 mol%). For clarity, one substitution with '*n*' multiples is illustrated

ODA functionalized SWNTs has indicated that the affinity of the amine groups to the nanotubes is significant.[206] Hence, the dissolution of ODA functionalized SWNTs is not entirely due to the covalent grafting.

Amine containing phthalocyanines have been attached to SWNTs through an acyl chloride reaction.[207] A coordination of Wilkinson's complex with the oxidized SWNTs renders a high degree of solubility in organic solvents. The ^{1}H and ^{31}P NMRs of a saturated solution of SWNT-Winkinson's adduct show that the Rh in [RhCl(PPh_3)$_3$] coordinates strongly with the oxygen atoms of the tubes forming a hexacoordinate structure.[208,209] It is also possible to dissolve the SWNTs through a carboxylate-zwitterion association by simply heating carboxylic acid groups containing SWNTs with ODA at 130 °C for 4–8 days.[108] The zwitterion-functionalized SWNTs with lengths of several micrometers are soluble in organic solvent. Acid groups of the SWNTs are reacted with 2-aminomethyl-18-crown-6 ether under vigorous stirring to form zwitterions-functionalized SWNTs, which are soluble in water in high concentration (1 mg mL^{-1}).[210] The functionalization of carbon nanotubes is strongly dependent on the reaction conditions such as temperature and duration.[211] The reaction of diamine-terminated oligomeric poly (ethylene glycol) with SWNTs showed a different extent of functionalization depending on the temperature (100–140 °C) and the duration of the reaction (24 h to 6 days). The percentage of functionalized tubes was determined based on the weight difference between the starting and the residual weights of SWNTs after the extraction procedure, which varies from 28 to 70%.

The SWNTs have been rendered soluble by reacting with poly (propionylethylenimine-co-ethylenimine) ($M_w \sim 200\,000\,g\,mol^{-1}$ and amine mole fraction ∼15%) at 165 °C for 20 min. The SWNTs grafted with the copolymer were extracted in chloroform and it was found that the solubilized SWNTs solution exhibited a strong luminescence.[212] The MWNTs have also been functionalized using several aminopolymers to produce polymer attached-MWNTs that are soluble in many common organic solvents and in water.[183] Optical properties of the solubilized SWNTs and the grafted MWNTs with copolymer show a strong dependence on the concentration.[213] The STM of the high molecular weight copolymer attached SWNTs shows that the attached copolymers have some ordering depending on the chirality of the tubes.[214] The network formation owing to multiple hydroxyl or amine groups of a single copolymer chain reacting with different SWNTs is difficult to determine experimentally. Such a cross-linking has not been identified in these reactions. Fluorinated SWNTs have also been used for the functionalization with hexamethylenediamine.[215]

Protein attached SWNTs have been synthesized by reacting bovine serum albumin containing amino groups using a diimide-activated amidation reaction at room temperature.[216] The acid groups of the SWNTs have been converted into N-hydroxysuccinimide ester in the presence of 1-ethyl-3-(3-dimethyl-aminopropyl)carbodiimide hydrochloride and reacted with amine terminal peptide nucleic acid (PNA) in DMF to form a peptide attached SWNTs. The hybridization of a single-stranded DNA through a molecular recognition is performed in water with the peptide attached SWNTs. The attachment of DNA to the carbon nanotubes is evident clearly in the AFM of the DNA/PNA-SWNTs hybrids (Figure 32).[217]

A polystyrene copolymer containing *p*-4-(4′-vinylphenyl)-3-oxabutanol as comonomer has been reacted with SWNT-COCl in THF for 48 h. The resulting dark suspension is recovered by centrifugation at 7500 rpm. The copolymer attached SWNTs are soluble in organic solvent and the UV–vis absorption is shown to follow Lambert-Beer's Law.[184] Monohydroxyl functional dendrons consisting of long alkyl chains and oligomeric poly (ethylene glycol) have been used in the esterification reaction with acylchloride containing SWNT and MWNTs. The reactions are done in bulk at 75 °C for 48 h and the dendrons attached carbon nanotubes are extracted with chloroform.[182] The dendron attached carbon nanotubes are soluble in common organic solvents and the ones with oligomeric poly (ethylene glycol) attached tubes are soluble in water. Hydrolysis of ester linkages between the carbon nanotubes and the dendrons have resulted in the recovery of carbon nanotubes.[218] It has been observed that these functionalization reactions require high temperatures and longer reaction times to drive a heterogeneous reaction forward. In most of the reactions, the soluble portion of the reaction mixture has been recovered either by centrifugation or dialysis. These procedures, in general, do not separate carbon nanotubes that are adsorbed or coated with organic or polymeric reagents.

The surface initiated polymerization has been performed from the SWNTs and the MWNTs through a covalently attached atom transfer radical initiators.[186,188,190,219,220] Polymer grown MWNTs after a thorough washing and drying procedure show the characteristic vibration bands for the presence of polymer in the IR spectrum and the corresponding polymer decomposition in the thermogravimetic analysis. The surface initiated polymerization has been carried out either in bulk or at a high concentration of monomer. In some cases, the surface initiated polymerization has been performed in the presence of added free initiator to enhance the growth and to monitor the propagation kinetics.[188] The homo, block, and copolymers consisting of polystyrene and poly (methyl methacrylate) brushes chemically bound to the surfaces of MWNTs up to 70 wt% have been synthesized and characterized (Figure 33).[186] The polymer-*g*-nanotubes are soluble in organic solvent and have been characterized using ^{1}H NMR, UV, near-IR and Raman. The TEM and SEM

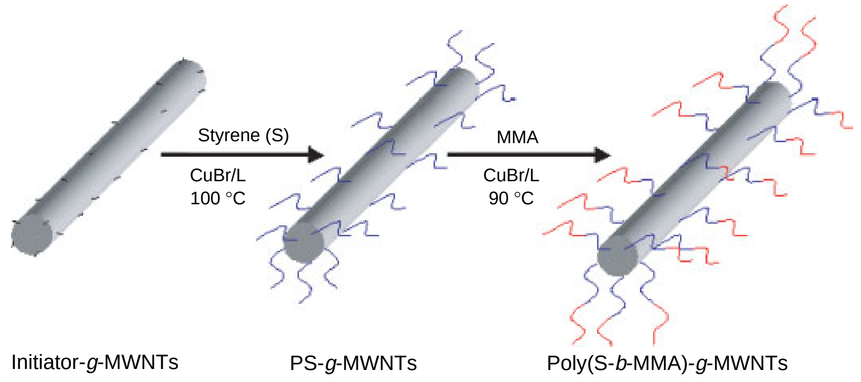

Figure 33 Surface initiated block copolymerization of styrene and methyl methacrylate through atom transfer radical polymerization[186]

of polymer-*g*-nanotubes show clearly the presence of a discontinuous amorphous layer on the surface of the nanotubes with layer thickness of around 2–8 nm. However, the overall percentage of polymer present on the surface of the tubes is very low on the basis of total monomer conversion. It is believed that a large amount of polymer forms from smaller tubes having a higher functionality. Owing to a broad functionality distribution within different size distributed carbon nanotubes, the polymer-*g*-carbon nanotubes contain multiple distributions of samples exhibiting different solubility characteristics.

7.1.2 Direct Reaction with the Surface

Covalent sidewall functionalization of SWNTs has been performed using several organic reactions such as cycloaddition of nitrenes[193] and bromomalonates,[221] addition of nucleophilic carbenes,[193] 1,3-dipolar cycloaddition of azomethine ylides,[189,192,222] reductive alkylation[223] ozonalyzes,[201,203,204] and carbanion addition[224,225] (Figure 34). The functional groups such as alkyl chains, aromatic groups, dendrimers, crown ethers, and oligoethylene glycol have been introduced by reacting such a functional group containing ($R-$) -oxycarbonyl nitrenes with SWNTs in 1,2-dichlorobenzene at 160 °C for 45 min.[226] The supernatant of the reaction mixture is decanted and the derivatized SWNTs are recovered by flocculation and centrifugation. Crown ether containing SWNTs are found to have a high solubility up to 1.2 mg mL^{-1}. Similarly, a different substituted azomethine ylides prepared by condensation of α-amino acid and an aldehyde have been used for the functionalization of SWNTs and MWNTs.[189,192,222] Ozone treatment of the carbon nanotubes introduces mainly oxygenated functionalities such as carboxylic acids, anhydrides, and alcohols. The main problem associated with the organic reactions performed directly on the sp^2 carbon network is the possibility of diminishing the integrity of CNTs. Introducing functional groups by cleaving the sp^2 carbon network would have a detrimental effect on the mechanical and electronic properties of the CNTs.

Alkyl halides have been attached radically to the sidewalls of SWNTs in liquid ammonia using lithium.[185,223] Addition of carbanion onto the double bonds of SWNTs using sec-butyllithium has been shown to generate anions on the surface of the SWNTs. The polymerization of styrene using the surface anions as the initiator has resulted in polystyrene grafted SWNTs with up to 15 wt% polymer.[224] Alkyl groups have been added to fluorinated SWNTs by reacting with alkyl magnesium bromide or alkyl lithium reagents. The alkylated SWNTs are found to be soluble in common organic solvents with 35 wt% functionalization.[225] Reaction of osmium tetroxide (OsO_4) with SWNTs in toluene in the presence of UV irradiation has produced nanotube bundles densely coated with OsO_4.[227] Detailed Raman studies reveal that the metallic SWNTs are more reactive toward osmylation than the semiconducting ones. Functionalization of SWNTs with various 4-substituted anilines has been performed in the absence of solvent and in the presence of isoamyl nitrile, sodium nitrile, and acid under a vigorous stirring condition.[228]

Free radicals have been used to introduce functional groups on the surface of carbon nanotubes (Figure 35).[193,229–233] Organic peroxides such as benzoyl, and lauroyl peroxides have been reacted with SWNTs.[230,233] The reactions are done generally for a longer reaction time (days) at a high temperature, though the half-lives of these free radicals are much shorter (hours). Introduction of acid functionality on the SWNTs has been achieved by reacting succinic or glutaric acid acylperoxides in *o*-dichlorobenzene at 90 °C.[232] The Raman, IR, and near-IR spectroscopy and TGA analyses of the functionalized SWNTs confirmed the attachment of radical groups. Aryl diazonium salts have been used to generate radicals for addition to SWNTs using electrochemical reduction.[196,197,229] Up to 49 wt% aryl functionality has been achieved and a stable homogeneous solution of aryl functionalized SWNT (50 mg L^{-1}) up to 36 h in chloroform is obtained after a 30 min sonication. Polymeric radical addition to SWNTs has been shown to occur during in situ free radical polymerization of styrene in toluene and sodium 4-styrenesulfonate in water.[231,234]

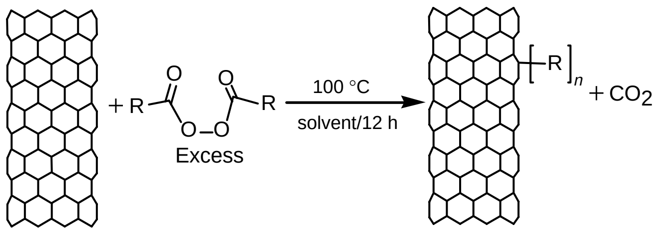

Figure 35 Radicals addition to carbon nanotubes. For clarity, one substitution with '*n*' multiples is illustrated

7.2 Noncovalent Functionalization

Noncovalent interactions of carbon nanotubes with polymers or organic molecules also provide a viable method for a dispersion of SWNTs, as reported by Stoddart,[235] Dai,[194] and coworkers, and others.[194,198,199,236–238] Nanotubes have been known to adsorb gas molecules (H_2, N_2, O_2, and H_2O) through adsorption.[236–240] Some polymers have strong noncovalent interactions with the carbon nanotubes. High molecular weight ionic or electron-rich polymers coat or wrap themselves around the carbon nanotubes. Polyvinyl pyrrolidone and polystyrene sulfonate and their copolymers, polyvinyl sulfate, and poly (metaphenylene vinylene) have been used to wrap around SWNTs.[198,235,241] The wrapping of polymer is accomplished by mixing solutions of purified SWNTs and polymer. The polymer wrapped SWNTs are soluble in organic solvents and in water depending on the solubility of the precursor polymer. It is not known whether these polymeric molecules wrap around or partially coat the surface of the SWNTs. It was proposed that the dissolution occurs in the case of water-soluble polymer wrapping or coating due to the thermodynamic driving force to eliminate the hydrophobic interface between the carbon nanotubes and

aqueous medium and in the case of organic solvents, it is due to $\pi-\pi$ molecular interactions.[198,242]

Several surfactants and oligoethyleneoxides have been shown to disperse SWNTs through a nonspecific adsorption in water.[243,244] A natural polymer such as Gum Arabic is able to disperse SWNTs in water through a noncovalent adsorption.[245] However, the dissolution of carbon nanotubes using polymer wrapping has been shown to occur only with a few specific polymers. The mechanism of wrapping supposedly involves intermolecular noncovalent binding of polymers with SWNTs. Molecular interaction associated with this kind of adsorption can be characterized by a donor–acceptor complex formation through noncovalent interactions.

Rigid conjugated poly (aryleneethynylene)s have been shown to interact with SWNTs through $\pi-\pi$ stacking.[242] A significant up field shift of the substituent α-CH_2-signal of the poly (aryleneethynylene) with a signal broading has been noticed in the ^{1}H NMR indicating the presence of noncovalent interactions (Figure 36). Polyaromatic molecules such as pyrene and anthracene derivatives have been found to adsorb strongly onto SWNTs noncovalently through $\pi-\pi$ molecular interactions.[194,246] A substituted pyrene containing succinimidyl ester has been used to attach a protein on the surface of SWNTs through $\pi-\pi$ stacking.[194] Various copolymers containing pyrene pendant groups have been attached to the surface of MWNTs through $\pi-\pi$ interaction to render solubility in organic solvents.[247] The surface initiated polymerization has been performed using $\pi-\pi$ interaction with pyrene substituted with a metathesis polymerization initiator on the surface of SWNTs.[187] The polymerization of norbornene resulted in a homogeneous noncovalent coating (5–10 nm) of poly(norbornene) on the SWNTs. A dispersion of the SWNTs in aqueous solution is possible by mixing SWNTs and amphiphilic peptides using sonication.[248] It has been shown that a folding of certain peptides into amphiphilic α-helix in a segregated hydrophilic and hydrophobic faces enhances the formation of noncovalent interaction with the nanotubes. Porphyrin has been shown to interact noncovalently, specifically with semiconducting SWNTs in a mixture of semiconducting and metallic SWNTs.[249] The mechanism of such a selective interaction could be related to the differences in electronic structures associated with the nanotubes and the porphyrin. The porphyrin induced noncovalent solubilization and extraction in THF is a convenient method to separate the semiconducting SWNTs from the metallic SWNTs.

8 SUMMARY

An overview of the basic developments in the field of carbon nanotubes has been presented. The fundamental understanding of carbon nanotubes in terms of their synthesis, characterization, and structural manipulation has given a great impetus for the development of a multitude of applications exploiting their unique nanostructures. Research in the field of carbon nanotubes has seen a substantial amount of growth within a short span of time that simply reflects the enormous potential of carbon nanotubes in basic and applied science. Although the development is rapid, it is fair to say that the progress is continuing to gain control over the synthesis towards tailor-made carbon nanotubes with specific chirality and diameter. Revolutions in tailor-made and cast-effective carbon nanotube synthesis, separation, and controlled functionalization would undoubtedly bring closer to realization the forecasted opportunities in nanoscience and nanotechnology.

Acknowledgments

I would like to thank Prof. David A. Atwood, Department of Chemistry, University of Kentucky for the invitation to write this article. I thank the U.S. Army for a grant in support of this work (DAAD19-01-2-002). I express my sincere gratitude to Prof. Jimmy W Mays and Mrs. Patricia Boyd for their constant support. I wish to deeply thank Mr. Tom Malmgren (UTK, US), Drs. C. Ramesh (NCL, India) and W. U. David (ORNL, US) for their help during the preparation of this article. I am thankful to my wife, Mrs. B. Meenakshi Sundari, and my kids for allowing me to undertake this task during the summer holidays.

Inorganic Ring Systems

1 INTRODUCTION

Cyclic compounds played an important role in organic chemistry from its very beginning. Both rings with carbon-only skeletons (cyclic hydrocarbons and their derivatives) and with heteroatom skeletons (an endless diversity of heterocycles) have been known for a long time. The discovery of the cyclic structure of benzene is a landmark in the history of chemistry, and it has been followed by a rapid progress in this branch of science, even in the nineteenth century, when elemental analysis and the chemist's intuition and imagination were the most important research tools.

The development of inorganic chemistry followed a different path. Earlier attempts to apply the structural principles of organic chemistry to elements other than carbon almost ceased for a while after Werner introduced the coordination chemistry. It should be pointed out, however, that these early attempts led to correct assignments of cyclic structures to compounds such as metaphosphates,[1,2] cyclophosphazenes ('phosphonitrile chlorides'),[3] and cyclosiloxanes.[4] The chemistry of inorganic rings continued its evolution in fragments, as chapters of the chemistry of individual elements or groups of related elements, with little emphasis on the ring concept. The discovery of borazine (initially called 'borazole' or 'inorganic benzene')[5] is another landmark in the development of modern chemistry and contributed much to focusing some attention upon inorganic cyclic structures. This era is reflected in some splendid monographs covering inorganic rings within the chemistries of sulfur,[6,7] phosphorus[8,9] and boron.[10]

The integrated approach to the chemistry of inorganic rings as *a self-consistent field of inorganic chemistry* across the periodic table has been promoted after 1960 by a series of other monographs.[11–18]

Now, the chemistry of inorganic ring compounds as an independent branch of chemistry is legitimized by the biannual International Symposia on Inorganic Ring Systems (IRIS).

The inorganic rings raise interesting questions of structure and bonding and quite often they challenge the theory. Thus, a subject of continuous interest is the stability and the possible aromaticity of inorganic rings.[19,20] The applicative interest for inorganic rings is related to their use as precursors for thermally stable polymers, ceramics, semiconductors, catalyst supports, or various other advanced materials.[21]

The nomenclature rules for inorganic rings are discussed in some publications.[22]

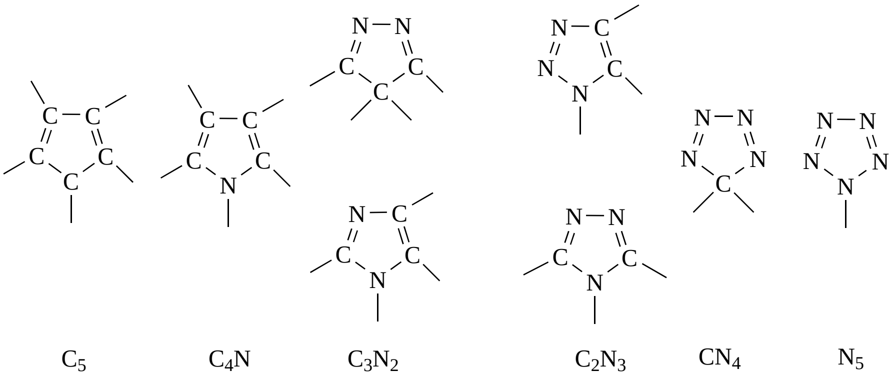
2 DEFINING THE INORGANIC RING CONCEPT

The organic cyclic structures are molecular constructions in which carbon atoms and possibly additional noncarbon atoms (heteroatoms) connected through covalent bonds form a closed ring. Consequently, inorganic rings could be simply defined as similar carbon-free molecular species. In fact, it is rather difficult to draw a separation line between organic and inorganic rings. Thus, in a five-membered ring series, the transition from cyclopentadiene (a purely organic C_5 homocycle) to cyclopentazadiene or pentazole (a purely inorganic N_5 ring)[23] occurs through the intermediacy of a series of organic heterocycles (pyrrole, pyrazole, imidazole, triazole, and tetrazole) (Scheme 1), all containing carbon and nitrogen heteroatoms.

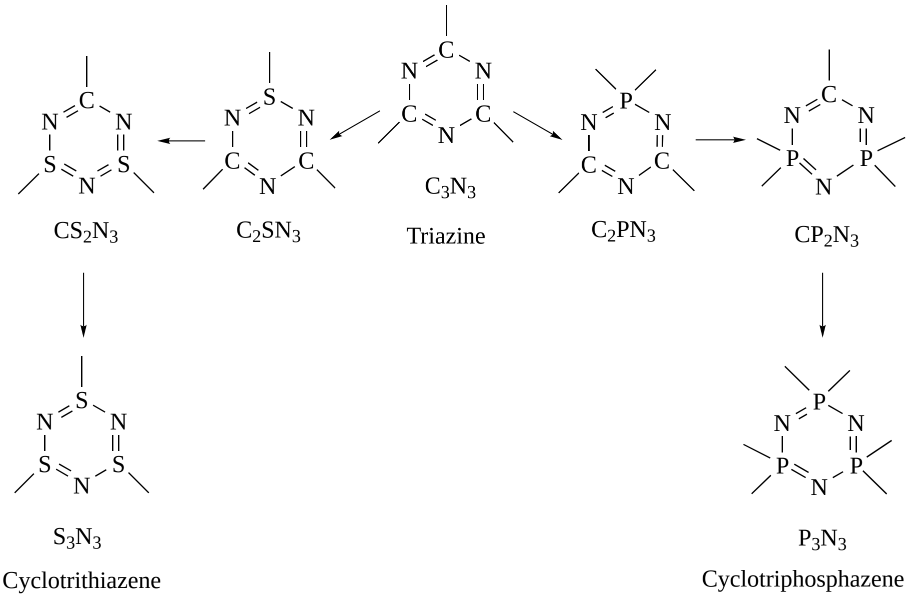
Similarly, organic-inorganic ring transition series can be written as connecting a symmetric organic C_3N_3 heterocycle (triazine) with purely inorganic rings, for example, cyclotriphosphazene, P_3N_3, and cyclotrithiazene, S_3N_3 (Scheme 2).

The question is: which of these rings are 'organic' and which are 'inorganic'? Sometimes organic chemists include pentazole in the family of heterocycles and refer to such species as 'heteroatom-only' rings. On the other hand, there is a tendency among inorganic chemists to consider a ring as 'inorganic' if the majority of ring atoms are different from carbon. If these two extremes are accepted, then it becomes impossible to draw a line between organic and inorganic rings. In a pragmatic approach, inorganic rings should be defined as '*carbon-free*' rings, leaving to organic chemistry all rings that contain at least one carbon atom. Such a solution is adopted in this article.

Inorganic chemistry displays a rich diversity of ring structures, not limited to cyclic molecules formed through covalent bonds. Inorganic ring structures can be built by combining a number of various *building blocks* connected through covalent bonds (*synthons*) or by assembling supramolecular structures from molecular units (*tectons*) connected through noncovalent intermolecular forces (dative, secondary, ionic or hydrogen bonds).



Scheme 1 The transition from an organic homocycle (cyclopentadiene) to an inorganic homocycle (pentazole) through intermediate heterocycles



Scheme 2 The transition from organic heterocycles to inorganic analogs

The term *synthon* is more familiar to organic chemists and describes fragments from which various molecules can be built by synthetic procedures. Sometimes the term was also used to describe '*structural units within supermolecules which can be formed and/or assembled by known or conceivable synthetic operations involving intermolecular interactions*'.[24] To avoid confusion, the term *tecton* was introduced to describe the molecular units of supramolecular structures assembled through noncovalent forces. Thus, the *tecton* has been defined as '*any molecule whose interactions are dominated by particular associative forces that induce self-assembly of an organized network*'.[25,26] Here, we will use the term *synthon* for the fragments of covalent molecules and the term *tecton* for the molecular building blocks of supermolecules self-assembled through noncovalent interactions.

Since reference was made to supramolecular chemistry, perhaps it is useful to remember some definitions. Supramolecular chemistry is '*the chemistry of molecular assemblies and of the intermolecular bond*'. It is '*the chemistry beyond the molecule*' and deals with '*organized entities of higher complexity that result from the association of two or more chemical species held together by intermolecular forces*'.[27,28]

There are two types of subjects in supramolecular chemistry: (a) the *supramolecular assemblies* or systems, also called supramolecular arrays, that is, '*polymolecular entities that result from the spontaneous association of a large undefined number of components*', and (b) *supermolecules*, that is, '*well-defined discrete oligomolecular species that result from the intermolecular association of a few components*'.[29]

3 TYPES OF INORGANIC CYCLIC STRUCTURES

In the organic rings (homo- and heterocycles), the carbon atoms are constantly tetravalent and display sp^3 (tetrahedral), sp^2 (trigonal planar), or sp (linear) hybridizations with the corresponding bonding geometries. The most common heteroatoms are oxygen, sulfur, and nitrogen. Inorganic chemistry operates with all elements of the periodic table and consequently it has at its disposal a broader range of possibilities in terms of bond types, hybridizations of atomic orbitals, coordination geometries, and oxidation states within the building blocks (synthons). Thus, a much broader variety of structures can be expected for inorganic cyclic structures.

3.1 Covalent Rings (Homo- and Heterocycles)

The closest similarity between organic and inorganic cyclic structures is displayed by the *covalent rings.* These include both homo- and heterocycles. Homocycles contain identical atoms; in heterocycles the constituent atoms are different. Covalent inorganic rings are basically formed by nonmetals and Main Group metals, but transition metals are not excluded. To participate in ring formation, an atom should be able to form at least two covalent bonds, that is, to be at least a divalent element. This condition is satisfied by numerous elements of the periodic table and therefore a great *variety of compositions* can be expected.

The inorganic rings formed through covalent bonds are the real counterparts of organic cyclic molecules and illustrate the ability of other elements to imitate carbon. Although characteristic of elements close to carbon in the periodic table (in particular, boron, silicon, germanium, phosphorus, arsenic, antimony, sulfur, and selenium, alone or in association with oxygen, nitrogen, or sulfur), this ability is not restricted to nonmetals and covalent rings containing metals, for example, aluminum, gallium, tin, or lead, as well as transition metals are also well known.

There are two types of covalent inorganic rings:

1. *homocyclic ring systems* – consisting of catenated identical atoms, and
2. *heterocyclic ring systems* – containing different elements.

Inorganic homocycles containing three, four, five, six, seven, eight, or more identical atoms are known for various elements (Scheme 3).

Table 1 Inorganic (carbon-free) homocycles

–	Si_3	Ge_3	Sn_3	N_3	P_3	As_3	Sb_3	–	–	–
–	Si_4	Ge_4	Sn_4	N_4	P_4	As_4	Sb_4	–	–	–
B_4	Si_5	Ge_5	Sn_5	N_5	P_5	As_5	Sb_5	–	–	–
B_6	Si_6	Ge_6	Sn_6		P_6	As_6	Sb_6	S_6	Se_6	Te_6
								S_7	Se_7	–
								S_8	Se_8	Te_8
								S_n ($n > 8$)	Se_{12}	

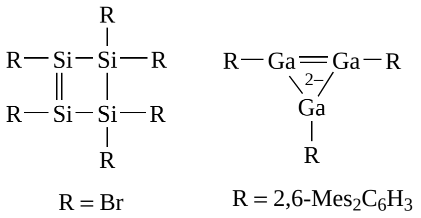
A probably incomplete list includes the homocyclic rings E_n shown in (Table 1).

The homocycles are usually ‘saturated’ species, but occasionally double bonds may occur in silicon-based three-, four-, and five-membered rings with Si=Si double bonds[30,31] or in the cyclotrigallane anion $[Ga_3R_3]^{2-}$ (R = 2,6-$Mes_2C_6H_3$)[32] (Scheme 4).

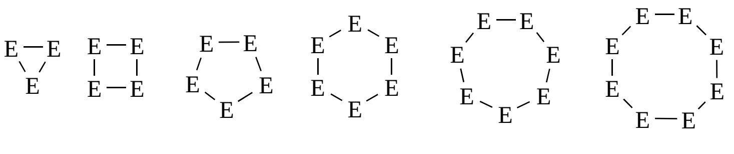
The ability of chemical elements to form homocyclic rings depends upon their ability to concatenate. The propensity for catenation of chemical elements varies greatly and no other nonmetal can fully imitate carbon. Inorganic homoatomic rings usually need to be protected by organic groups and – unlike hydrocarbons – the kinetic stability of catenated hydrides of elements other than carbon is low. Therefore, cyclic polysilanes $(SiR_2)_n$, polygermanes $(GeR_2)_n$, and polystannanes $(SnR_2)_n$, are much more stable with R = alkyl or aryl instead of R = H.

Heterocycles can be formally generated in three different ways (Scheme 5):

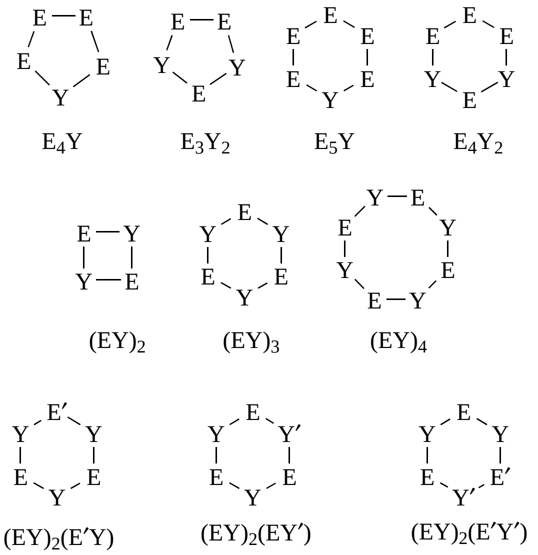
1. by *insertion* of one or more heteroatoms in a parent homocycle and maintaining some E–E bonds (between identical atoms) to form rings of the type E_mY_n (m and n differing);
2. by *regular alternation* of two different elements E and Y that is, by combining a discrete number of *identical EY*



Scheme 4 Unsaturated homocyclic rings



Scheme 3 Homocyclic systems



Scheme 5 Various types of inorganic heterocycles

repeating units to form rings of the type $(EY)_n$ ($n = 2, 3, 4, 5, 6 \ldots$);

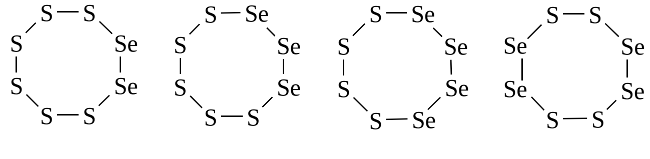
3. by combining a number of *different repeating units* EY and E'Y or EY', to form rings of the type $(EY)_m(E'Y)_n$ or $(EY)_m(EY')_n$ or even $(EY)_m(E'Y')_n$.

Usually, E and Y are elements of different electronegativities and the best combinations are obtained when E is less electronegative (i.e. more electropositive) than carbon (i.e. B, Al, Si, Ge, Sn, Pb, P, As, Sb, Se, Te) in association with an element Y that is more electronegative than carbon (O, N, S).

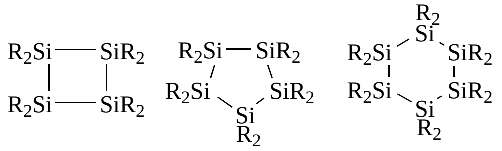
Inorganic rings can be treated as chemical graphs and an enumeration of all possible structures can be deduced using this approach.[33]

Almost all these cyclic graphs have correspondents in real inorganic covalent rings. The rarest are heterocycles containing bonds between identical atoms avoiding a regular alternation, but the sulfur–selenium pair offers beautiful examples (Scheme 6).[34,35]

There are several ways to combine rings into polycyclic and cage structures (e.g. spirocyclic systems and fused rings). These will not be discussed here. Theoretical speculations have been made about the possible existence of purely inorganic (carbon-free) fullerene-like polycyclic cages, for example, boron–nitrogen molecules[36–38] or silicon analogs.[39]



Scheme 6 Some mixed sulfur–selenium rings preserving bonds between identical atoms



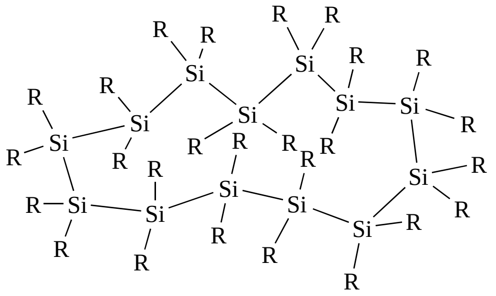
(**1**) (**2**) (**3**)

R = Me, Ph, etc.

3.1.1 *Selected Homoatomic Inorganic Covalent Rings*

Cyclosilanes. Cyclopolysilanes, (**1–3**) based upon silicon–silicon bond backbones, are known as stable compounds mainly as organosubstituted derivatives, $(SiR_2)_n$ but derivatives with R = H or Cl are also known.[40] The organocyclopolysilanes $(SiR_2)_n$ are usually prepared by dehalogenation of diorganodichlorosilanes, either with alkali metals (Wurtz coupling) or by electrochemical reduction. In most cases, the major product is the pentamer ($n = 5$) and/or hexamer ($n = 6$), but larger ring oligomers have been sometimes obtained, for example, with R = Me ($n = 9$, 1% yield; $n = 10–19$, 0.09–0.26% yield) in addition to the pentamer (12%), hexamer (59%), heptamer (3%) and octamer (1.8%). All members of the $(SiMe_2)_n$ series up to $n = 35$ have been separated by column chromatography and the members up to 19 silicon atoms have been isolated as individual compounds.[41] The nature of products formed depends greatly upon the solvent and the presence of complexing agents (e.g. crown ethers to solvate the alkali metal salt).[42]

The molecular structures of several cyclosilanes, for example, $(Me_2Si)_n$ ($n = 4$, 6 and 7)[43] and $(Ph_2Si)_n$ ($n = 4$, 5 and 6)[44] and also of the large ring compounds $(SiMe_2)_{13}$ (**4**) and $(SiMe_2)_{16}$ (**5**) have been established by single-crystal X-ray diffraction.[45]

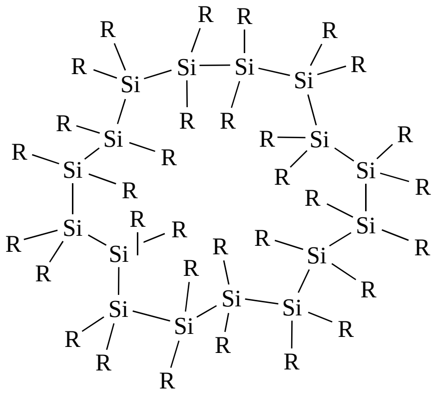


$(SiMe_2)_{13}$

(**4**)

In the case of $MePhSiCl_2$, the Wurtz coupling dehalogenation produces three fractions, containing low-molecular weight cyclics, intermediate molecular weight cyclic oligomers, and high polymeric materials.[46]

Anionic $[RSi]_4^{2-}$ (with R = Bu^t_2MeSi) has been reported recently and described as a sila analog of the cyclobutadiene dianion.[47]



$(SiMe_2)_{16}$

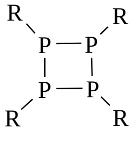
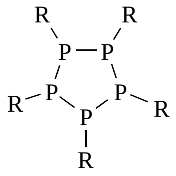
Cyclogermanes. Cyclogermanes are prepared by methods similar to those used for polysilanes, for example, Wurtz dehalogenative coupling.[48] Cyclogermanes $(R_2Ge)_n$ with $n = 3$, 4, and 5 can be isolated.[49,50]

Cyclostannanes. Cyclostannanes, $(SnR_2)_n$, containing from 3 to 9 tin atoms,[51,52] are prepared from diorganotin dihalides with alkali metals (Wurtz coupling)[53] or from diorganotin hydrides by dehydrogenative coupling,[54] by coupling with diorganotin amides,[55] by electrochemical reduction of diorganotin dihalides,[56] or by reduction with samarium diiodide.[57] Cyclic polystannanes include dialkylstannanes $(R_2Sn)_n$ (R = Et, $n = 6$–9; R = Cy, $n = 5$; R = Bu, $n = 5$ and 6; R = Bz, $n = 4$ and 6)[58] and diarylstannanes, for example, $(Ph_2Sn)_6$.[59] Even three-membered ring cyclotristannanes (with bulky substituents) have been synthesized.[60]

Cyclophosphanes. Cyclophosphanes $(PR)_n$ ($n = 3$–6) (**6–8**) are well known with common organic substituents (alkyl, phenyl);[61] larger cyclic oligomers are stabilized only as transition metal complexes, for example, $[M_2(CO)_6(PMe)_9]$ (M = Cr, Mo, W) (**9**) and are formed in reactions involving ring expansion rearrangements.[62]



(**6**)



(**7**)

The cyclic P_5 anion can form ferrocene analog pi-complexes.[63]

Cycloarsanes and Cyclostibanes. Cyclopolyarsanes (**10**, **11**) of small and regular size, $(AsR)_n$ with $n = 3$–6, are well documented[64] and macrocyclic oligomers are formed in ring expansion reactions with metal carbonyls and stabilised as metal complexes. Thus, nine-membered rings $(AsR)_9$ (with R = Me or Ph) and ten-membered $(AsMe)_{10}$ (**12**) can be formed from the corresponding cyclic hexamers in reactions with chromium and molybdenum hexacarbonyls.[65]

Related cyclostibanes and some cyclobismuthanes are well covered in the review literature.[66]

Cyclosulfanes (Elemental Sulfur Allotropes). Elemental sulfur displays a great propensity for catenation and polysulfur rings (cyclosulfanes) of various ring sizes (**13–22**) are known as allotropic forms of elemental sulfur.[67]

Currently all cyclic sulfur molecules S_n with $n = 6$, 7, 8, 9, 10, 11, 12, 13, 14, 15, 18, 20, 25 are known and single-crystal X-ray diffraction determinations of the molecular structure are available for S_6,[68] S_7,[69] S_8,[70] S_{10},[71] S_{11},[72] S_{12},[73] S_{13}, S_{14},[74] S_{18},[75] and S_{20}.[76] All these rings are puckered.

Most sulfur homocycles have been synthesized by reacting $(C_5H_5)_2TiS_5$ with appropriate open-chain polysulfur dichlorides (α, ω-dichloropolysulfanes); the various rings

formed in a complex mixture can be separated with the aid of high-performance liquid chromatography.[77]

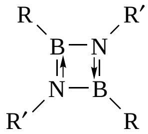
The eight-membered ring S_8 is the only thermodynamically stable form and all other rings undergo molecular rearrangements with formation of the octamer. Ring–ring and ring–chain thermal equilibria occur in sulfur melts, in variable concentrations.[78]

Similar, but less stable, selenium homocycles, as well as mixed sulfur–selenium related heterocycles formed by heteroatom replacement, are also well documented.[79] Cationic chalcogen homocycles are also known and have been reviewed.[80]

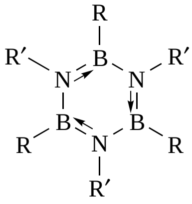
3.1.2 *Selected Heteroatomic Covalent Inorganic Rings*

Cycloborazanes, Cycloboroxanes, and Related Rings. In association with nitrogen, oxygen, sulphur, and selenium boron tends to form six-membered rings $(BY)_3$ (Y = N, O, S, Se), although some derivatives of the four- and eight-membered rings with the same synthons are known. Their chemistry has been reviewed.[81]

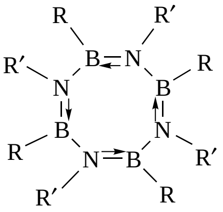
The boron–nitrogen rings (*see* ***Boron–Nitrogen Compounds***) are probably stabilized through some electron donation from nitrogen. Four-, six-, and eight-membered rings (**23–25**) consisting of RB-NR′ synthons have been described and some interconversions have been reported.[82]



(**23**)



(**24**)



(**25**)

In the six-membered ring B_3N_3 of borazine, the electron delocalization leads to bond length equalization, but in the eight-membered ring the B–N bonds display differing bond lengths, which is reminiscent of the situation in the carbon isoelectronic rings (benzene and cyclooctatetraene).

The six-membered boron–oxygen ring, B_3O_3, is present intact as a building unit in numerous polymeric borates, which have been thoroughly reviewed in the Gmelin Handbook.[83] Organosubstituted cyclotriboroxanes (boroxines), $(RBO)_3$, are also well known.[84] Boron-sulfur[85] and boron-selenium[86] rings are also well documented.

Aluminum Heterocycles. A unique aluminum–nitrogen Al_3N_3 ring compound, $[MeAlN(2,6\text{-}Pr^i_2C_6H_3)]_3$, containing a planar Al_3N_3 heterocycle (**26,27**), can be regarded as a borazine analog.[87]

Most frequently, cubane or other aluminum–nitrogen cage supermolecules are formed through additional dative bonds (making the metal four-coordinate).[88]

Cyclosilazanes. The silicon–nitrogen pair displays a great tendency of ring formation and stable four-, six-,

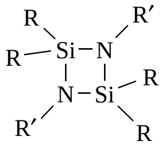
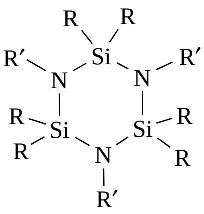
(**33**)

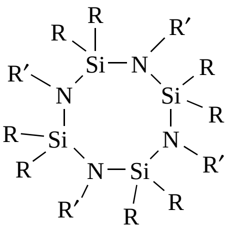
and eight-membered rings are well known. Organocyclosilazanes can be readily obtained by ammonolysis of diorganodichlorosilanes, R_2SiCl_2, but the reaction produces only cyclotri- and cyclotetrasilazanes, $(R_2SiNH)_n$ ($n = 3$, 4).[89] Cyclodisilazanes are usually obtained by condensation or coupling reactions, with elimination of amines [from diorganodiaminosilanes, $R_2Si(NHR')_2$] or metal halides [from $R_2Si(NLiR')_2$ and R_2SiCl_2]. The best known are cyclodisilazanes (**28**), cyclotrisilazanes (**29**), and cyclotetrasilazanes (**30**).[90] Many have been structurally characterized, but we cite here only the methyl trimer $(Me_2SiNH)_3$ and tetramers $(Me_2SiNH)_4$ and $(Me_2SiNMe)_4$.[91,92] The ammonolysis of organotrichlorosilanes yields cage and polymeric (probably polycyclic) silazanes and one such structure (a SiN prismane $[Me_6Si_6(NH)_9]$) has been demonstrated by X-ray diffraction.[93]



(**28**)



(**29**)

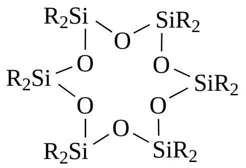


(**30**)

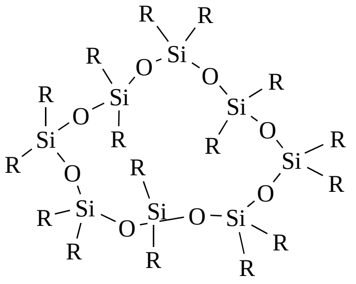
Silicon-phosphorus heterocyclic structures (rings, cages, polycyclic ladders) are also well investigated.[94]

Some germanium–nitrogen ring chemistry has been developed.[95]

Cyclosiloxanes and Cyclogermoxanes. Cyclosiloxanes (**31–35**) are among the most important inorganic rings. Organocyclosiloxanes $(R_2SiO)_n$ are formed in the hydrolysis



$(R_2SiO)_6$
(**34**)



$(R_2SiO)_8$
(**35**)

R = Me

of diorganodichlorosilanes. Catalytic molecular rearrangements of trimeric and tetrameric organocyclosiloxanes produce larger ring cyclosiloxanes. The most common and best studied are the poly(dimethylcyclosiloxanes), $(Me_2SiO)_n$, a family of compounds of great industrial importance as precursor of silicone materials (*see* ***Polysiloxanes & Polysilanes***).

A careful study of the hydrolysis of H_2SiCl_2, $MeHSiCl_2$ and Me_2SiCl_2, using gas chromatography, mass spectrometry, and NMR spectroscopy, revealed that oligomeric cyclosiloxanes $(H_2SiO)_n$ (up to $n = 23$), $(MeHSiO)_n$ (up to $n = 19$) and $(Me_2SiO)_n$ (up to $n = 17$) can be detected in the hydrolysis product.[96] Rings containing from 5 to 8 Me_2SiO units have been separated from the hydrolysis product of Me_2SiCl_2 by traditional procedures of fractional distillation.[97]

Several organocyclosiloxanes have been structurally characterized by X-ray diffraction. Among these, hexamethylcyclotrisiloxane $(Me_2SiO)_3$ contains a planar six-membered ring Si_3O_3,[98] octamethylcyclotetrasiloxane $(Me_2SiO)_4$ contains a nonplanar eight-membered ring Si_4O_4,[99] and larger rings, for example, $(Me_2SiO)_5$,[100] $(Me_2SiO)_8$,[101] have also been analysed. Large stereoregular cyclosiloxanes $[Ph(Me_3SiO)SiO]_n$ ($n = 6$ and 12) have been synthesized by an indirect route and structurally characterized.[102] The lowest members of the series, cyclodisiloxanes (with bulky organic groups) have been obtained by oxidation of disilenes and characterized by X-ray diffraction.[103]

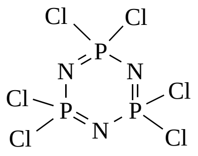
An interesting recent development is the synthesis and structural characterization of unusual cyclosiloxanolate metal complexes,[104] the crown ether-type complexation

of potassium by a permethylcycloheptasiloxane[105] and the synthesis of dendrimers based upon mono- and polycyclic (cage) siloxanes.[106]

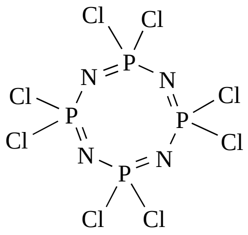
Catalytic equilibrations involving ring-opening molecular rearrangements of cyclosiloxanes, for example, of the tetramer $(Me_2SiO)_4$, produced mixtures containing cyclosiloxane oligomers and polymers $(Me_2SiO)_n$ with $n = 5-25$ (KOH used as catalyst)[107] and an extensive study of this type of reaction revealed that cyclic poly(dimethylsiloxanes) with up to $n = 1000$ can be thus obtained, by using a variety of basic or acidic catalysts.[108] The reaction has been extensively investigated and reviewed.[109] Silicon–oxygen rings are also present in numerous cyclosilicates and polycyclic silicates.

Germanium analogs of cyclosiloxanes reported to date include $(R_2GeO)_n$ trimers and tetramers (e.g. with R = Me, Et, Pr, Ph, etc.) but they did not attract as much interest as their silicon relatives.[110,111]

Cyclophosphazenes and Cyclophosphazanes. Cyclophosphazenes are an important class of inorganic rings, based upon an alternation of phosphorus(V) and nitrogen, that is, the –P=N–P=N– sequence. The general formula $(R_2PN)_n$ covers a large family in which R = halogen, functional group (alkoxo, amino, thiolato, etc.) or organic group (alkyl, aryl). The chemistry of cyclic and polymeric phosphazenes has been extensively covered in several reviews and books.[112] The six- and eight-membered rings (**36**, **37**) are the most important members of this class and their chemistry is quite comprehensive. Larger cyclic oligomers have also been investigated (*see* ***Phosphorus–Nitrogen Compounds***).



(**36**)



(**37**)

Usually the entry into phosphazene chemistry is based upon the formation of perchlorocyclophosphazenes, $(Cl_2PN)_n$, which are readily prepared by reacting phosphorus pentachloride with ammonium chloride in refluxing tetrachloroethane or other organic solvent. The major products are the trimer and the tetramer, but larger ring oligomers with $n = 5-8$ have also been isolated.[113]

The crude mixture also contains larger rings, as demonstrated by fluorination with potassium fluoride in liquid sulfur dioxide at 90–125° under pressure, producing cyclic oligomers $(F_2PN)_n$ with $n = 3-17$, which can be separated by a combination of fractional distillation and vapour-phase chromatography.[114] Cyclic bromophosphazenes $(Br_2PN)_n$ with $n = 3-6$ have also been obtained.[115]

The halogens can be readily replaced by various functional groups, for example, alkoxy and aroxy, to give $[(RO)_2PN]_n$ (R = Me, CH_2CF_3, Ph; $n = 3-8$) and dimethylamino groups to give $[(Me_2N)_2PN]_n$ ($n = 3-8$),[116] or with organic groups, to give $(Me_2PN)_n$ ($n = 3-10$) (**38–45**).[117]

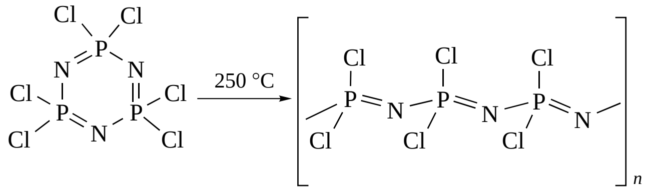
skeleton, but involves an $[–(HO)_2P{=}N–]/[–(HO)(O)P–NH–]$ tautomerization.[118]

Numerous single-crystal X-ray diffraction studies confirmed the structures of cyclophosphazenes, for example, $(F_2PN)_3$,[119] $(Cl_2PN)_3$,[120] $(F_2PN)_4$,[121] $(Cl_2PN)_4$,[122] for example, $(F_2PN)_5$,[123] $(Cl_2PN)_5$,[124] $(Br_2PN)_5$,[125] $(Me_2PN)_5$,[126] $(Me_2PN)_6$,[127] $(Me_2PN)_7$, $(Me_2PN)_8$,[128] and $(Me_2PN)_n$ ($n = 9-12$).[129] The crystal and molecular structures of the hexamers $[(MeO)_2PN]_6$[130] and $[(Me_2N)_2PN]_6$[131] and octamers $[(MeO)_2PN]_8$[132] and $[(Me_2N)_2PN]_8$[133] have also been reported.

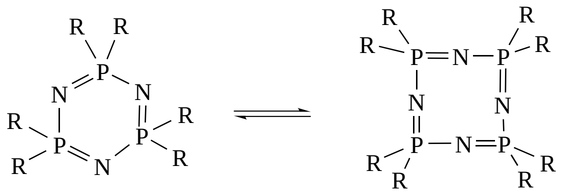
The conformations of these large rings are irregular and demonstrate the flexibility of the phosphazene chains, which allows the formation of phosphorus–nitrogen rings of practically any size.

Cyclophosphazenes (**46**) undergo both thermal ring-opening polymerization with formation of linear polymers (**47**) (*see* ***Polyphosphazenes***) and ring–ring equilibria (resulting in ring expansion).



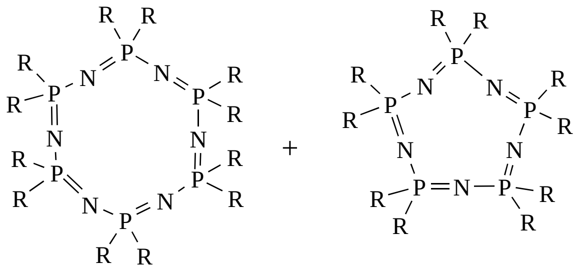
(**46**) (**47**)

The six-membered ring (**48**) can expand to 8-, 10-, and 12-membered rings (**49–51**) (and larger) and a mechanism has been suggested in which the first step is the conversion of the six-membered ring to a 12-membered ring.[134]



(**48**) (**49**)

+

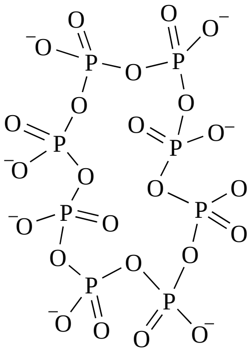


(**51**) (**50**)

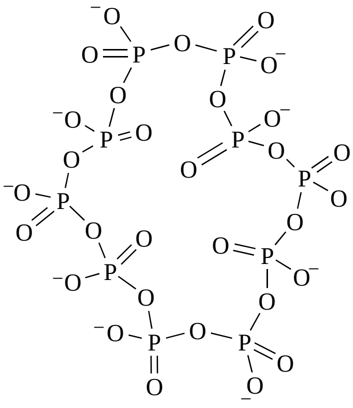
Anionic derivatives of cyclodiphosph(III)azanes and cyclodiphosph(V)azanes have emerged recently as versatile ligands.[135,136]

Partial replacement of phosphorus by other elements is possible leading to heterocyclophosphazenes. Among these, the P–N–B, P–N–As, P–N–Sb,[137] P–N–S[138–140] and group 13 heterocyclophosphazenes[141] are the most interesting. Several four-membered PN_2E rings with E = B, Al, Ga, In, Si, As, S have also been reported.[142]

Phosphorus-oxygen Rings. The most important cyclic compounds based upon phosphorus-oxygen backbones are the so-called metaphosphates or cyclophosphates (*see* ***Phosphates: Solid-state Chemistry***). They contain $[PO_3]_n^{n-}$ ring anions of various sizes, from $n = 3$ to $n = 12$ (isolated and structurally characterized).[143] The trimers and tetramers are readily obtained and have been thoroughly investigated, but it took considerable skill to isolate the higher members (**52**,**53**) of the series.



$(PO_3)_8^{8-}$
(**52**)



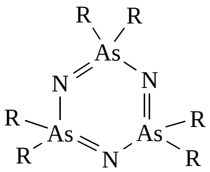
$(PO_3)_{10}^{10-}$
(**53**)

Cyclotri- and tetraphosphates have been known since the nineteenth century (see Ref. 144 for earlier literature). The cyclohexaphosphates have been isolated next, as sodium, potassium, and ammonium salts[145] and has been followed by isolation and characterization of cyclooctaphosphates,[146] cyclodecaphosphates,[147] and cyclododecaphosphates.[148] Cyclopenta- and cycloheptaphosphates are much more difficult to obtain.[149]

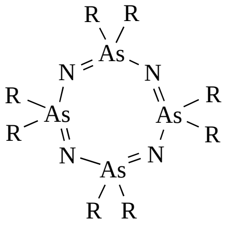
Phosphorus(III)-oxygen rings $(RPO)_n$ ($R = NPr^i_2$, $n = 4$ and 5) can be stabilized as metal complexes, but so far have not been isolated in free state.[150]

Cycloarsazanes, Cycloarsoxanes, Cycloarsathianes; Antimony Analogs. Cycloarsazene trimers and tetramers, $(R_2AsN)_n$ (R = Ph, $n = 3$ and 4), are well known.[151]

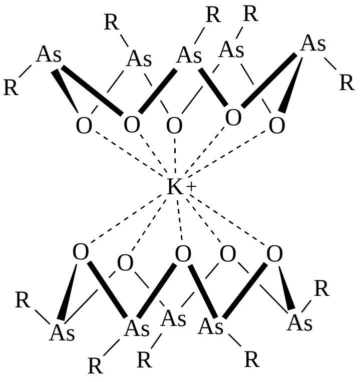
Cyclic organoarsenic oxides, $(RAsO)_n$, are readily interconvertible. According to ^{1}H NMR data, the methyl and ethyl arsoxanes (R = Me, Et) are mixtures of cyclic oligomers ($n = 2-5$) with the trimer (**54**) and tetramer (**55**) predominating.[152] Crystalline $(MeAsO)_4$ and $(MesAsO)_4$ have been structurally characterized by X-ray diffraction.[153] The cycloarsoxane rings are very labile. Ring expansion readily occurs and various ring sizes can be stabilised by complexation. Thus, crown ether-type complexation of sodium stabilizes the tetramer as $[Na(EtAsO)_4]^+$ whereas potassium and caesium stabilize the pentamer (**56**) as $[M(EtAsO)_5]^+$ (M = K, Cs).[154] Copper complexes of $(MeAsO)_4$ are also known.[155] Alkylcycloarsoxane hexamers $(RAsO)_6$ (R = Me, Et) have been stabilized as chromium, molybdenum,[156] rhenium, ruthenium, and copper[157] complexes, e.g. (**57**) and the methyl octamer $(MeAsO)_8$ as ruthenium or osmium complexes.[158]



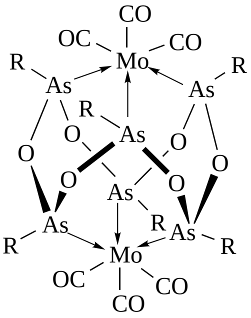
(**54**)



(**55**)



(**56**)

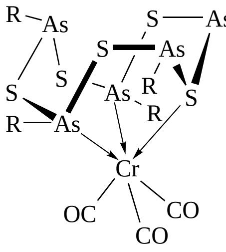


(**57**)

Only metal complexes of cycloarsathianes have been structurally characterized, and these include a tetramer $(EtAsS)_4$ (as ruthenium complex)[159] and the methyl cyclic oligomers $(MeAsS)_n$ with $n = 4$, 5, and 6 (as chromium and molybdenum complexes), e.g. (**58**) the later starting from a trimer-tetramer equilibrium mixture $(MeAsS)_n$, $n = 3$ and 4.[160] The structure of the pentamer complex is shown here.

The cycloarsoxanes and cycloarsathianes are versatile ligands owing to the presence of As(III) donor sites. Their coordination chemistry has been reviewed.[161]

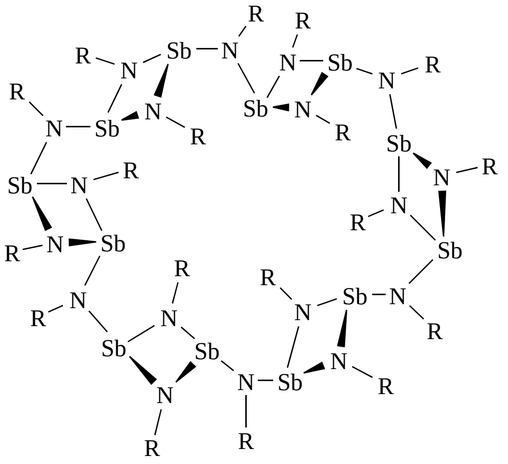
These examples not only indicate an interesting chemistry of arsenic(III) rings but also illustrate their versatility as macrocyclic ligands. It is important to underscore that the coordinated ligand is formed in a metal induced ring



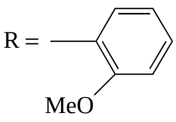
(**58**)

expansion of the smaller ring precursors. Surprisingly, no similar cycloarsazane chemistry has been reported so far.

Related antimony chemistry is less developed. A cyclic oligomer, a 'ring of rings' (**59**) containing six four-membered Sb_2N_2 synthons, has been formed in the reaction of 2-methoxyaniline with $Sb(NMe_2)_3$ and the compound was structurally charecterized.[162] Other Sb_2N_2 ring derivatives have also been reported recently.[163]



(**59**)



Trimeric and tetrameric organoantimony oxides $(RSbO)_n$ ($n = 3$ and 4) and sulfides $(RSbS)_n$ ($n = 2$, 3, and 4) have been prepared and some were structurally characterized.[164]

Sulphur-nitrogen and Related Selenium and Tellurium Rings. The unsubstituted sulphur-nitrogen pair forms a series of cyclic molecules (*see* ***Sulfur: Inorganic Chemistry***), which include the dimer S_2N_2 and the tetramer S_4N_4.[165] The pentamer is known only in cationic form $S_5N_5^{+}$[166] and no unsubstituted trimeric S_3N_3 ring compound is known.

In substituted form, sulphur(IV) forms a series of trimeric and tetrameric $[XSN]_n$ (X = F, Cl, etc.; $n = 3$ and 4) cyclic compounds, and similarly, sulphur(VI) forms trimeric and tetrameric $[X(O)SN]_n$ ($n = 3$ and 4). There is an extensive chemistry of these rings, which is well reviewed in some monographs.[167]

Selenium–nitrogen and tellurium–nitrogen heterocycles are less stable, but several are known.[168]

Other Covalent Rings. In addition to the inorganic heterocycles discussed, other element pairs form rings based upon the principle of repeating units. Among these there are inorganic rings containing germanium,[169] tin,[170] lead,[171] and antimony.[172] They are generally limited to a few regular size rings (four-, six-, or eight-membered, that is, made up of two, three, and four repeating units, respectively). Five- and six-membered nonalternating rings $Me_4Si_2E_2MR_2$ (M = Si, Ge, Sn, B; R = Me or Ph), $E(SiMe_2SiMe_2)_2E$, and $[Me_4Si_2E_2SiMe\text{-}]_2$ (E = S, Se, Te) have been reported.[173] The literature before 1980 is covered in a monograph.[174]

Inorganic Covalent Heterocycles Containing Transition Metals. There are numerous inorganic (carbon-free) rings containing transition metal atoms. We will present only a few selected examples, to illustrate the principles of their structures and formation.

Transition metals can be incorporated in covalent rings, as components of repeating building units. There are three possible ways:

1. formation of rings from repeating units made up by association of a transition metal with an electronegative atom, for example, nitrogen, oxygen, sulfur, just as in the previous cases discussed above for nonmetals and main group metals;
2. incorporation of the transition metal as heteroatom into a nonmetal inorganic ring;
3. formation of covalent rings based upon metal–metal bonds, and containing only metal atoms in the ring.

Case (a) mentioned is illustrated by some rings in which the metal atoms alternate with oxygen. Thus, cyclopentadienyltitanium oxide trimers (**60**) and tetramers (**61**) e.g. $[Cp^*TiX(\mu\text{-O})]_n$ ($n = 3$ or 4, X = F, Cl, Br),[175] the vanadium analogs $[Cp^*VCl(\mu\text{-O})]_4$[176] or the organozirconium oxide $[Cp_2Zr(\mu\text{-O})]_3$[177] fit into this category. These cyclic and related polycyclic cage organometallic oxides have been reviewed.[178,179]

A second possibility, mentioned above, is the incorporation of the metal as heteroatom into covalent nonmetal rings, to give for example, metallacyclophosphazenes,[180] metallacyclosiloxanes,[181] metallacyclosilazoxanes,[182] metallaborazines,[183] and so on. Many such rings are known (for a review, see 184).

The third type of transition metal-containing rings is illustrated by a spectacular metal–metal bond, planar 12-membered ring (**62**) made of six $-Os(CO)_4-SnPh_2-$ repeating units (obtained from Ph_2SnCl_2 and the $[Os(CO)_4]^{2-}$ anion).[185]

3.2 Inorganic Rings and Polycyclic Cages Self-assembled Through Dative Bonds

Chemical bonds in inorganic chemistry are not limited to covalency. Very important are the *dative* (*donor–acceptor*) *bonds*. Unlike normal covalent bonds, which are formed by pairing of electrons with a one-electron contribution from each atom, dative bonds are two-electron bonds formed by donation of an electron pair from one atom to another. There is a general tendency to assume that the two-electron bonds between a certain pair of atoms (*e.g.* boron and nitrogen in H_2B–NH_2 and $H_3B \leftarrow NH_3$) are identical, regardless of the origin of electrons (i.e. covalent and dative), but it has been pointed out that a distinction between the two types should be made.[186,187]

The normal covalent and dative bonds differ in several major aspects:

1. the nature of the fragments formed when the bonds are broken;
2. the nature of the bond rupture process;
3. the magnitude of the bond cleavage enthalpy.

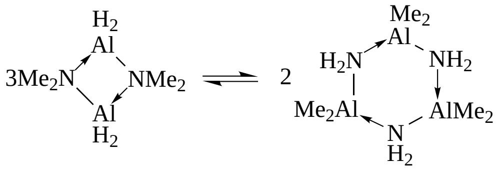
Thus, if two isoelectronic molecules, ethane, H_3C–CH_3, and amine-borane, $H_3B \leftarrow NH_3$, are compared the distinction becomes obvious: the normal covalent C–C bond ruptures homolytically and the neutral species formed are $\bullet CH_3$ (paramagnetic) free radicals, with an energy of 89.8 kcal·mol^{-1} spent in the process. The dative N → B bond rupture proceeds heterolytically, with formation of neutral diamagnetic molecules, BH_3, and NH_3, and only 31.1 kcal·mol^{-1} are spent in the process. Note that the cleavage of the dative bond requires only about one-third of the energy needed for the cleavage of a normal covalent bond between the same atoms.

When an electron donor and an electron acceptor site are present in the same molecule, intermolecular association may occur with formation of cyclic species. This process is called *self-assembly*. Self-assembly is defined as *a spontaneous association of molecules under equilibrium conditions into stable aggregates held together by noncovalent forces*.[188] The resulting species is a *supermolecule* (see above).

Numerous monomeric molecules are able to self-assemble into cyclic supermolecules. One example is H_2Al–NMe_2, which self-assembles into dimeric $[H_2Al$–$NMe_2]_2$ and trimeric $[H_2Al$–$NMe_2]_3$ cyclic supermolecules, which undergo facile interconversion under equilibrium conditions (Scheme 7).[189] The isomeric Me_2Al–NH_2 also self-assembles into cyclic trimers $[Me_2Al$–$NH_2]_3$.[190] Numerous other dimeric and trimeric $[R_2Al$–$NR'_2]_2$ rings[191,192] are known, as well as aluminum-phosphorus polycyclic supermolecules[193] and gallium, indium, and thallium analogs with nitrogen, phosphorus, arsenic, and antimony donors.[194–197] Such compounds are attractive single-source precursors for metal nitrides and phosphide or arsenide semiconductors and other high-tech materials.[198] Self-assembled cyclic organoaluminum and -gallium hydroxylamides are interesting as they display different modes of association, to form four-, five-, or six-membered rings.[199]

The aminoboranes, R_2B–NR'_2, and phosphinoboranes, R_2B–PR'_2, can also exist in monomeric molecular form or as dimeric, trimeric or polymeric supermolecules (depending upon the nature of R and R′).[200] Dative bond self-assembly is not limited to amino derivatives. Halogen bridging can induce similar effects and numerous organometallic fluorides[201] and chalcogenolates[202] also form cyclic supermolecules.

Some large ring supermolecules are formed by dative bond self-assembly of monomers containing both donor and acceptor binding sites. Spectacular examples are the tetrameric trimethyltin diphenylphosphinate $[Me_3SnO_2PPh_2]_4$,[203] and cupferronate $[Me_3SnON(Ph)NO]_4$,[204] and hexameric $[Ph_3SnO_2P(OPh)_2]_6$[205] and $[Ph_3SnO_2P(OMe)Me]_6$,[206] (Scheme 8) whereas diorganoaluminum phosphinates and



Scheme 7 Dimer-trimer equillibrium between two self-assembled cyclic supermolecules

their organogallium analogs, are only dimers, *for example*, $[Me_2AlO_2PPh_2]_2$,[207] and $[Bu^t_2GaO_2PPh_2]_2$[208] (Scheme 9).

Dative bond self-assembly may also lead to polycyclic cage supermolecules, with cubane and prismane shapes, for example, in organoaluminum[209,210] and organogallium[211,212] phosphonates (Scheme 10).

There are numerous inorganic rings containing transition metals, self-assembled through dative bonds. Only a few illustrative examples are presented here.

Among the first to be named are the transition metal nitrido chlorides and alkoxides. Thus, nitride-chlorides $[Cl_3MN]_n$ (**63**), where M = Mo or W, are associated into cyclic trimers (**64**) or tetramers (**65**) and exhibit bond length alternation, owing to the alternation of triple and dative bonds.[213] Theoretical calculation on $[Cl_3MN]_n (n = 3, 4, 5,$ and 6) explains the formation of d^6 transition metal nitrido chlorides through weak donor–acceptor bonds between the lone pairs at nitrogen and the empty d orbitals at metal.[214] The theory predicts that chromium chloro-nitride Cl_3CrN will be stable as monomer and molybdenum chloro-nitride Cl_3MoN as tetramer. A bonding analogy between chlorophosphazenes and metal chloro-nitrides has also been analysed theoretically.[215]

(**65**)

In the molybdenum–nitrogen four-membered ring, the metal-nitrogen bond lengths alternate (1.67 and 2.17 Å).

Good examples of cyclic (mostly polycyclic) structures are provided by metal alkoxides.[216] Some spectacular rings are the gold(I)-phosphido complexes of the type $[AuPR_2]_n$ ($n = 3$, 4 or 6).[217]

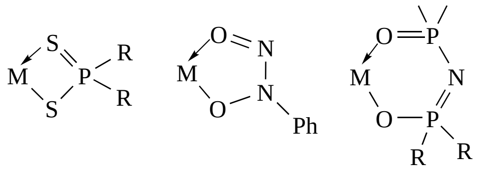
Incorporation of inorganic rings formed through dative bonds into wheel-shaped 'metallacoronands' is also worth mentioning. Examples include $[Fe_6Cl_6L_6]$ and $[In_6Cl_6L_6]$ macrocyclic compounds (L = substituted diethanolamines),[218] $[Fe_8(OH)_4(OPh)_8(O_2CBu^t)_{12}]$,[219] $[Fe_{12}(OMe)_{24}L_{12}]^{-12}$ (L = proline)[220] and $[(Bu^t_3SiS)_{12}M_{12}X_{12}]$ (M = Co, Ni, X = Cl or Br)[221] to cite only a few of the numerous examples known.

3.3 Inorganic (Carbon-free) Chelate Rings

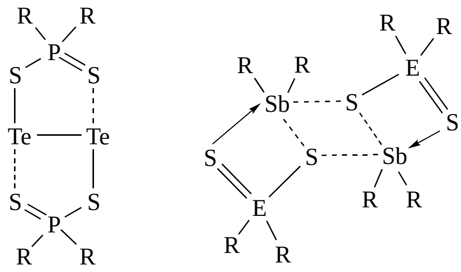
Dative bonds can lead to ring closure with formation of inorganic (carbon-free) chelate rings, for example, dithiophosph(in,on)ates,[222] cupferronates,[223] dichalcogenoimidodiphosphinates,[224] and many others[225] (Scheme 11). This type of inorganic cyclic structures can involve all transition and nontransition metals in combinations with chelating ligands not containing carbon in their molecular skeleton. Therefore, the number of possible inorganic chelate rings is legion and are not discussed here in any detail.

Numerous chelate rings are formed with polychalcogenide ligands.[226]

An extensive class of inorganic chelate ring complexes is represented by pyrazolylborates and related ligands ('scorpionates').[227] Another group of versatile chelating ligands are the inorganic backbone di- and polyphosphines, that is, compounds containing phosphinyl groups ($–PR_2$) attached to inorganic divalent moieties such as – NR–(diphosphinoamines), –O–(diphosphoxanes), –S–(thiobis(phosphines)), –NR–NR–(bis(phosphinohydrazines)), –NR–PR–NR–(bis{phosphinoamino}phosphines), $–R_2Si–$(diphosphinylsilanes) and $–O–SiR_2–O–$(diphosphinylsiloxanes), $–NR–SiR_2–NR–$bis(phosphinoamino) silanes.[228,229] Other inorganic chelating ligands are di- and polysiloxanediolates,[230] sulfur diimido anions, $[S(NR)_2]^{-2}$.[231]



Scheme 11 Some inorganic (carbon-free) chelate rings



E = Sb, As

R = Ph

Scheme 12 Formation of quasi-cyclic structures through secondary bonds

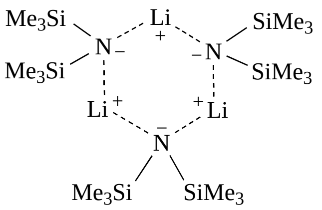
3.4 Quasi-cyclic Molecules and Supermolecules Self-assembled Through Secondary Bonds

Another type of noncovalent forces which may lead to supramolecular self-assembly are the so-called *secondary bonds or soft–soft interactions.*[232–234] They are characterized by interatomic distances longer than covalent bonds but shorter than van der Waals interatomic distances. Such interactions are weaker than two-electron covalent or dative bonds, but are strong enough to influence the coordination geometry of the atoms involved and to hold together pairs of atoms, either to intramolecularly close a ring or to induce supramolecular self-assembly with formation of cyclic structures.[235] Rings formed by this route have been named *quasi-cyclic structures.*[236] As examples can be cited the formation of a tellurium quasi-bicylic system in $[Te_2(S_2PPh_2)_2]$[237] and the dimeric self-assembly of $[Ph_2SbS_2EPh_2]_2$ (E = P, As) into a quasi-tricyclic system[238] (Scheme 12).

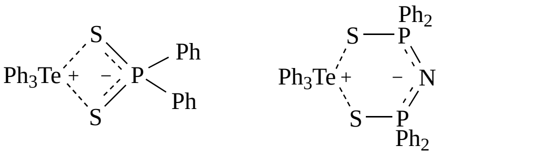
3.5 Inorganic Ring Structures Self-assembled Through Ionic Interactions

Ionic (electrostatic) interaction may also lead to cyclic self-assembly. Numerous alkali metal and alkaline-earth molecular compounds fall into this category. These include three types of associated ring compounds:

1. alkali metal and alkaline earth alkyl and aryl derivatives, in which the metal-carbon is essentially ionic;
2. alkali and alkaline-earth metal amides, phosphides, arsenides, alkoxides, thiolates, and so on, that is, compounds not containing a direct metal–carbon bond; innumerable examples are known.[239–241]



Scheme 13 Ring formation through ionic interactions



Scheme 14 Quasi-cyclic systems formed through ionic and secondary interactions

3. organometallic compounds which contain functional groups with mobile hydrogen, which can be readily displaced by an electropositive metal, to form cation-anion ion pairs (e.g. metal silanolates).

There are several relevant reviews covering the subject.[242]

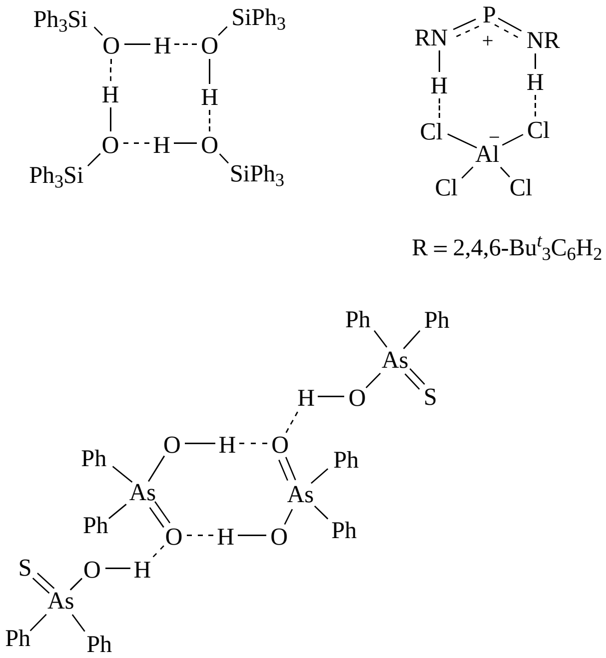
Simple examples of cyclic oligomers formed through ionic interactions are the trimer of lithium bis(trimethylsilyl)amide, $[LiN(SiMe_3)_2]_3$ (Scheme 13),[243] and hexameric $[Li\{SC_6H_3(CH_2NMe_2)_2\text{-}2,6\}]_6$[244] More intricate cage, ladder, and other polycyclic structures are formed in various other compounds.[245]

The sodium analog, $[NaN(SiMe_3)_2]_3$ has a similar structure,[246] and the lithium phosphide, $[LiPBu^t_2(THF)]_4$ is a tetramer.[247] Cyclic alkoxides can be illustrated by trimeric $[Li\{OC_6H_2(CH_2NMe_2)_2\text{-}2,6\text{-Me-}4\}]_3$, hexameric $[NaOBu^t]_6$ and nonameric $[NaOBu^t]_9$.[248] Thiolates can be trimeric, for example, $[Li(SC_6H_2Bu^t_3\text{-}2,4,6)(THF)]_3$[249] and even hexameric $[LiSC_6H_3(CH_2NMe_2)_2\text{-}2,6]_6$.[250] Numerous other examples are cited in Ref. 251.

In triphenyltellurium diphenyldithiophosphinate, $[Ph_3Te]^+$ $[S_2PPh_2]^-$ and triphenyltellurium tetraphenyldithioimidodiphosphinate, $[Ph_3Te]^+$ $[(SPPh_2)_2N]^-$, probably ionic interactions and Te···S secondary bonding are simultaneously acting to close a four- and a six-membered quasi-cycle, respectively (Scheme 14).[252]

3.6 Cyclic Supermolecules Self-assembled Through Hydrogen Bonds

Hydrogen-bond self-assembly may lead to formation of carbon-free cyclic structures containing oxygen and hydrogen in a ring, such as tetrameric $[Ph_3SiOH]_4$[253] or more complex cyclic structures such as dimeric



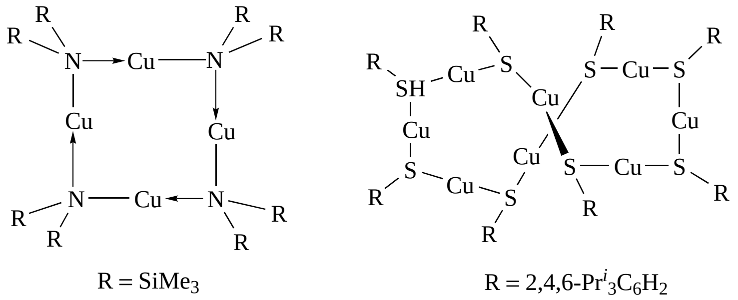
Scheme 15 Cyclic supermolecules formed through hydrogen bonds

diphenylarsinic-diphenylthioarsinic aggregate[254] (in solid state) or the anion-cation hydrogen-bond quasi-cyclic self-assembly in $[RNH\text{–}P\text{–}NH\text{–}R]^+$ $[AlCl_4]^-$ ($R = 2,4,6\text{-}Bu^t_3C_6H_2$)[255] (Scheme 15). The simplest examples are in fact some water cyclic supermolecules formed through hydrogen bonds, some of which have been found trapped in various crystal structures,[256] for example, the hexamer $(H_2O)_6$,[257] octamer $(H_2O)_8$,[258] decamer $(H_2O)_{10}$.[259] There is much interest for the cyclic water trimer $(H_2O)_3$.[260]

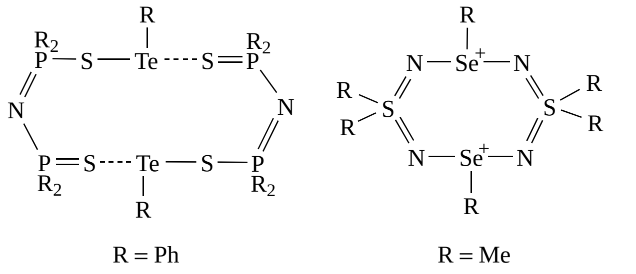
4 COMBINING BUILDING BLOCKS FOR INORGANIC RING FORMATION: A CHEMICAL ‘LEGO’

It was shown above that inorganic ring structures can be built by combining a number of various building blocks (synthons). A building block or inorganic synthon consists of a *central element* surrounded by a number of *connecting atoms*, located at the corners of a regular or irregular polyhedron. The central atom is usually an element less electronegative than carbon (i.e. B, Si, Ge, P, As, Sb, S, Se, Te, or a metal) and the connecting atom is an electronegative elements (i.e. O, N, S^{II}, even halogen if the ring is formed by dative bond self-assembly).

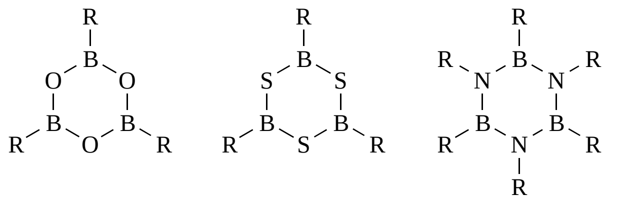
Inorganic ring systems are formed through linkage of a discrete, small number of synthons by sharing corners, edges, or faces through common connecting atoms. The four-, six-, and eight-membered rings are most common. The synthons



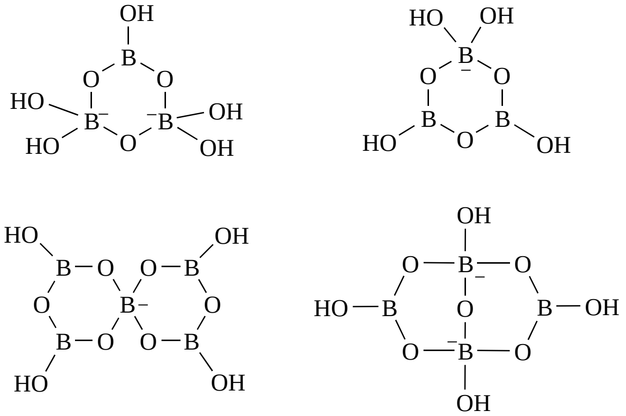
Scheme 16 Self-assembled cyclic supermolecules from linear copper(I) synthons



Scheme 17 T-shaped tellurium and selenium synthons in inorganic rings



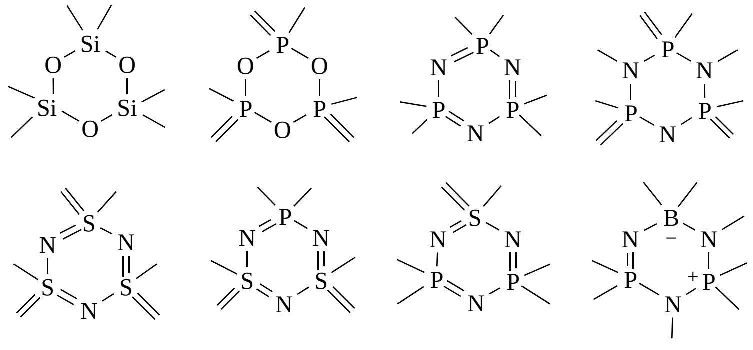
Scheme 18 Trigonal planar boron synthons in inorganic rings



Scheme 19 Rings made from trigonal planar and tetrahedral boron synthons

available for building inorganic ring systems, with their coordination numbers and geometries, can be summarized as follows:

- dicoordinate: linear and bent (sp and ψ-sp^2 or ψ-sp^3 hybridization of the central atom);
- tricoordinate: trigonal planar (sp^2), trigonal pyramidal (ψ-sp^3), or T-shaped (ψ-sp^3d);
- tetracoordinate: tetrahedral (sp^3), square planar (spd^2), or ψ-trigonal bipyramidal;



Scheme 20 Six-membered rings containing tetrahedral synthons

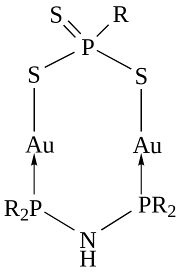
– five-coordinate: trigonal bipyramidal (sp^3d), rarely square pyramidal;
– six-coordinate: octahedral (sp^3d^2), rarely pentagonal bipyramidal.

Bent synthons are the sulfur atoms connected in homocyclic rings of various sizes cited above. Linear building blocks are illustrated by gold(I), silver(I), and copper(I) atoms bridged by nitrogen or sulfur in various self-assembled cyclic supermolecules, for example, Cu_4N_4 in $[CuN(SiMe_3)_2]_4$[261] or Cu_8S_8 in macrocyclic $[CuS(C_6H_2Pr^i_3\text{-}2,4,6)]8$ (Scheme 16).[262]

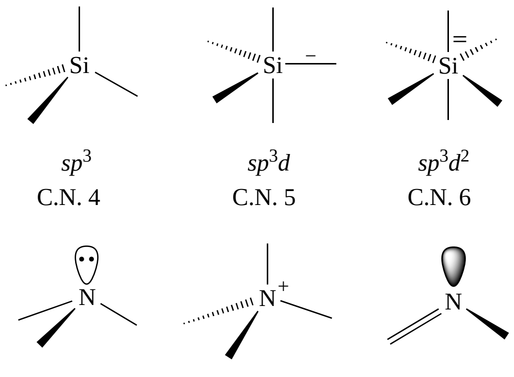
T-Shaped synthons are rare, but the RTe groups in some self-assembled quasicycles, for example, dithioimidodiphosphinates can be cited as examples.[263] The $MeSeN_2$ unit is trigonal pyramidal in $Me_2S({=}N\text{-}SeMe\text{-}N{=})_2SMe_2$ where the sulfur synthon is tetrahedral[264] (Scheme 17).

Examples of rings made up of planar triangles only are the boron heterocycles B_3O_3, B_3N_3, B_3S_3, and many others (Scheme 18). A combination of triangles with tetrahedra is illustrated by boron−oxygen rings present in various mono- and bicyclic borates[265] (Scheme 19).

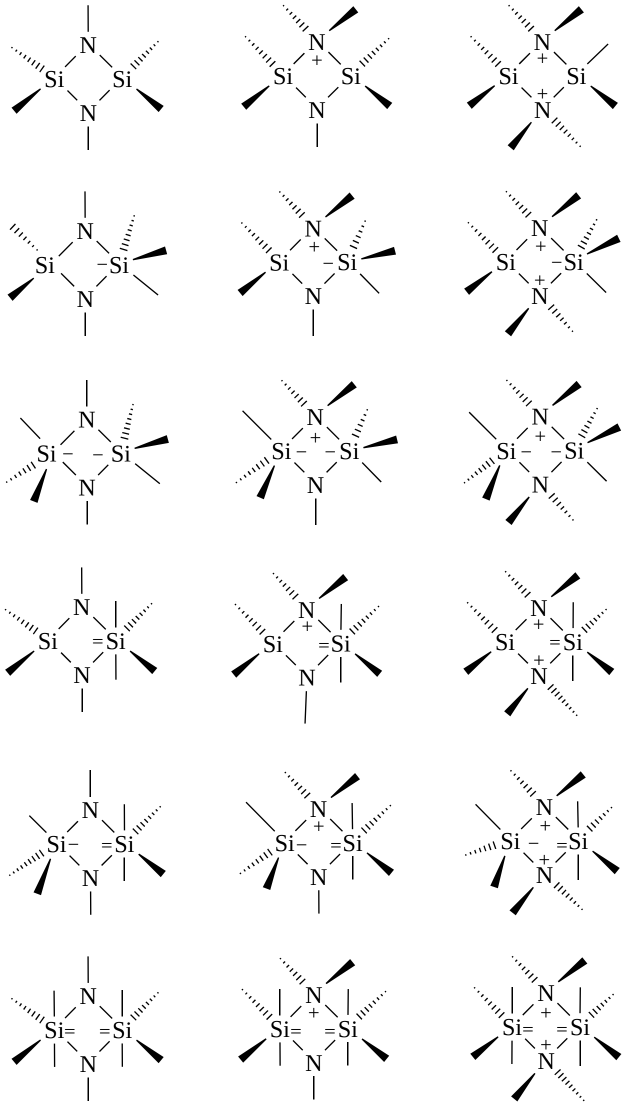
Combinations of tetrahedra are numerous as four-, six-, and eight-membered rings and also as macrocyclic systems, for example, cyclosiloxanes, cyclophosphates,



Scheme 21 An inorganic ring made up of linear and tetrahedral synthons



Scheme 22 Synthons of variable coordination numbers of silicon and nitrogen



Scheme 23 Cyclodisilazane rings containing silicon synthons of different coordination numbers

cyclophophosphazenes, cyclothiazenes, and the innumerable hybrid rings that may result by the intercombination of the large number of possible tetrahedral synthons. Only some six-membered rings are illustrated in Scheme 20.

Ring structures based upon tetrahedral building units connected through dative bonds can also be formed. Only a spectacular example is cited here as illustration: the Cu_nN_{2n} rings associated with Cu_nO_n rings in the pyrazolato cyclic complexes $[Cu(\mu\text{-OH})(\mu\text{-pz})]_n$ with $n = 6$, 8, 9, 12, and 14.[266]

An example of combining linear synthons with tetrahedral synthons in the same ring is provided by the gold(I) complexes of dithiophosphonates and a mixed ring consisting of linear, angular, and tetrahedral synthons is illustrated by the gold(I) complex[267] (Scheme 21).

For the same composition of the ring skeleton, owing to variations in the coordination numbers of the central elements in the building block (synthons), a large number of different ring systems may occur. Thus, for the Si_2N_2 composition by assuming four-, five-, and six-coordinate silicon, *that is*, tetrahedral, trigonal bipyramidal, and octahedral coordination geometries of the synthons and trigonal (planar or pyramidal) and tetrahedral for nitrogen (Scheme 22).

No less than 18 different cyclodisilazane ring systems can be formed from the synthons shown above, illustrated in Scheme 23.[268]

In these rings, silicon maintains a constant oxidation state IV and no Si=N double bond formation was considered, although some monomeric compounds containing such bonds are known. Some hypothetical cyclodisilazanes containing Si=N double bonds can be taken into consideration (Scheme 24).

If two additional sources of structural diversity, namely, variable oxidation state and double bond incorporation, in the ring are taken into account, the variety of four-membered ring systems increases greatly. This is illustrated by the phosphorus–nitrogen pair. In this case, the coordination number varies from two to three for phosphorus(III), from three to six for phosphorus(V) and two to four for nitrogen (Scheme 25).

Thus, four-membered P_2N_2 rings may occur as cyclodiphosphazanes and cyclodiphosphazenes, and the numerous possibilities are given in Schemes 26 and 27.[269]

When the substituents at phosphorus and nitrogen are also considered, geometrical isomerism adds to the structural diversity which can be expected. In addition, even four-membered rings can display various conformations (planar and bent) and this adds a new dimension to their diversity.[270,271]

Many of these ring systems are actually known (*see* ***Phosphorus–Nitrogen Compounds***). The phosphorus–nitrogen analog of cyclobutadiene deserves a special citation, because – unlike its organic (carbon) analog – it can be isolated as stable compound.

A selection of six-membered S_3N_3 rings containing sulfur–nitrogen synthons of various oxidation states and coordination numbers is illustrated in Scheme 28.

A particular case is the combination of octahedral synthons. If two octahedra share an edge the result is a four-membered ring. There are numerous examples, some being already shown above for P_2N_2 rings in the dimeric $[X_3PN–R]_2$ (*see* ***Phosphorus–Nitrogen Compounds***). Four octahedra are combined to form cyclic tetramers, for example, $[MF_5]_4$ (M = Mo, Nb, etc.) and six-octahedra form a larger ring known in some polyoxometallates.

The most spectacular was the discovery of large polyoxometallate rings containing as many as 154 molybdenum atoms in $[Mo_{154}O_{448}(NO)_{14}(H_2O)_{70}H_{28}]^{14-}$ anion[272] and 176 molybdenum atoms in $[(MoO_3)_{176}(H_2O)_{80}H_{32}]$ neutral species.[273,274] These contain octahedral and pentagonal bipyramidal building blocks. Other polyoxometallate macrocycles built from octahedral synthons are also known.[275–277] (*see* ***Polyoxometalates***).

METHOD SUMMARY

Acronyms, Synonyms

- Transmission High Energy Electron Diffraction (THEED)
- Reflection High Energy Electron Diffraction (RHEED)
- Convergent Beam Electron Diffraction (CBED)
- Nanoarea (or Nanobeam) Electron Diffraction (NED)
- Large Angle Convergent Beam Electron Diffraction (LACBED)

Measured physical quantities

- diffraction pattern geometry
- diffraction intensity and its distribution
- temperature-dependent diffraction pattern geometry and intensity.

Information available

- d-spacings measured from the diffraction pattern geometry
- crystal orientations and interfacial relationships
- crystal unit cell and strain
- crystal symmetry
- atomic positions determined from diffraction intensities
- radial distribution function from diffraction ring patterns
- surface structure and the structure of surface adsorbates from RHEED
- crystal electron density distribution and bonding.

Information not available, limitations

- magnetic spins or isotopes
- study limited to thin foils of several hundreds of nanometers thick
- samples compatible with vacuum required for electron diffraction
- radiation damage for biological samples
- incompatible with high pressure.

Examples of questions that can be answered

- Is the material crystalline or amorphous?
- What is the crystal structure and where are the atoms?
- What is the interface between two crystals?
- What is the structure of a nanotube or nanoparticle?
- What is the surface structure and surface orientation?
- Where are the bonding electrons?

Major advantages

- It works with very small volumes, for example, a single nanoparticle or nanotube.
- It does not require single crystals.
- It can be combined with electron imaging for structural mapping.

Major disadvantages

- Samples must be electron transparent; destructive sample preparation is sometimes required.
- Dynamic diffraction effects must be considered for quantitative interpretation of diffraction intensities of thick crystals.
- Radiation damage can limit the type of structural information that can be extracted.

Sample constraints

- The sample must be electron transparent.
- It must be compatible with vacuum; observation of biological samples requires *cryo*-freezing.
- Air sensitive materials must be handled using a special sample transfer chamber.
- The sample must be free standing (like a thin disc) or supported on thin foils.

1 INTRODUCTION

Electron diffraction is a structural probe widely used for characterization of both inorganic and organic materials. The principle of electron diffraction is similar to that of X-ray diffraction. Both use atomic scattering and their interference to probe the atomic structure. The difference is that electrons are charged particles and electrons interact with both the electrons and nucleus of the atom (X rays only see the electrons). The electron elastic scattering cross section is also $\sim 10^6$ times larger than that of X rays. Electron beams can also be shaped into small probes or used for imaging using electron magnetic lenses. The combination of the large scattering cross section and electron small probes makes electron diffraction very useful for studying ''small'' crystals, surfaces, or the microstructure of materials. The strong scattering can also lead to electron multiple scattering (EMS) in the case of a thick crystal, which complicates the interpretation of electron diffraction intensities for ab initio structure determination. For a known crystal, EMS effects can be taken into account by simulation. This is used for accurate measurement of lattice parameters and electron structure factors for electron density mapping.

There are several electron diffraction techniques based on (i) electron energy, (ii) the diffraction geometry, and (iii) the electron probe (Figure 1). Each has its own unique applications. High-energy electron diffraction (HEED) uses electrons with energy from tens of kilo electron volts (keV) to several millions of electron volts (MeV), while low-energy electron diffraction (LEED) uses the other end of the energy spectrum with electron energy ranging from few tens to hundreds of electrons volts. Electron diffraction patterns are recorded in either the transmission or reflection geometry. Transmission high-energy electron diffraction (THEED) is mainly a bulk structure characterization technique because of the electron penetration. The incident electron beam can be a focused probe with a convergent beam or spread out as a parallel illumination. A focused probe is used in convergent-beam electron diffraction (CBED) for parallel recording of diffraction intensities of different incident-beam directions. CBED is used for studying single crystals.[1] Parallel, or nearly parallel, beams are used in selected area electron diffraction (SAED) and nanoarea electron diffraction (NED). Both techniques can be used for studying crystalline or noncrystalline structures. Reflection high-energy electron diffraction (RHEED) and LEED are sensitive to surface structures. They are used primarily as surface characterization techniques. RHEED is performed in the glancing angle diffraction geometry which is very useful in a growth chamber for monitoring film growth. These two techniques are generally treated separately from transmission electron diffraction (TED). Readers interested in these two techniques are refered to the Ref. 3 and 2, respectively.

A closely related technique to electron diffraction is electron imaging where diffracted electrons are brought

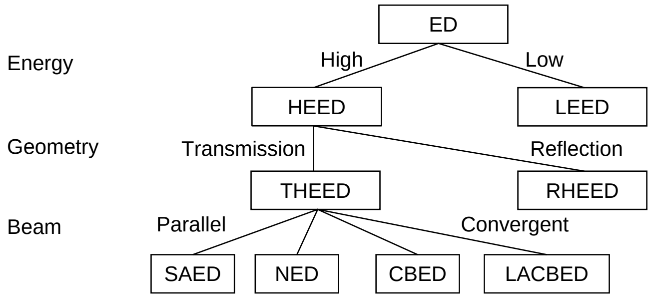

Figure 1 Classification of electron diffraction techniques

together to interfere and form atomic resolution images.[4] In modern transmission electron microscopes (TEM), electron diffraction patterns and images can be recorded from the same area to provide complementary information in real and reciprocal spaces. In scanning transmission electron microscopy (STEM), an angstrom-sized electron probe is scanned across the sample and the diffraction intensity is recorded by integrating over an area detector and displayed as a raster image.[5] The image, thus, can be viewed as a map of diffraction intensities. The commonly used detector for STEM has a hole in the middle (annular dark-field detector), which records electrons scattered into high angles. Electron diffraction is required for the interpretation of both TEM and STEM image contrast.

The study of electron diffraction dates back to 1927 when Davisson and Germer in USA, and Thompson and Reid in Scotland, reported electron scattering by a crystal and the formation of interference patterns by electrons similar to the pattern formed by light waves scattered by a diffraction grating. The Davisson and Germer's experiment used low-energy electrons, which was the start of LEED that is used today. Thompson and Reid used high-energy electrons in the transmission geometry. The first CBED pattern was recorded by Möllenstadt as early as 1939 using a two-magnetic lens setup.[6] MacGillavry first attempted structure factor measurement by using the two-beam theory of Blackman for dynamic electron diffraction.[7] The multi-beam theory of electron dynamic diffraction has its origin in the Bloch wave method originally formulated by Hans Bethe in his Ph.D. thesis. More recent developments of electron diffraction are entwined with the development of electron microscope technologies and the development of computer algorithms for data analysis. The development of field emission guns (FEG) in the 1970s and their adoption in conventional TEM brought high source brightness, small probe size, and improved coherence to electron diffraction. Electron energy filters, such as the in-column Ω-energy filter, allow the inelastic background from plasmon, or higher electron energy losses, to be removed from recorded diffraction patterns with an energy resolution of a few electron volts. The development of array detectors, such as crystal charge density (CCD) cameras, or imaging plates (IPs), enables parallel recording of diffraction patterns and quantification of diffraction intensities over a large dynamic range that was not available to electron microscopy before. These developments in the electron diffraction hardware were accompanied by the development of efficient and accurate algorithms to simulate electron diffraction patterns and modeling structures on a first-principle basis using fast computers, which has significantly improved our ability to interpret experimental electron diffraction patterns. The more recent developments are time-resolved electron diffraction at the time resolution approaching femtoseconds[8–11] and coherent NED for the study of individual nanostructures.[12] Further developments of these techniques will significantly improve our ability to interrogate structures at high spatial and time resolution that hitherto has not been available.

This chapter covers both the basics and the modern aspects of electron diffraction. The intention is to provide an integrated review that both the novice and the expert will find useful as a guide for modern electron diffraction. Some of the details that are not covered here can be found in monographs on electron diffraction.[1,13–15] The chapter is organized as follows. First, an introduction to different electron diffraction techniques is given. This is followed by background theories which are required for the interpretation of diffraction patterns. Experimental procedures are described after the technical background. The applications section has a large collection of examples from relatively straightforward tasks to more advanced ones that are under development for their promises. Experimental details are provided when it is appropriate to give some idea of what it takes to do electron diffraction.

2 TECHNICAL BACKGROUND

2.1 Electron Diffraction Techniques

The basic setup for electron diffraction is an electron gun, a sample, and an electron detector. The electron beam used for HEED is shaped using either magnetic or electrostatic lenses or both. A modern TEM uses at least three magnetic lenses for the illumination system, condenser I, II, and the objective prefield, which is a part of the objective lens magnetic field before the sample that also acts as a lens. Some of microscopes come with an additional condenser lens (condenser III, or condenser mini lens), which can be used for nanodiffraction. The high-energy electron gun used in RHEED typically comes with one or two magnetic or electrostatic lenses to produce a small electron beam. Figure 2 illustrates different electron illumination configurations for electron diffraction in a TEM using the combination of condenser II, III, and the objective prefield. The difference between different illuminations is the strength (or focal length) of the condenser II and III. The focal length of condenser II is varied continuously in electron microscopy. Condenser

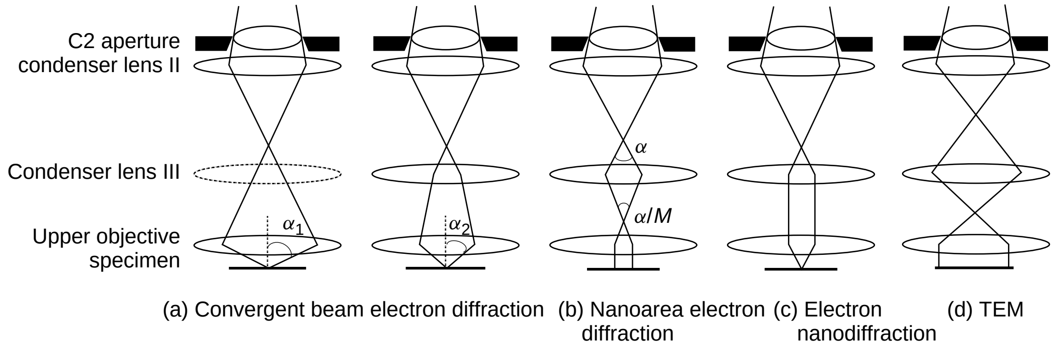

Figure 2 Electron illumination modes for transmission high-energy electron diffraction. The first two in (a) represent two different convergent beams used for convergent beam electron diffraction. The M in (b) is the magnification of the condenser III.

III has different settings for the focal length. Each of these illuminations is associated with a different electron diffraction technique.

2.1.1 Selected Area Electron Diffraction (SAED)

SAED is formed using the TEM illumination (Figure 2d), which is spread out over a large area of the specimen as a parallel beam. The diffraction pattern is recorded from an area of interest by placing an aperture in the imaging plane of the image forming objective lens. Only electron beams passing through this aperture contribute to the diffraction pattern. For a perfect lens without aberrations, electron beams recorded in the diffraction pattern come from an area that is defined by the image of the selected area aperture at the specimen. The aperture image is demagnified by the objective lens (a factor of ~20). In a conventional electron microscope, rays at an angle to the optic axis are displaced away from the center because of the spherical aberration of the objective lens (C_s). The displacement is proportional to $C_s\alpha^3$, where α is twice the Bragg angle. The smallest area that can be selected in SAED is thus limited by the objective lens aberrations. This limitation is removed using an electron microscope equipped with a TEM aberration corrector placed after the objective lens.[16]

SAED is the most popular diffraction technique in TEM. The technique can be applied to study both crystalline and noncrystalline structures. The large area illumination is useful for recording diffraction patterns from polycrystalline samples or averaging over a large volume (e.g., a large number of nanoparticles). SAED can also be used for low-dose electron diffraction, which is required for studying radiation sensitive materials, such as organic molecules.

2.1.2 Nanoarea Electron Diffraction (NED)

NED uses a small (nanometer-sized) parallel illumination with the condenser/objective setup shown in Figure 2(b).[12] The small, parallel, beam is achieved by reducing the convergence angle of the condenser II crossover and placing it at the focal plane of the objective prefield, which then forms a parallel beam illumination on the sample. A third condenser lens, or a mini lens, is required for the formation of a nanometer-sized parallel beam. For a condenser aperture 10 micron in diameter, the probe diameter is ~50 nm with an overall magnification factor of 1/200 in the JEOL 2010 electron microscopes (JEOL, USA). The beam size is much smaller than what can be achieved using a selected area aperture. The diffraction pattern recorded in this mode is similar to SAED. For crystals, the diffraction pattern consists of sharp diffraction spots. The major difference is that the diffraction volume is defined directly by the electron probe in NED. Since all electrons illuminating the sample are recorded in the diffraction pattern, NED in a FEG microscope also provides higher beam intensity than SAED (the probe current intensity using a 10 micron condenser II aperture in JEOL 2010F is ~10^5 e/s-nm^2).[12]

The small probe size allows the selection of an individual nanostructure and reduction of the background in the electron diffraction pattern from the surrounding materials. An example is given in Section 3.5 for the structure characterization of individual carbon nanotubes (CNT) by electron diffraction.

The beam size in NED can be further reduced by weakening the condenser II and placing the crossover at the front focal plane of the condenser III lens. This results in a focused probe with the sample close to the back of the focal plane of the pre-objective lens. The probe size formed with coherent illumination can be as small as a few angstroms. The diffraction patterns recorded in this case consists of small disks, which are the same as those recorded in the nanodiffraction mode in STEM. This technique is useful for probing local structure variations.[17]

2.1.3 Convergent-Beam Electron Diffraction (CBED)

CBED is recorded using a focused electron probe at the specimen (see Figure 2a, c). Compared to SAED, CBED

has two main advantages for studying crystals. First, the diffraction pattern is taken from a much smaller area using a focused probe. The smallest electron probe currently available in a high-resolution FEG-STEM is close to 1 Å. Thus, CBED patterns can be recorded from individual atomic columns. For crystallographic applications, CBED patterns are typically recorded with a probe of a few angstroms to hundreds of nanometers. The second advantage is that CBED patterns record diffraction intensities as a function of incident-beam directions. Such information is very useful for symmetry determination and quantitative analysis of electron diffraction patterns.

A comparison between the SAED and CBED is given in Figure 3. CBED patterns consist of disks. Each disk can be divided into pixels, each pixel approximately represents one incident-beam direction. For example, the beam P in Figure 3 gives one set of diffraction patterns shown in full lines. The geometry of the diffraction pattern by the incident-beam P is the same as the selected area diffraction pattern with a parallel illumination. For a second beam P′, which comes at a different angle compared to P, the diffraction pattern is displaced from that of P by α/λ with α as the angle between the two beams.

Experimentally, the size of the CBED disk is determined by the condenser aperture and the focal length of the probe-forming lenses. In modern microscopes with an additional mini lens placed in the objective prefield, it is also possible to vary the convergence angle by changing the strength of the mini lens. Underfocus of the electron beam also gives a smaller convergence angle; however, this leads to a bigger probe, which can be an issue for specimens with a large wedge angle.

The ability to record diffraction intensities over a range of incident-beam angles makes CBED readily accessible for quantitative comparison with simulations. In the past 15 years, CBED has evolved from a tool primarily for crystal symmetry analysis to the most accurate technique for strain and structure factor measurement.[18] For defects, large-angle CBED technique can characterize individual dislocations, stacking faults, and interfaces.[15] For applications to defect structures and structures without three-dimensional periodicity, parallel-beam illumination with a very small beam convergence is required.

2.1.4 *High-Resolution Electron Microscopy*

The power spectrum of high-resolution electron microscopy (HREM) images contains useful diffraction information, which can be used for studying defects, small particles or other local structures that are difficult to study by diffraction alone. For thin specimens below a certain thickness, the Fourier transform of the image intensity ($I(\vec{S})$) can be related to the Fourier transform of the potential ($F(\vec{S})$, the structure factor):

$$I_{\text{image}}(\vec{S}) = \delta(\vec{S}) + 2\sigma F(\vec{S})T(\vec{S}) \quad (1)$$

where $T(\vec{S})$ is the contrast transfer function (CTF) of the objective lens and σ is electron interaction constant. As a diffraction technique, HREM is also limited by several factors. The CTF modifies the image spectrum; the function itself depends sensitively on the lens properties and the defocus. Electron images are also sensitive to noise introduced during image recording and inelastic scattering that reduce the image contrast. The largest diffraction angle obtainable in HREM is limited by the image resolution. Nonetheless, electron images contain useful phase information for structure determination. There are several successful cases using HREM to solve inorganic crystal structures using image processing techniques.[19–21]

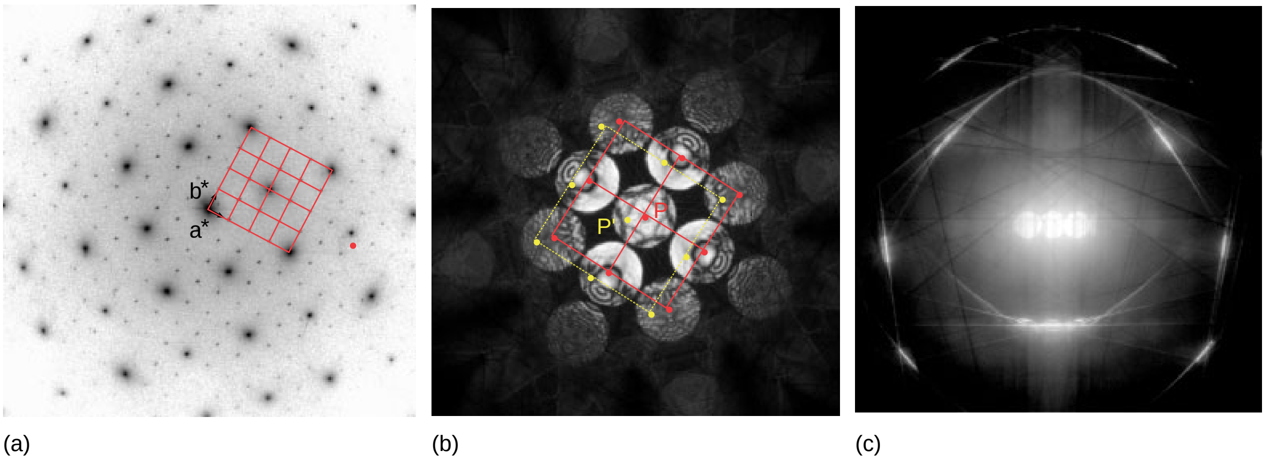

Figure 3 Examples of (a) selected area electron diffraction, (b) zone-axis CBED pattern, and (c) off-zone axis CBED pattern showing Kikuchi lines in the diffraction pattern

2.1.5 Hybrid Electron Diffraction and Imaging Techniques

There are several hybrid electron diffraction and imaging techniques that mix diffraction and imaging information. These techniques include large-angle convergent-beam electron diffraction (LACBED),[15,22] convergent-beam imaging (CBIM),[23] parallel recording of dark-field images (PARODI),[24,25] and fluctuation electron microscopy (FEM).[26,27] Both LACBED and PARODI use a focused probe that is placed above or below the specimen (Figure 4). Because of this, electron beams of different angles travel through different areas of the sample. The diffraction pattern recorded thus carries both reciprocal and real-space information. LACBED, as indicated by its name, is formed using electron beams with a large convergence angle (see Figure 4 for an example). The overlapping of diffraction disks resulting from the large convergence angle is removed by placing a small aperture around one of the diffraction spots that can be observed in the imaging plane of the objective lens because of the focused beam placed away from the sample. In comparison, PARODI uses a small convergence angle that avoids the overlapping of diffraction disks. LACBED is used for studying defects and crystal symmetry. PARODI, which is a relatively new technique, is useful for studying interfaces and crystals with large unit cells.[24]

FEM is another hybrid electron diffraction and imaging technique. In the original version of this technique, a hollow cone illumination was used for dark-field imaging, in which the electron beam is tilted away from the optical axis by an angle and rotated azimuthally. The image is formed by placing a small aperture at the center of the diffraction pattern (Figure 5).[26] Only electrons scattered with the selected angle are allowed for imaging. The variance of the image intensity is then calculated and tabulated as a function of the hollow cone illumination angle. The variance comes from the change in the scattering power of a projected sample volume. The area diameter is one over the aperture size in reciprocal space. A large image intensity variance is expected when the sample contains nano-crystallites and fluctuation in crystallite orientations leads to the variance. Theoretically, it has been shown that the calculated variance in the kinematical limit can be related to the many body correlation functions; a large variance is indicative of medium range ordering.[26] Applications of FEM to amorphous materials show that this technique is very sensitive to the structural differences in different amorphous materials.[27]

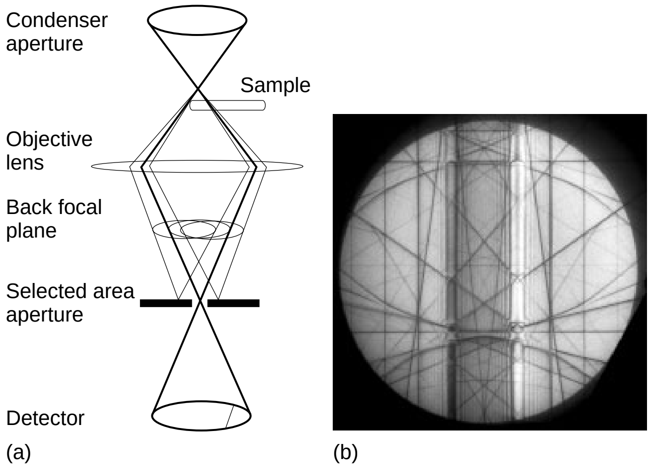

Figure 4 (a) Schematic illustration of large-angle CBED technique and (b) an example of LACBED pattern taken from Si near [113] zone axis showing high order Laue zone lines in the disk

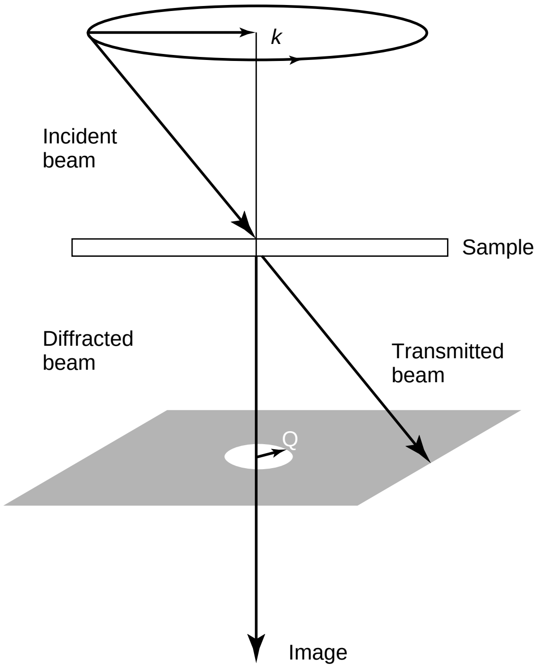

Figure 5 Schematic dark-field hollow cone imaging for fluctuation electron microscopy

2.2 Interpretation of Diffraction Pattern Geometry

Electron diffraction patterns in general appear as (i) broad halos for materials with amorphous structure, (ii) multiple concentric rings for powder samples, (iii) sharp diffraction spots (conventional diffraction pattern), and (iv) disks for CBED (see Figure 6). In the case of crystals, in addition to the diffraction spots, diffuse scattering or diffuse background may be observed including sharp lines for thick specimens. The lines, the so-called Kikuchi lines (see also Figure 3), are formed by Bragg diffraction of the diffuse background. Diffuse scattering comes from the perturbation of crystal lattices, which has its origin in composition, atomic displacements, or lattice terminations such as small particles or precipitates.

Structural information obtainable from electron diffraction patterns are lattice d-spacings, crystal unit cell

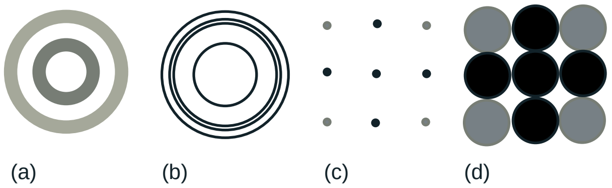

Figure 6 Schematic illustration of different types of electron diffraction patterns

symmetry, crystal orientations and texture, interatomic distances, atomic positions, atomic thermal vibrations, (the Debye–Waller factors), and crystal potential and charge density. A survey of procedures used to retrieve the structural information is given here. Some of the analyses involved are relatively straightforward and can be carried out by nonexperts without the requirement of extensive training. Others, involving quantitative analysis of diffraction intensities, require some expertise with electron diffraction.

2.2.1 *The Geometry of Conventional Electron Diffraction Patterns*

The diffraction spots are expected where transmitted and diffracted electron beams intersect with the detector. The basis for diffraction pattern geometry analysis, thus, is the crystal reciprocal lattice and the Laue diffraction condition, or the equivalent Bragg's law, for diffraction:

$$\vec{k} - \vec{k}_o = \vec{g} = h\vec{a}^* + k\vec{b}^* + l\vec{c}^* \quad (2)$$

where $\vec{k}_o$ and $\vec{k}$ are incident and diffracted electron wavevectors respectively and $\vec{g}$ is a reciprocal lattice vector. The lattice d-spacing is given by $d_{hkl} = 1/|\vec{g}| = 1/|h\vec{a}^* + k\vec{b}^* + l\vec{c}^*|$. The d-spacing can be obtained by measuring the length of $\vec{g}$ in the experimental diffraction pattern (D) using:

$$d = L\lambda/D \quad (3)$$

Where L is the experimental camera length (CL) and λ is the electron wavelength determined by the electron accelerating voltage, Φ, in volts:

$$\lambda = h/\sqrt{2me\Phi} \approx 1.226/\sqrt{\Phi}\sqrt{1 + 0.97845E - 6\Phi} \quad (4)$$

Experimentally, only the camera constant of the product of $L\lambda$ is needed, which can be calibrated using a sample with known d-spacings. For single crystals or polycrystals with grain size comparable to, or larger than, the selected area for diffraction, the lattice planes observed in the experimental diffraction patterns are nearly parallel to the electron beam. The wavelength of high-energy electrons is relatively short. For 200 kV electrons, the wavelength is 0.025 Å, the Bragg angle ($2d\sin\theta = \lambda$) is very small. For example, θ is 5 mrad for $d = 2.5$ Å.

The intersection of two sets of lattice planes defines a zone axis $[u,v,w]$. For a given zone axis, the reflections (h,k,l) that are allowed in the diffraction pattern must satisfy:

$$hu + kv + lw = n \quad (5)$$

Here n is an integer. Each n denotes a planar section of the reciprocal space, which is perpendicular to the zone axis. In diffraction, these planar sections are called the *Laue zones*. Zero order Laue zone (ZOLZ) refers to $n = 0$, while others are called *high order Laue zones* (HOLZs). An example of a single crystal electron diffraction pattern is shown in Figure 3(a). The lattice geometry of the ZOLZ is described by two, nonparallel, reflections $\vec{g}_1$ and $\vec{g}_2$, which are selected as the closest ones to the transmitted beam. The projected lattice of the HOLZs is the same as that of the ZOLZ, however, the lattice can be shifted relative to the ZOLZ. The offset of HOLZs is described by an additional reflection $\vec{g}_3$, which is independent of $\vec{g}_1$ and $\vec{g}_2$ and is also closest to the origin. Once these three reflections are identified, all reflections can be indexed using these three vectors as the basis:

$$\vec{g} = i\vec{g}_1 + j\vec{g}_2 + n\vec{g}_3 \quad (6)$$

Experimentally, for crystals of known structure, any two reflections in the ZOLZ can be used to identify the zone axis and the approximate crystal orientation using

$$\vec{Z} = \vec{g}_1 \times \vec{g}_2 = \begin{pmatrix} \vec{a} & \vec{b} & \vec{c} \\ h_1 & k_1 & l_1 \\ h_2 & k_2 & l_2 \end{pmatrix} \quad (7)$$

and reduce $\vec{Z}$ to the shortest lattice vector. Diffraction pattern indexing is performed by comparing the measured d-spacings referring to the powder diffraction files or a list of d-spacings generated using a crystallographic utility program. The angle between $\vec{g}_1$ and $\vec{g}_2$ is useful for indexing single crystal diffraction patterns, especially in case of a high index zone axis or a crystal with low symmetry. For crystals with unknown structure, the three dimensional unit cell can be reconstructed using two zone-axis diffraction patterns with a known rotation angle or from a single diffraction pattern with HOLZ reflections. A reduced unit cell can be identified from these diffractions which then can be converted to the Bravais lattice.[28]

The surface diffraction geometry of RHEED and LEED is determined by the intersection of the Ewald sphere with the 2-D reciprocal rods of the surface. The incidence for LEED is normal to the surface; the diffraction pattern is a projection of the positions of the rods. In RHEED, the incident beam is nearly normal to the surface reciprocal rods. The diffraction spots fall onto a semicircle, which is defined by the Ewald sphere. For more details on RHEED and LEED, refer to Ref. 3 and 2 respectively.

2.2.2 *The Geometry of CBED*

The diffraction pattern has the same geometry as the SAED pattern except that the sharp diffraction spots are replaced with disks. Within the disk, the intensity varies depending on the sample thickness. The variation comes from the change in diffraction condition for each point inside the CBED disk. This change can be seen in the Ewald sphere construction, which is illustrated in Figure 7. By the requirement of elastic scattering, all diffracted beams are on the Ewald sphere. Consider the incident-beam P, which satisfies the Bragg condition for the reflection of g, and an incident-beam P′ to the left of P; the diffracted beam of P′ also moves to the left. The deviation of the electron beam P′ from the Bragg condition is measured by the distance excitation error, which is defined by

$$S_g = (k_0^2 - |\vec{k} + \vec{g}|^2)/2|k_0| \quad (8)$$

The excitation error for g increases linearly away from the Bragg condition along the direction of g and stays constant, perpendicular to g. To see this, take $k_g = -g/2 + \Delta$ then

$$S_g = \lambda \left(\left(-\frac{g}{2} + \Delta \right)^2 - \left(\frac{g}{2} + \Delta \right)^2 \right) \Big/ 2 = -\lambda g \Delta \approx -g\delta\theta \quad (9)$$

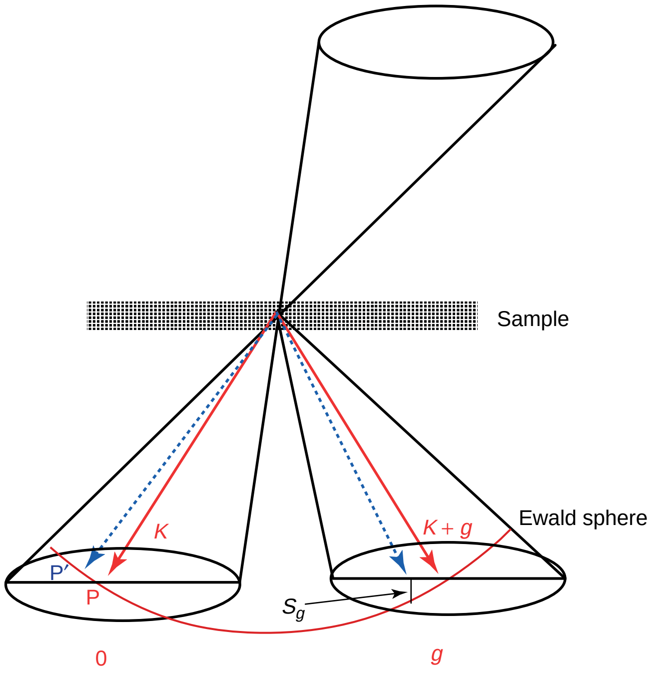

Figure 7 The schematic ray diagram of CBED. This figure demonstrates the variation of excitation errors at different positions of the CBED disk. The beam marked by the full line (P) is at Bragg condition, while the one marked by the dashed line is associated with a positive excitation error (S_g)

Here the positive Δ corresponds to a tilt towards g and $\delta\theta$ is the deviation angle from the Bragg condition. S_g is negative for positive Δ and positive for negative Δ. An incident beam moving to the left in the transmitted CBED disk gives a positive excitation error. Correspondingly, a beam, moving to the right of P, gives a negative excitation error. The range of excitation errors within each disk is proportional to the length of g and the convergence angle. Consequently, the excitation error of a HOLZ reflection changes much faster than that of a low-order reflection in the ZOLZ.

2.2.3 *Kikuchi Lines and HOLZ Lines*

Kikuchi lines are produced by Bragg diffraction of electron diffuse scattering produced by inelastic scattering, and appear as background intensities in the diffraction pattern (see Figure 3 for an example). The average electron energy loss is small, and the wavelength of the inelastic background is approximately the same as the incident electron beam. HOLZ lines are sharp lines observed in the CBED disks. They are produced by Bragg diffraction of lattice planes of high order reflections. The rapid increase in the excitation error of a high order reflection away from the Bragg condition results in a rapid decrease in the diffraction intensity. The maximum diffraction intensity occurs at the Bragg condition under the kinematic approximation, which appears as a straight line within the CBED disk. Since Kikuchi lines also mark the Bragg conditions, Kikuchi lines superimpose on HOLZ lines inside the disk and continue outside the disk. A major difference between the two is the contrast. Kikuchi lines are mostly observed for low and medium order reflections, while HOLZ lines can be observed for high order reflections.

The position of HOLZ lines is very sensitive to small changes in lattice parameters and the local strain. The sensitivity comes from the large scattering angle. This can be seen in the case of a cubic crystal for which $\theta \approx g\lambda/2 = \sqrt{h^2 + k^2 + l^2}\lambda/2a$. A small change in a gives $\delta\theta \approx 0.5 g\lambda\delta a/a$. The amount change in the Bragg angle is proportional to the length of g. The positions of these lines move relative to each other when the lattice parameters change. This effect can be used for accurate measurement of lattice parameters.

The direction of a HOLZ line is normal to the reciprocal lattice vector and its position is decided by the Bragg condition. In diffraction analysis, it is useful to express HOLZ lines using line equations in an orthogonal zone-axis coordinate system (x, y, z), with z parallel to the zone-axis direction. The x direction can be taken along the horizontal direction of the experimental pattern and y is normal to x. The Bragg diffraction equation (2) expressed in this coordinate is given by

$$k_y = -\frac{g_x}{g_y} k_x + \frac{2g_z - g^2}{2g_y} |k_z| \quad (10)$$

Here

$$|k_z| = \sqrt{k_0^2 - k_x^2 - k_y^2} \approx k_0 = 1/\lambda \qquad (11)$$

The approximation holds for high-energy electrons of small wavelengths and the typical acceptance angles in electron diffraction. Within this approximation, beams that satisfy the Bragg condition form straight lines.

2.3 Diffraction Pattern Symmetry and Crystal Space Group

The crystal symmetry is reflected in the diffraction patterns. For example, if the crystal has a rotation axis, two diffraction patterns related by rotation should be the same. The same is true for mirror symmetry. Additional symmetries are produced in electron diffraction because of (i) the principle of reciprocity and (ii) the projection along the zone axis for ZOLZ.[14] The principle of reciprocity states that the intensity of the diffracted beam (B) with a source (A) is the same as the intensity detected at A with the source at B by the same scatter. The projection of crystal structure along the zone-axis orientation used in the observation produces a mirror symmetry at the middle of the sample which may or may not exist in the crystal. The combination of reciprocity and projection with the crystal point groups produces 31 diffraction groups, whose relationships with the 32 point groups were tabulated by Buxton.[29] The correspondence is often not unique. The determination of crystal point groups comes down to elimination of multiple choices using the symmetry of diffraction patterns recorded along several major symmetric orientations and/or using information about the lattice determined from the diffraction pattern geometry. The diffraction pattern symmetries used in the determination are those of the whole pattern, the transmitted beam (Bright), the diffracted beams (dark-field), and the symmetry between $+g$ and $-g$ beam. It should be emphasized that the Friedel symmetry ($I_g = I_{-g}$) is absent in electron diffraction because of dynamic scattering. The point groups can be uniquely determined by electron diffraction.

The screw and glide axes present in the crystals can be determined by observing dynamic extinction in kinematical forbidden reflections (zero structure factor due to the glide or screw axes). These reflections generally show some intensities due to electron multiple scattering. The dynamic extinction is observed when the incident beam is in the glide plane in case of a glide; this was first reported by Gjonnes and Moodie (G-M lines) using CBED (the extinction appears as dark lines subsequently named as the *G-M lines*). The dynamic extinction of a screw axis is more complicated, and is described in detail in Ref. 29.

The combination of point group determination and identification of translation symmetry allows the unique identification of space groups.[30,31] Both CBED and LACBED techniques can be used for this purpose. Applications of symmetry determination by CBED include phase identification and determination of unknown structures.

2.4 Interpretation of Diffraction Pattern Intensity

The diffraction intensity of ultrathin films and small nanocrystals can be approximated by summing scattering from an assembly of atoms (kinematic approximation):

$$I(\vec{S}) \propto \left| \sum_i f_i T_i(\vec{S}) e^{2\pi i \vec{S}\cdot\vec{r}_i} \right|^2 \qquad (12)$$

where the summation is over individual atoms i, $\vec{S} = \vec{k} - \vec{k}_o$ is the scattering vector, f_i and T_i are the atomic scattering and temperature factor, respectively, and $T(\vec{S}) = \exp(-B|\vec{S}|^2/4)$ in case of isotropic atomic vibrations. For a crystal, the sum is limited to atoms within the unit cell and $\vec{S} = \vec{k} - \vec{k}_o = \vec{g}$ and the intensity is proportional to the square of the crystal thickness and the structure factor $V_g = \sum_i f_i T_i(\vec{g}) e^{2\pi i \vec{g}\cdot\vec{r}_i}$. The kinematic approximation breaks down at a certain crystal thickness when the diffracted intensity approaches that of the incident beam. A useful criterion for kinematic approximation is $t \le \xi_g/4$, where ξ_g is the extinction distance of the strongest reflection in the diffraction pattern. The extinction distance is orientation dependent. In case only one set of lattice planes is strongly diffracting (the two-beam condition), the extinction distance is given by $\xi_g = h^2 2me\lambda V_g$.

For inorganic crystals, the typical extinction of a strong reflection is on the order of a few tens of nanometers. For a crystal of more than a few nanometers thick, multiple scattering must be taken into account for the interpretation of diffraction intensities. There are several approaches to EMS.[14] For perfect crystals, the Bloch wave approach is most useful, which is based on the Bloch wave method formulated by Hans Bethe in his thesis. The diffraction intensity in the Bloch wave theory is given by

$$I_g(x, y) = |\phi_g(x, y)|^2 = \left| \sum_i c_i(x, y) C_g^i(x, y) \exp[2\pi i \gamma^i(x, y) t] \right|^2 \qquad (13)$$

Here the eigenvalue γ and eigenvector C_g are obtained from diagonalizing the equation:

$$2KS_g C_g + \sum_h U_{gh} C_h = 2K\gamma C_g \qquad (14)$$

where

$$U_g = \frac{2me}{h^2} V_g = \frac{2me}{h^2} \sum_i (f_i + i f_i') T_i(\vec{g}) e^{2\pi i \vec{g}\cdot\vec{r}_i} \qquad (15)$$

is the electron interaction structure factor. The imaginary term f_i' is included to describe the effect of inelastic scattering (absorption). Details on the evaluation of absorption potentials

can be found in Refs. 32–34. S_g is the deviation from the Ewald sphere (excitation error) defined in Section 2.2.2. The c_i are obtained from the first column of the inverse eigenvector matrix as determined by the incident-beam boundary condition. The solution of equation (14) converges with the increasing number of beams included in the calculation. The strong beams are included in the diagonalization, while weak beams can be treated by perturbation. In practice, an initial list of beams is selected using the criteria of maximum g length, maximum excitation error, and their perturbational strength. Additional criteria are used for selecting strong beams.

Figure 8 shows an example of simulated CBED patterns using the Bloch wave method described here for the ZnO [10−10] zone axis and electron accelerating voltage of 200 kV. The simulation includes 99 beams in the ZOLZ. Standard numerical routines were used to diagonalize the complex general matrix. The whole pattern simulation on a modern PC only takes a few minutes.

Another method commonly used for dynamic electron diffraction simulation is the multislice method developed by Cowley and Moodie.[35] This method models electron wave propagation in the presence of a potential field by separating the potential into thin slices and then approximating wave propagation in each slice by introducing a phase change in the electron wave followed by wave propagation through the slice thickness. As a numerical method, multislice has the advantage that it can treat both crystals and nonperiodic structures such as defects. Because of this, the multislice method is used widely for high-resolution electron image simulation and also increasingly for simulation of diffraction of nanocrystals.

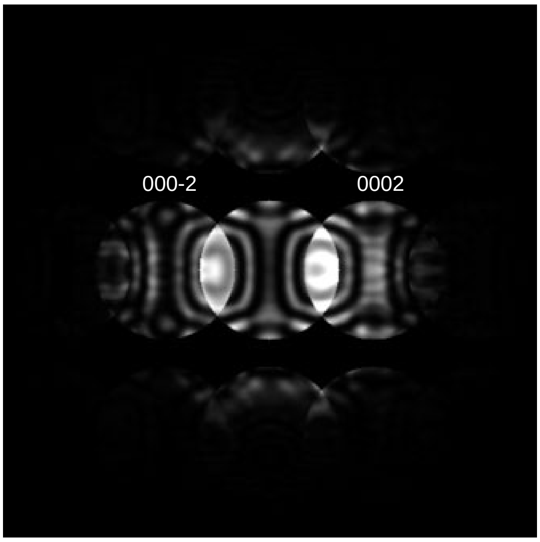

Figure 8 Simulated CBED pattern of hexagonal ZnO along [10−10] zone axis for crystal thickness of 165 nm and the electron voltage of 200 kV. The asymmetry between ±(0002) comes from the polarity of ZnO along the c-axis direction

2.4.1 *Ab initio Structure Determination*

Ab initio structure determination is based on the Fourier relationship between the diffraction intensity and the crystal potential for electron diffraction. In such cases, several crystallographic methods can be used to determine the atomic structure. The main advantage of using electron diffraction to determine structure is that it can be applied to nanocrystals, or 2-D membranes, or minor phases embedded in a matrix. Another advantage is that phase information can be obtained from HREM images which can help with structure determination, especially, noncentrosymmetric structures. This is important in a number of applications, for example, studying polymorphs in organic structures and determining the structure of precipitates in metals. Electrons also interact with both crystal electrons and nuclei so that electrons can see hydrogen atoms in organic molecules. This was the motivation behind the pioneering work of the Russian group led by Pinsker and Vainstein in the 1960s.[36]

The commonly used methods for solving the phase problem required for structure solutions are the direct methods[37,38] and Patterson maps.[39] Direct methods use relationships between phases such as triplets ($\theta = \phi_{\vec{h}} + \phi_{\vec{k}} + \phi_{-\vec{h}-\vec{k}} \approx 0$). The probability of $\theta \approx 0$ increases with the magnitude of the product of the normalized structure factors of the three reflections involved. Once these triplets associated with high certainty are identified based on diffraction intensities, they are used to assign new phases based on a set of known phases. Since the number of phase relationships is large the problem is over determined. Another approach is based on the Sayre equation, which is derived based on the relationship between the electron density and its square:

$$F_{\vec{h}} = \frac{\Theta}{V} \sum_{\vec{k}} F_{\vec{k}} F_{\vec{h}-\vec{k}} \tag{16}$$

where Θ is a constant and V the unit cell volume. The structure factor F is complex; thus, the relationship contains phase relationships. The Sayre equation was found useful in the limited data set situation which happens often in electron diffraction.[37]

Crucial to the success of ab initio structure determinations is the collection of 3-D diffraction data. The conventional TEM sample holders can handle limited rotation (up to ±35° e.g., in some HREM), which leaves a wedge-shaped gap in reciprocal space. Special holders used for tomography with a large rotation range can be used to address this problem. The diffraction patterns recorded at different rotations are merged to produce the 3-D data set. Special care must be taken to normalize the diffraction intensities because of the 3-D shape of the crystal and possible dynamic diffraction effects. In the absence of 3-D diffraction data set, diffraction patterns can be recorded along zone-axis orientations and reconstructed to obtain the projection maps. These maps then

can be used to build a structural model or models of the crystal. The projection maps do not give 3-D atomic bond distances.

The number of structures solved using 3-D electron diffraction data sets is relatively small because of the experimental difficulties associated with the collection of 3-D diffraction data and dynamic scattering effects on diffraction intensities. A major development toward solving these difficulties is the precession electron diffraction technique, which allows a large number of reflections to be collected in a single orientation and averages over different beam directions to minimize dynamic effects. Progress is under way; for more information see Refs. 40 and 41.

2.4.2 *Refinement of Electron Diffraction Intensities*

Once an estimate of the structure is obtained, the structure or its parameters can be refined with high accuracy using the refinement method.[18,42] The refinement method works by comparing experimental and theoretical intensities and optimizing for the best fit. During optimization, parameters in the theoretical model are adjusted in search of the minimum difference between experiment and theory. Multiple scattering effects can be taken into consideration by using dynamical theory to calculate diffraction intensities during the refinement. Previously, strong EMS had made it difficult to use the kinematical approximation for electron structure determinations in the manner of X ray and neutron diffraction. In the case of accurate structure factor measurement, electron interference from multiple scattering actually enhances the electron diffraction sensitivity to crystal potential and thickness and improves the accuracy of electron diffraction measurements.

The refinement is automated by defining a goodness of fit (GOF) parameter and using a numerical optimization routine to do the search in a computer. One useful GOF parameter for a direct comparison between experimental and theoretical intensities is χ^2

$$\chi^2 = \frac{1}{n-p-1}\sum_{i,j}\frac{1}{\sigma_{i,j}^2}(I_{i,j}{}^{\text{exp}} - cI_{i,j}{}^{\text{Model}}(a_1, a_2, \ldots, a_p))^2 \quad (17)$$

Here, $I_{i,j}^{\text{exp}}$ is the experimental intensity (in units of counts) measured from an experimentally recorded diffraction pattern, $(i,\ j)$ is the pixel coordinate of the detector, and n is the total number of points. $I_{i,j}^{\text{Model}}$ is the model intensity calculated with parameters a_1 to a_p and c is the normalization coefficient. χ^2 is best used when the differences between theory and experiment are normally distributed and when the variance σ is correctly estimated. The optimum χ^2 has a value close to unity.

To model diffraction intensities, both the detector response and background intensity from thermal diffuse scattering must be included. A general expression for the model intensity including both factors is

$$I_{i,j}^{\text{Model}} = I^{\text{Theory}}(i,\ j) \otimes H'(i,\ j) + B(i,\ j) \quad (18)$$

Here, the theoretical intensity I^{Theory} is convoluted with the detector response function H′ plus the background B. The detector response is a combination of the pixellated detector and the electron detector response function. The background intensity B, in general, is slowly varying, which can be modeled using a slowly varying function.

The structural parameters are the atomic positions, Debye–Waller factors, electron structure factors, and electron diffraction parameters, which include the absorption potential, sample thickness, and crystal orientation. Not all parameters can be refined together. Diffraction patterns that are sensitive to certain parameters are collected and they are often refined independently. Figure 9 shows an example of a structure factor measurement by fitting CBED intensities recorded in the systematic orientation where one row of reflections are set at or near the Bragg conditions. Details about this method and its applications for structure factor measurement and atomic structure refinement are given in Ref. 18 and 43.

2.4.3 *Radial Distribution Function Analysis*

Electron diffraction patterns of amorphous and nanocrystalline materials are analyzed to measure the radial distribution function (RDF) to provide interatomic distances and their distribution. The principle of RDF analysis using electron diffraction is similar to X ray diffraction with the

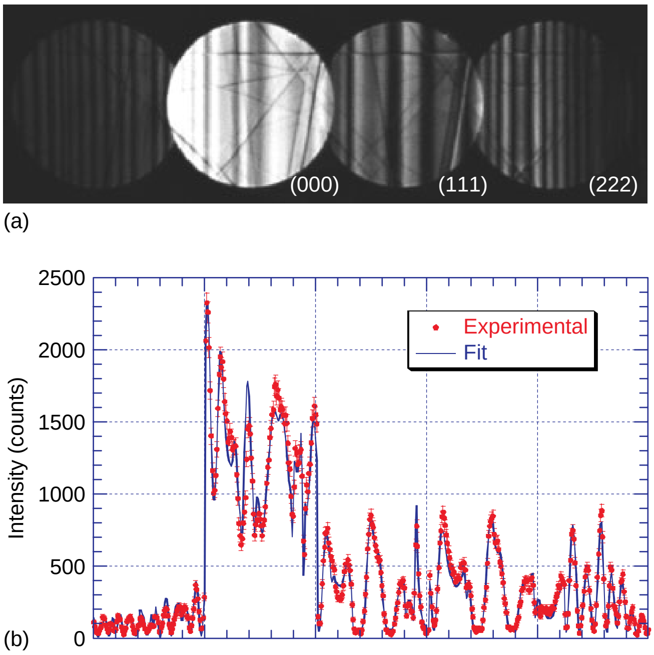

Figure 9 An example of the best fit obtained from an electron structure factor refinement. The experimental intensities are from a few selected line scans across the experimental pattern shown in (a). The fit was obtained using Si(111) and (222) structure factors as adjustable parameters together with parameters describing the electron diffraction geometry

exception of experimental procedures and the difference that electrons are scattered by strong Coulomb potentials.[44,45] The RDF gives the distance correlation between a pair of atoms. Following Warren,[46] the RDF is calculated by

$$rG(r) = 4\pi r^2[\rho(r) - \rho_o] = \frac{2r}{\pi}\int_0^{\infty} S\left[\frac{I(S)}{Nf^2} - 1\right]\sin rS\mathrm{d}S \qquad (19)$$

where $\rho(r)$ is the reduced density, which corresponds to the number of atoms per unit volume at a distance r from the reference atom, and $4\pi r^2\rho(r)\mathrm{d}r$ is the number of atoms contained in a spherical shell of radius r and thickness dr. Other quantities involved in equation (1) are ρ_o, which is the average density of atoms in the sample, $S = 4\pi\sin\theta/\lambda$, $I(S)$ the recorded electron diffraction intensity minus the inelastic background, N the normalization factor. The $\langle f\rangle$ is the averaged atomic scattering factor with $\langle f\rangle = \sum_i c_i K_i f$, the assumption made is that the atomic scattering is proportional to their atomic number. The f is determined from $\langle f^2\rangle = \sum_i c_i f_i^2 = \sum_i c_i K_i^2 f^2$ and $f_i = \sum_i c_i \int_0^{\infty} 4\pi r^2 V_i(r)(\sin Sr/Sr)\mathrm{d}r$ where V is the atomic potential and c the concentration. The RDF analysis can provide a general description of the degrees of order, the distribution of correlation distances, and the average nearest-neighbor coordination numbers. Orientation ordering or local geometrical packing of atoms cannot be retrieved from the one-dimensional RDF analysis, and we need to resort to other techniques like fluctuation microscopy.[47] The advantage of electron diffraction for RDF analysis is that it can be applied to thin films and small volumes because of the large electron elastic cross sections. For the same reason, electron diffraction must be limited to very thin films to avoid multiple scattering.

2.5 Experimental Procedures

The experimental procedures for electron diffractions involve: (i) the preparation of samples suitable for electron beam observation, (ii) selection of the instrument and the diffraction technique best suited for the sample, (iii) collection of diffraction data, and (iv) interpretation of diffraction patterns and data analysis. The sample must be compatible with the vacuum environment of the microscope or diffraction camera. In situ experiments are carried out using special holders for cooling, heating and cryogenic or environmental transfer. Special microscopes are also available to provide the gaseous or ultrahigh vacuum environment for investigating structures under gas or pressure environment or preparing samples in situ.

The samples used for RHEED and LEED are single crystals with carefully prepared flat surfaces. For THEED of thin films, the observed areas of the samples must be electron transparent with thickness less than or comparable to the inelastic mean free path of electrons. The inelastic mean free path increases with the electron voltage. The typical sample thickness ranges from tens to hundreds of nanometers for electrons of hundreds of kilo volts.

The preparation of samples is critical to the success of electron diffraction and its quantification. The same sample preparation techniques used for TEM are used for electron diffraction. The sample preparation techniques separate into two categories: (i) bulk-based and (ii) powder-based techniques. The bulk-based techniques involve mechanical cutting, thinning/polishing, and perforation. An ion beam is typically used in the last step of perforation to create a thin area around the edge of a hole for electron beam observation. Mechanical thinning and polishing are sometimes done with a wedge angle with the help of a tripod. The thin region around the edge only requires a brief ion beam bombardment to make it electron transparent. The powder-based techniques use dispersion of powders on thin supporting films placed on metal grids specially made for TEM observations. For micron or larger sized powders, additional grinding is done to produce smaller particles. The observation is performed on the edge of the powders. Typically used supporting films are continuous amorphous carbon films, holey carbon films, networked carbon fibers (lacey carbon), amorphous silicon nitride, and SiO_x. For amorphous carbon films, an ultrathin version is available which is useful for observing nanoparticles. Biological molecules are prepared by dispersing them with water onto holey carbon films then quenched into liquid methane to freeze the molecules together with water, which is then transferred to the electron microscope using a cryogenic transfer holder. The carbon film is treated by exposing it to a plasma which makes the film hydrophilic. Special instruments that help with the rapid freezing process are available from commercial suppliers. For organic molecules, some useful crystallization techniques for TEM are described in the book by Dorset.[37]

Instruments suitable for electron diffraction should have the sample rotation range that is required, the probe-forming capability for CBED or NED if needed, and a suitable detector such as a CCD camera or imaging plate. For quantification of electron diffraction intensities, an imaging electron energy filter is best to remove the inelastic scattering background. The different diffraction modes described in Section 2.1 can be achieved through a three condenser lens setup. There are two types of energy filters that are currently employed. One is the in-column Ω-energy filter[48] and the other is the post-column Gatan Imaging Filter (GIF).[49] Each has its own advantages. The in-column Ω-filter takes full advantage of the post-specimen lens of the electron microscope and can be used in combination with detectors such as film or IPs, in addition to the CCD camera. For electron diffraction, geometric distortion, isochromaticity, and angular acceptance are the important characteristics of filters.[48] Geometrical distortion complicates the comparison between experiment and theory and is best corrected by experiment. Isochromaticity defines the range of electron energies for each detector position. Ideally, this should be the same across the

whole detector area. Angular acceptance defines the maximum range of diffraction angles that can be recorded on the detector without a significant loss of isochromaticity.

Another consideration is the choice of electron sources. The field emission electron guns provide better lateral coherence, smaller probes, and higher brightness in general than the thermionic source; they are more suitable for CBED and NED.

Electron diffraction data collection involves the required microscope optical alignment and special attention to the sample position, sample thickness and rotation, diffraction CL and diffraction lens focusing, and the detector used to record electron diffraction patterns. The CL is determined by the projection lenses in combination with the objective lens (the first lens after the specimen). To use the calibrated CL, the sample position and the objective lens setting must be the same setting between the calibration and experiment.

Current 2-D electron detectors include CCD cameras and IPs. The performance of the CCD camera and IP for electron recording has been measured.[50] Both are linear with large dynamic range. At low-dose range, the CCD camera is limited by the readout noise and dark current of CCD. The readout noise places a limit on what information can be recovered from recorded images if the CCD camera has a limited resolution. IP has a better performance at low-dose range due to the low dark current and readout noise of photomultiplier. For medium and high dose, the IP is limited by a linear noise due to the granular variation in the phosphor and instability in the readout system. The CCD camera is limited by the linear noise in the gain image, which can be made very small using averaging. There is an uncertainty in the uniformity of a CCD because its dependence on the gain image as prepared in the electron microscope. The performance of CCD also varies from one to another, which makes the individual characterization necessary.

The noise in the experimental data can be estimated using the measured detector quantum efficiency (DQE)

$$\mathrm{var}(I) = mgI/DQE(I) \quad (20)$$

Here I is the estimated experimental intensity, var denotes the variance, m is the mixing factor defined by the point spread function and g is the gain of the detector.[50] This expression allows an estimation of variance in experimental intensity once DQE is known, which is especially useful in the χ^2-fitting, where the variance is used as the weight. For the characterization of electron detectors, see Ref. 50.

3 APPLICATIONS

The main applications of electron diffraction are structure characterizations of inorganic and organic materials. Electron diffraction is also used for structure characterization of 2-D biological membranes.[51] The examples given here are limited to inorganic crystals. For electron diffraction study of organic molecules, see examples in Dorset's book.[37] The examples are used to demonstrate the materials problems that can be addressed by electron diffraction and the procedures involved in the analysis.

3.1 Phase Identification—CuO Nanowires

One of the common applications of HEED is phase identification. Figure 10 shows an example. The sample is copper oxide nanowires formed by heating a TEM Cu grid in air at temperatures ∼400 °C.[52] The wires are a few tens of nanometers wide (Figure 10a). To identify the structure of the nanowires, electron diffraction patterns were recorded on IPs in the SAED mode with a selected area of a few microns. The electron energy used is 200 kV and the diffraction pattern was recorded at the CL of 100 cm. The size of IPs is 94 × 75 mm. The largest diffraction angle recorded is about $s = \sin\theta/\lambda = 0.71$ Å^{-1}. The diffraction pattern shows incomplete powder rings because of the preferred wire orientations that are seen in the electron image. To index the diffraction pattern, the diffraction intensities were projected onto a one-dimensional radial profile; this was achieved by first locating the center of the diffraction pattern using the powder rings and then averaging the intensity around the circle. The diffraction pattern radius was then converted into $s = \sin\theta/\lambda$ using equation (3). A search in the powder diffraction data base showed that all diffraction peaks can be indexed based on the monoclinic CuO structure with $a = 4.6927$, $b = 3.4283$, $c = 5.1370$ and $\beta = 99.546°$. The indices of the first few peaks are shown in Figure 10(c). Low-order Cu_2O reflections are absent in the diffraction pattern suggesting that the sample consists entirely of a single phase, CuO.

3.2 Crystal Orientation and Microstructure—the Structure of a CuO Nanowire

Electron diffraction can be used to identify the crystal orientation and orientation relationships between different crystals. In the case of the CuO nanowires discussed in the previous section, NED was used to characterize the structure of individual CuO nanowires. Diffraction patterns were recorded using a probe of 100 nm in diameter. The probe was placed on an isolated single wire (an image of the wire and probe is shown in Figure 11) for diffraction. The diffraction pattern shown consists of two set of diffraction spots; one belongs to the [101] zone axis and the other is from the [15−6] zone (Figure 11). The pattern was indexed using the length of g calculated based on the calibrated CL and the angle; both are measured directly from the experimental pattern. For the diffraction spots belonging to [101], the two shortest g-vectors have almost identical length (the experimental ratio is 1.017) and an angle of 83.8° between the two. The length

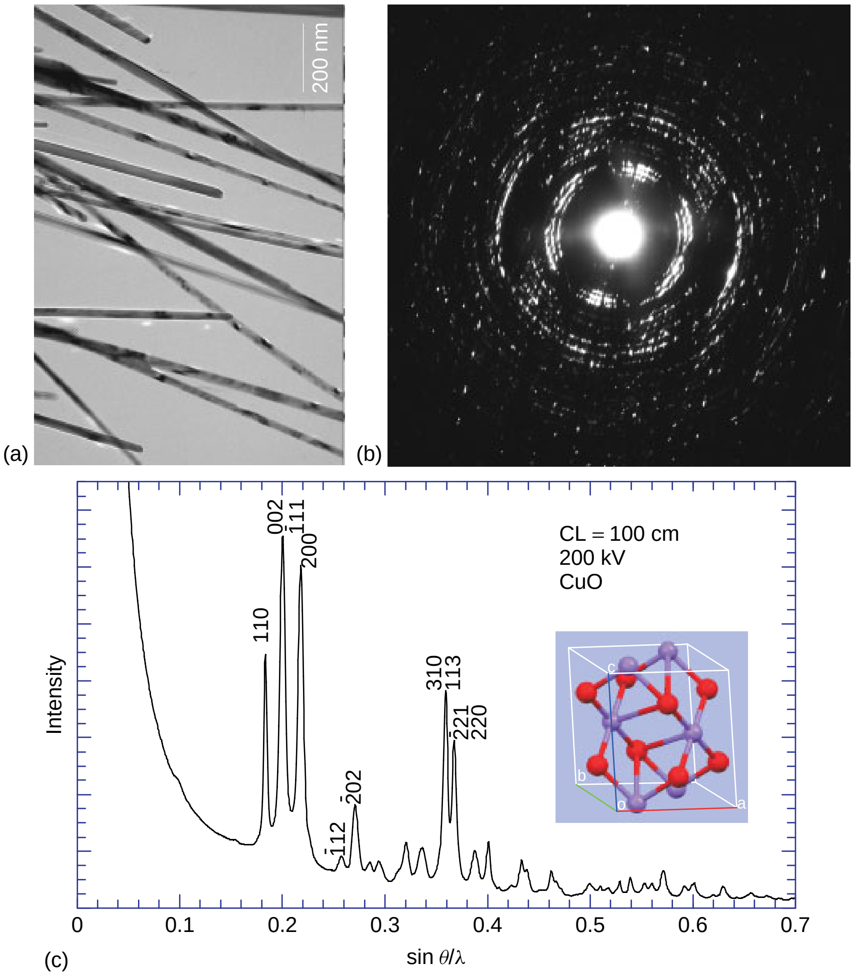

Figure 10 Phase identification of CuO nanowires. (a) An electron image of the wires, (b) the recorded diffraction pattern, (c) the diffraction intensity plotted as a function of sin θ/λ and indexing diffraction peaks based on CuO monoclinic structure

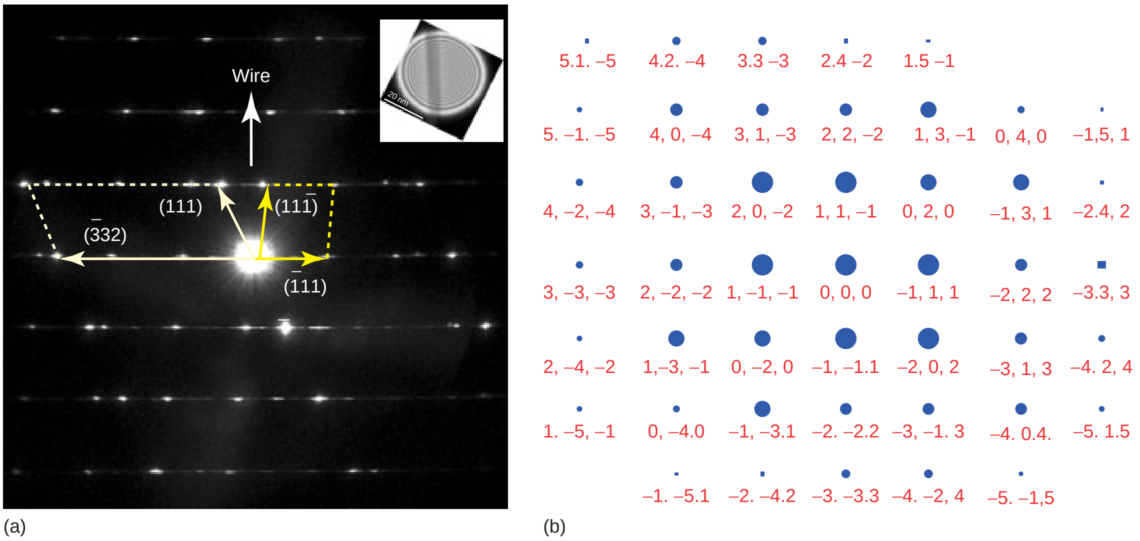

Figure 11 Electron diffraction pattern recorded from a single CuO nanowire and its indexing

of 0.394 1 Å^{-1} was obtained using the calibrated CL, which is very close to that of (−111) or (11−1) reflections. The calculated angle between (−111) or (11 − 1) is 85.03°, which is 1.2° higher than the experimental value. (The measurement accuracy is better than 1°.) The indexing is confirmed by simulation (see Figure 11b) using the WebEMAPS software (see the reference materials section for details). The diffraction pattern shows that the wire is twinned. The twin interface is parallel to the wire which can be seen in the electron image. The relationship between the two crystals is [101]||[15−6] and (−111)‖(−332).

3.3 Structure Characterization of Supported Nanoclusters and Epitaxy

The combination of electron imaging and electron diffraction is very useful for characterization of supported nanoclusters, or nanoparticles, and their orientation relationships with the substrate. The particles can be observed either in plane view or in cross section. The plane-view geometry is most suited for electron diffraction over many particles. The two examples shown in Figure 12 are from Ag nanoparticles supported on hydrogen-terminated Si(100) surfaces as deposited and after annealing.[53–55] The samples were prepared by first thinning the Si substrate followed by surface treatment and Ag deposition using an e-beam evaporation source.[55] The electron microscopy observation was performed using a JEOL2010F electron microscope at 200 kV. The diffraction patterns were taken at an orientation off the [001] zone axis to avoid strong multiple scattering in a zone-axis orientation. The diffraction pattern of the as-deposited sample consists of a strong and continuous Ag(111) ring, short Ag(200) arcs on a weak Ag(200) ring, short Ag(220) arcs on a weak Ag(220) ring and weak (311) rings. Upon annealing at 400 °C, Ag(020) and (200) reflection intensities increase significantly. Both have diffuse streaks along (110) and (1−10) directions. The Ag(020) and (200) are asymmetrical because of the off-zone axis orientation of the diffraction pattern. Meanwhile, the diffraction intensity in the continuous ring decreases significantly, but remains visible. Figure 12 shows high-resolution images of Ag clusters on H−Si(001). These images were taken at the Si[001] zone axis. At this orientation, the Si(220) and (2−20) planes are imaged. Most as-grown Ag clusters show no visible Moiré fringes, which is consistent with the diffraction pattern that is dominated by (111) ring. A few clusters with Moiré fringes are often defective. The clusters of dark contrast with no Moire fringes contribute to the strong (111) rings in the diffraction pattern. At first sight, orientation of these clusters appears to be random. However, a close inspection of the diffraction pattern shows a much weaker (200) ring than what it would be in a powder diffraction pattern of random polycrystalline Ag. For single crystals oriented with Ag[111]||Si[001] or Ag[001]||Si[001], strong Ag(220) is expected in both cases, while a strong Ag(200) is also expected in the case of Ag[001]||Si[001]. Both of these cases can be ruled out. In Figure 12(c), the Ag clusters show 2-D Moiré fringes (from interference between Ag and Si lattices[54]) perfectly parallel to Si(220) lattice planes. The corresponding electron diffraction pattern shows single crystal dominant diffraction of Ag[001] with Ag(220)||Si(220). At this stage, the transformation from random cluster orientation to epitaxial islands is not over, because we still see weak (111) diffraction rings from randomly oriented Ag clusters. The Ag(200) reflections have the shape of a plus-sign, centered at the Ag(200) position, which comes from the rectangular shapes of the epitaxial Ag islands. The edges of islands are along the Si(110) and (1−10) directions.

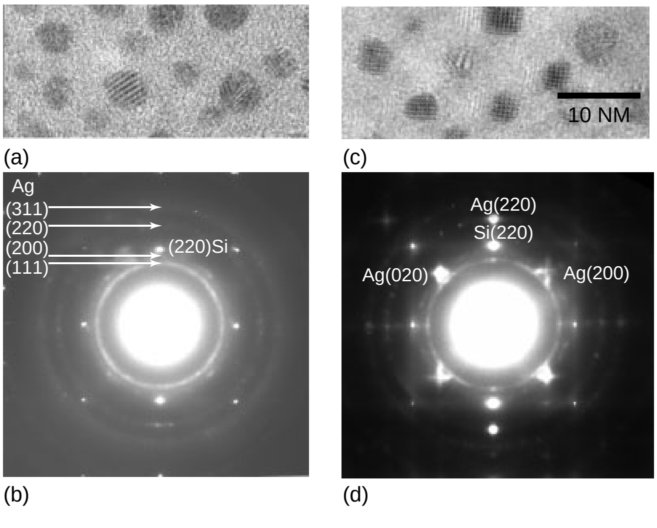

Figure 12 Combined electron diffraction and imaging characterization of supported Ag nanoclusters/nanocrystals on Si(100) substrate. (a) and (b) show randomly oriented nanoclusters. (c) and (d) show epitaxial nanocrystals after annealing

3.4 The Structure of Nanocrystalline Films—the Case of AgCu

For materials with nanocrystalline structure, RDF analysis is a powerful tool for structural analysis. The advantage of electron diffraction compared (DC) to X-ray/neutron diffraction is that it can be applied to technologically important thin films. The drawback is that electron diffraction averages overall atoms in the sample and consequently it cannot be used to study composition dependent local structures that is obtainable with extended X-ray absorption fine structures (EXAFS) (*see* ***X-Ray Absorption Spectroscopy***). The example shown in Figure 13 is a study of the structure of co-sputtered $Ag_{0.5}Cu_{0.5}$ films and its temperature-driven evolution. The eutectic Ag−Cu system is one of the glass-forming binary alloy systems with a positive heat of mixing in both solid and liquid states. Solid solution, amorphous or nanocrystalline, Ag−Cu alloys can be prepared by vacuum evaporation.[56–59] However, the solid solution of Ag and Cu alloy is unstable

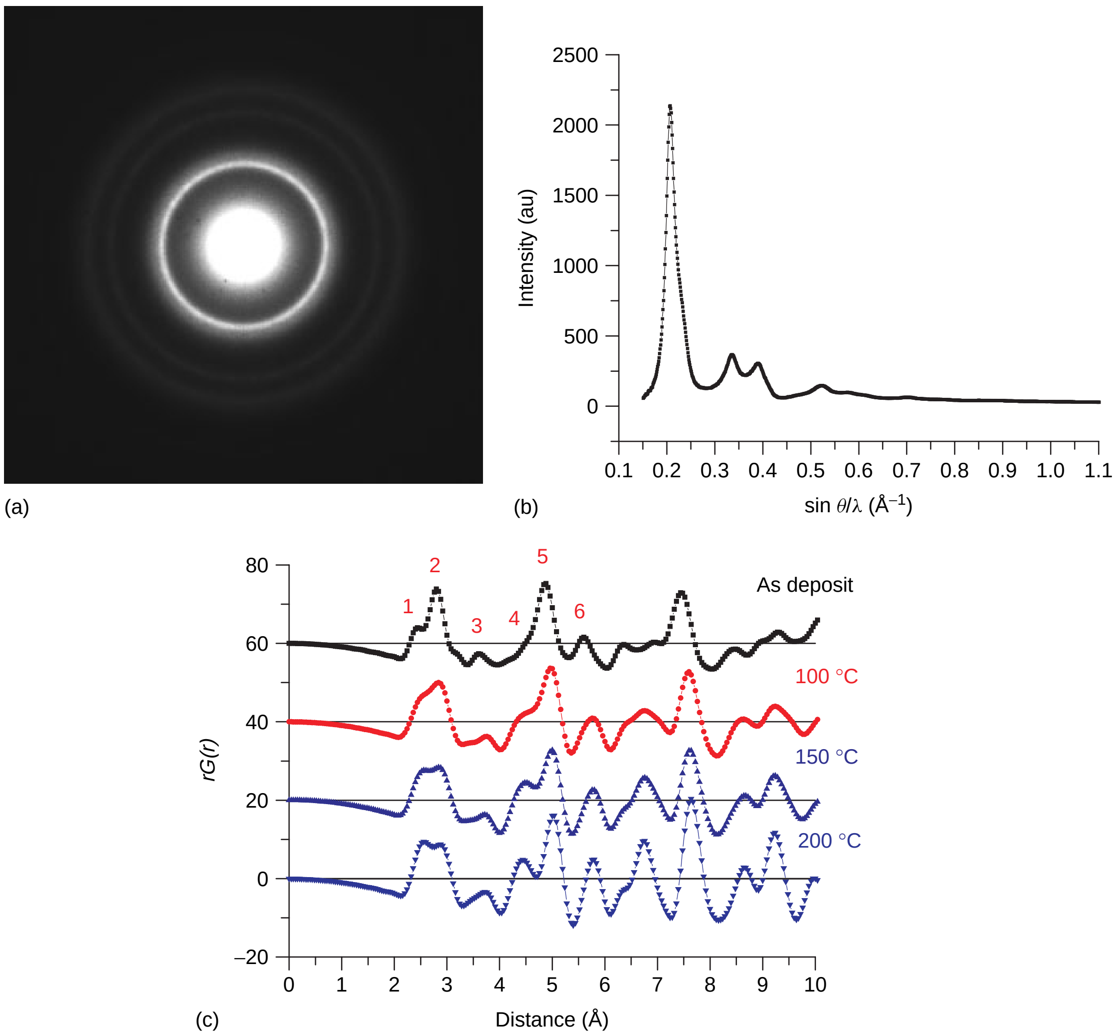

Figure 13 (a) An example of recorded electron diffraction pattern of as-deposited 28 Å $Ag_{50}Cu_{50}$ thin film sample. (b) The radial intensity profile of (a) obtained by averaging over the angle. (c) Radial distribution function (RDF) in the form of *rG(r)* obtained from the experimental diffraction patterns of $Ag_{50}Cu_{50}$28 Å samples at different annealing temperatures

since there is no barrier against decomposition. At higher cooling temperatures or upon reheating, Ag and Cu phase separate, or evolve, into crystalline structure from the initial amorphous or nanocrystalline state.[59] The Ag–Cu thin films (28 Å thick) studied in Figure 13 were deposited in a high-vacuum (HV) DC magnetron sputter deposition system by co-sputtering of high purity Ag and Cu targets onto amorphous carbon films at room temperature (RT). Quantitative structure analysis was carried out using the NED mode in the JEOL 2010F electron microscope with a highly parallel illumination of a submicron probe. Electron diffraction patterns were recorded from the samples at different annealing temperatures using image plates. The amorphous carbon background from the supported film was subtracted off using the diffraction intensity profiles recorded from amorphous carbon film alone. The diffraction intensity was used to investigate the structure and for RDF analysis.

The diffraction of as-deposited films gives diffuse ring patterns with a strong first peak at $\sin\theta/\lambda = 0.213$ Å^{-1} and a small shoulder at $\sin\theta/\lambda = 0.238$ Å^{-1}, which indicates a good mixing of Ag and Cu atoms in the alloy thin films (Figure 13). The peak position is closer to that of Ag ($\sin\theta/\lambda = 0.212$ Å^{-1}) than to Cu ($\sin\theta/\lambda = 0.240$ Å^{-1}). As the sample is annealed to higher temperatures, the intensity of the Cu peak increases and it forms two distinct peaks at $T = 200\,°C$ with peak positions at $\sin\theta/\lambda = 0.212$ and 0.240 Å^{-1}, which is an indication of Cu–Ag phase separation. A comparison of the RDF of the $Ag_{50}Cu_{50}$ film at different annealing temperatures is shown in Figure 13(c). The RDF of the as-deposited $Ag_{50}Cu_{50}$ sample is in good agreement with that obtained by Wagner *et al.* using X-ray diffraction,[58] except the Cu peak is slightly more pronounced in our case. From the RDF plot, two separated nearest-neighbor peaks can be seen. The second peak corresponds to Ag–Ag distance,

which shifts from 2.80 to 2.88 Å from the as-deposited sample to the sample annealed at 200 °C. The distance of 2.88 Å fits with the first nearest-neighbor peak of Ag crystal (2.875 Å) very well. At 200 °C, the first peak is situated at Cu–Cu atomic distance of 2.56 Å, which fit into the position of the first nearest-neighbor peak of Cu particles (2.55 Å) very well. Interestingly, for the as-deposited sample, the Cu–Cu peak is at 2.45 Å and is lower than the bulk Cu–Cu distance. A lower distance is expected for Ag with the doping of a smaller Cu atom, but not for Cu, for which we expected a large distance due to Ag doping. The reduced distance suggests that Cu is under compressive strain. The fourth and fifth peaks of RDF show splitting (Cu peak growing from Cu shoulder in Ag peak) and shifting during the annealing process, and this phase separation is due to Cu diffusing out of the Ag matrix. A detailed list of the position of the first 6 peaks in these RDF results is shown in Table 1. The peaks 1, 3 and 4 belong to Cu while 2, 5 and 6 belong to Ag. The ratio between the distances of peaks 5 and 2 is 1.74, which is close to $\sqrt{3}$ and the ratio between 6 and 2 is 2. The ratio of $\sqrt{3}$ comes from the third nearest neighbor, while 2 is from the fourth. Both are in agreement with a face-centered cubic cell. In the liquid, this ratio of 5 and 2 is 1.86 for close-packed liquid.[58] The ratios are temperature dependent. The ratio between peak 4 and 1 varies from 1.77 at 150 °C to 1.73 at 200 °C, while the ratio between peak 5 and 2 first increases to 1.76 with annealing temperature and then drops slightly to 1.75 at 200 °C. The same trend occurs for the ratio between peak 6 and 2. Thus, the early stage of phase separation appears to be associated with an initial increase in strain.

The experimental procedures used for RDF analysis are as follows. The electron diffraction patterns were recorded digitally using IPs. The CL of 600 mm was used to include $s = \sin\theta/\lambda$ up to 1.27 for rotation averaging. The recorded electron diffraction had a strong central peak that includes small angle inelastic scattering and the profile of the electron beam. This central peak was modeled by a pseudo-Voigt function and subtracted. The normalization coefficient, N, was found by fitting to large-angle scattering using the atomic scattering factors. Finally, the RDF was obtained by direct integration of equation (19).

Table 1 Peak positions in the radial distribution function of $Ag_{50}Cu_{50}$ as a function of the annealing temperature measured by electron diffraction (see Figure 13)

	Position of peaks in the radial distribution function (Å)					
	1	2	3	4	5	6
As-deposit	2.44	2.80	3.60	[a]	4.88	5.60
100 °C	[a]	2.84	3.76	4.56	4.96	5.76
150 °C	2.56	2.84	3.72	4.52	5.00	5.80
200 °C	2.56	2.88	3.72	4.44	5.04	5.80

[a]These peaks appear as a shoulder, whose position is difficult to measure.

The size of the nanocrystalline grains can be measured by taking the distance at which oscillation decreases to the noise level in the RDF spectrum. Using this, the size for the as-deposited film is estimated to be about 30 Å. Upon annealing, the strength of the first and fourth peaks increases which is a strong indication of the growth of a Cu-rich phase. The peak 2 decreases, which is associated with the decrease of nearest neighbors at that distance. This evidence can be taken as an indication of Cu separated out from the solutions. Substantial growth in overall crystal size is observed at 200 °C in the RDF.

3.5 In Situ Study of Phase Transformation—Charge Ordering in $La_{0.50}Ca_{0.50}MnO_3$

The doped manganite of $La_{0.50}Ca_{0.50}MnO_3$ (LCMO) undergoes a commensurate-incommensurate-commensurate phase transformation at low temperatures.[60,61] The LCMO belongs to a family of doped manganites $A_{1-x}B_xMnO_3$, where A-site atoms could be La, Pr, Nd, Bi, Sm, while B-site atoms are Ca, Sr, Ba, Pb. These materials have attracted considerable attention because of their interesting properties.[61] At high temperatures, the doped manganites have an ideal perovskite structure consisting of corner-shared MnO_6 octahedra. The A-site atoms fill in the holes of the MnO_6 octahedral network. At intermediate temperatures, the structure is distorted with an orthorhombic lattice (space group *Pnma*). The cell consists of $a_o \approx c_o \approx b_o/\sqrt{2} \approx \sqrt{2}a_c$, where a_c is the high-temperature cubic cell. In the case of LCMO, the commensurate-incommensurate-commensurate phase transformation is observed below 240 K. The transition is accompanied by a change in the transport property from conducting to insulating during cooling. The change in the transport property is believed to be caused by ordering of Mn^{4+} and Mn^{3+} ions, which is 50–50 LCMO. The nature of the charge ordering (CO) and its formation process has been a subject of considerable interest and debate.[62,63]

It is difficult to grow single crystals of LCMO and other compositions of this series except $LaMnO_3$. Electron diffraction (ED), because of its small probe size, can be used to study the phase transition within a single crystal grain. Figure 14 shows a single crystal ED pattern obtained from a polycrystalline grain of charge-ordered LCMO at the low temperature of 98 K recorded along the [010] zone axis. At the $x = 0.5$ Ca doping level, $La_{1-x}Ca_xMnO_3$ has an equal amount of Mn^{3+} and Mn^{4+} ions; the CO superlattice has a unit cell with $a_{co} = 2a_o$, where a_o is the orthorhombic cell constant at RT. Thus, the CO superlattice reflections (SRs) can be indexed as (h + 1/2, 0, l) in the units of the reciprocal lattice of the RT orthorhombic cell. In Figure 14, a pair of CO SRs around the $(00\bar{2})$ reflection are pointed out by arrows; they can be treated as the satellite reflections ($\pm q, q = 1/2$) of the fundamental reflection. The q is nearly commensurate ($q = 1/2$) at $T = 98$ K. As the temperature increases, q becomes incommensurate ($q = 1/2 - \varepsilon$) by moving toward

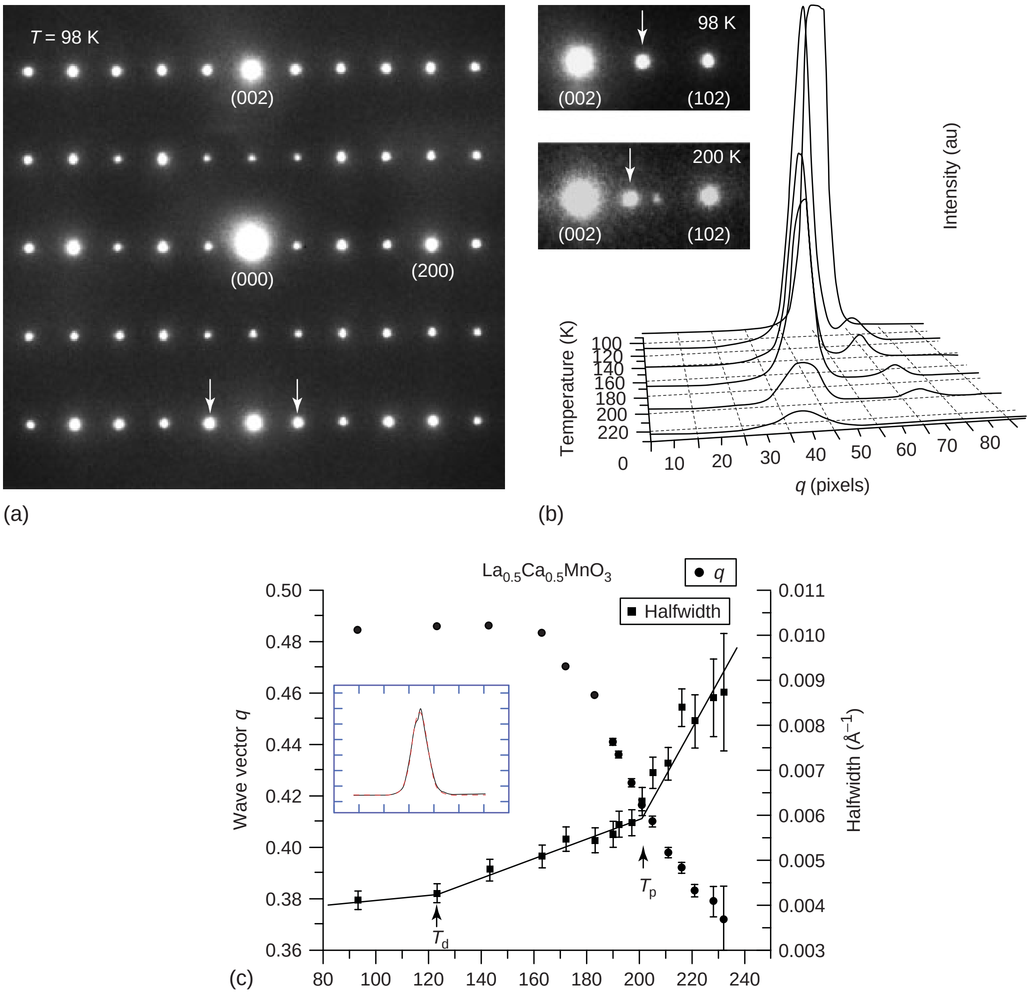

Figure 14 (a) An electron diffraction pattern obtained at 98 K in $La_{0.5}Ca_{0.5}MnO_3$ shows the CO ($h + 1/2$, 0, l) superreflections (CO SRs; indicated by arrows) at [010] zone axis. The profiles of the CO SRs between (002) and (102) reflections are plotted as a function of temperature in (b). The insets in (b) are the electron diffraction patterns at 98 and 200 K showing the movement of the CO SR superreflection. (c) Wave vector q (circles) and the Gaussian half width (squares) measured from the CO SRs in ED patterns are shown as a function of temperature. The half width was calculated by fitting the CO SRs in electron diffraction patterns using Gaussian functions (the fitting is shown in the inset). The half-width plot shows three linear relationships with the transition temperatures $T_o \sim 120$ K and $T_p \sim 200$ K

the fundamental reflections. The insets of Figure 14(b) are examples of the ED patterns at two different temperatures (98 and 200 K), showing the movement of CO SRs between the (002) and (102) reflections. The +q satellite reflection of (002) coincides with the $-q$ satellite SR of (102) at 98 K. The two SRs separate at $T = 200$ K. During the warming process, the SRs also become broadened and the intensities of the SRs change with temperature as well. Both can be seen from the intensity profile crossing the SR from the (002) to (102) reflections (see Figure 14b) as a function of the temperature.

To show the temperature dependence of the wave vector q and to characterize the CO structure, the position of q and the Gaussian half width (GHW) of the CO SRs were measured from the in situ recorded ED patterns during the warming process for LCMO. This is plotted in Figure 14(c). The GHW of the CO SRs was obtained by numerically fitting the intensity profile of the SRs[4] (an example is shown in the inset of Figure 14c). During warming, the wave vector q of the SR initially remains constant and then gradually decreases starting from ~160 K until the SR becomes difficult to measure at $T^* > \sim 230$ K. The change in the CO SR position (q) is contunous. In the same figure, the GHW plot has different features compared to q. Since the GHW is the inverse of real-space CO domain size, the different slopes in the GHW versus T plot indicate that the CO superstructure melts in stages: the GHW maintains the low value from low temperatures to $T_d \sim 120$ K; the GHW value starts to increase at a linear rate from T_d to $T_p \sim 200$ K; above T_p, the GHW increases at a higher rate until the SR disappears.

The GHW of the CO SR, measured from the ED patterns, reflects the coherent length of the CO superstructure.

Information obtained from the ED patterns about the CO phase transformation in LCMO is as follows. Commensurate CO exists at $T < T_d$ and becomes incommensurate by the appearance of CO defects above T_d during the warming process. The appearance of CO defects results in a melting of CO at a slow rate for $T_d < T < T_p$. Previously, synchrotron X ray and neutron powder diffraction (*see* ***Neutron Diffraction***) found that the lattice parameters change between T_d and T^*. There is hysteresis in the lattice parameters, the electrical transport property and the magnetism at $T_d < T < T_p$ in LCMO.[60,63] The appearance of CO defects can be considered as a first-order transition locally. Thus the pronounced hysteresis observed in the change of lattice parameters and resistivity in LCMO is strongly correlated with the generation and disappearance of CO defects between $T_d < T < T_p$. The change of CO from long-range order to short-range order has a significant influence on the transport property, for example, the resistivity has a steep drop at T_p.[5] At temperatures $T > T_p$, the CO superstructure, initially uniformly distributed in the entire single crystal domain, separates into isolated CO domains of the diameters of tens of nanometers (measured from the GHW). This percolation temperature T_p (transition from continuous to separate CO domains) of the CO phase transformation, was first found in the charge-ordered $La_{0.33}Ca_{0.67}MnO_3$,[63,64] which also has commensurate CO SRs at low temperatures. In this temperature range, the broadening of the GHW in Figure 14(c) comes mainly from the reducing size of the CO domains during the CO melting. At $T > T^*$ the CO superstructure completely melts away and the material reverts back to the RT paramagnetic phase. At this stage (RT), there is no visible CO SR in the recorded ED patterns.

3.6 Symmetry Determination—the Glide and Structural Models in $La_{0.33}Ca_{0.67}MnO_3$

The doped $La_{0.33}Ca_{0.67}MnO_3$ undergoes a similar commensurate-incommensurate-commensurate phase transformation as that of LCMO, but with a ratio of 1 Mn^{3+} to 2 Mn^{4+}.[62,63] The low-temperature commensurate structure is tripled along the a axis. Two different structural models have been proposed for this structure. One is the ‘‘Wigner-crystal’’ model proposed from the X ray and neutron powder diffraction study by Radaelli *et al.*[63] and the other is the ‘‘bi-stripe’’ model of Mori *et al.*[62] based on the high-resolution TEM images of the CO phase (Figure 15b). The two models are different in the crystal symmetry.[65] The space group of the ‘‘Wigner-crystal’’ model is *Pnma*, while the space group of the ‘‘Bi-stripe’’ model is *Pm*. The *Pnma* space group has an n-glide plane normal to the a axis and an a-glide plane normal to the c axis. The presence of the glide symmetry can be determined using G-M lines in CBED (see Section 2).

Figure 15(a) and (c) show the experimental CBED pattern from a single crystal domain in $La_{0.33}Ca_{0.67}MnO_3$ recorded at ~99 K and along the [010] zone axis. The indexing is based on the low-temperature structure at 99 K with a unit cell of $a \sim 1.6187$ nm, $b \sim 0.7499$ nm and $c \sim 0.5408$ nm.[63] The experimental CBED patterns were energy filtered via a GIF system. The thick sample required for CBED generates a certain amount of inelastic scattering and causes blurs in the experimental CBED patterns. A large portion of inelastic scattering has an energy loss of 10 eV or higher, which can be removed using the energy filter. Two types of extinction are observed. The dark lines crossing the four (303) type reflections are clearly visible; they are consistent with the n-glide of the *Pnma* space group. Figure 15(c) shows the line extinction across a series of odd-indexed reflections along the reciprocal $\vec{a}^*$ direction (the (3, 0, 0), (7, 0, 0), (9, 0, 0), (11, 0, 0), (13, 0, 0) and (15, 0, 0) reflections). The reflection (100) is overwhelmed by the direct beam (000) and the reflection (500) is too weak to identify its contrast. Among the reflections with the G–M lines, (700), (1100) and (1300) are from the low-temperature structure. Thus, the experimental CBED patterns clearly show that both the low-temperature modulated structure and the average structure in $La_{0.33}Ca_{0.67}MnO_3$ have a glide plane perpendicular to the c axis with the glide direction along the a axis of the crystal lattice and the n-glide normal to the b axis.

The symmetries revealed by the experimental CBED patterns are possessed by the structures described by the ‘‘Wigner-crystal’’ model but not by the ‘‘Bi-stripe’’ model. The ‘‘Wigner-crystal’’ model gives the CO structure a space group *Pnma* with a glide plane perpendicular to the c axis, while the ‘‘Bi-stripe’’ model does not have the glide plane symmetry (the space group is *Pm*). Therefore, the experimental CBED patterns with G–M lines can be considered as strong evidence against the structure described by the ‘‘Bi-stripe’’ model.

To verify the symmetry and identify the sensitivity of CBED to CO symmetry, dynamic simulations using the Bloch wave method were examined to see the difference between the two models. The atomic positions within the unit cells for the two models from Radaelli *et al.* are very close to each other.[63] To avoid the possible pseudo-symmetry generated in the ‘‘Bi-stripe’’ model, dynamic simulations from the CO structures described by the ‘‘Wigner-crystal’’ model and ‘‘Bi-stripe’’ model are calculated and compared for the thickness of 300 nm in Figure 15(d) and (e). The difference between the two simulations is that the G–M lines exist in four (303) reflections and $(2n + 1, 0, 0)$ reflections simulated by the ‘‘Wigner-crystal’’ model, as they are in the experimental CBED patterns, but do not show up in four (303) reflections simulated by the ‘‘Bi-stripe’’ model.

3.7 Polarity Determination

CBED can be used to determine the polarity of crystals without a center of symmetry. It can also be used for accurate determination of thickness. The principle of polarity determination is based on the difference between the

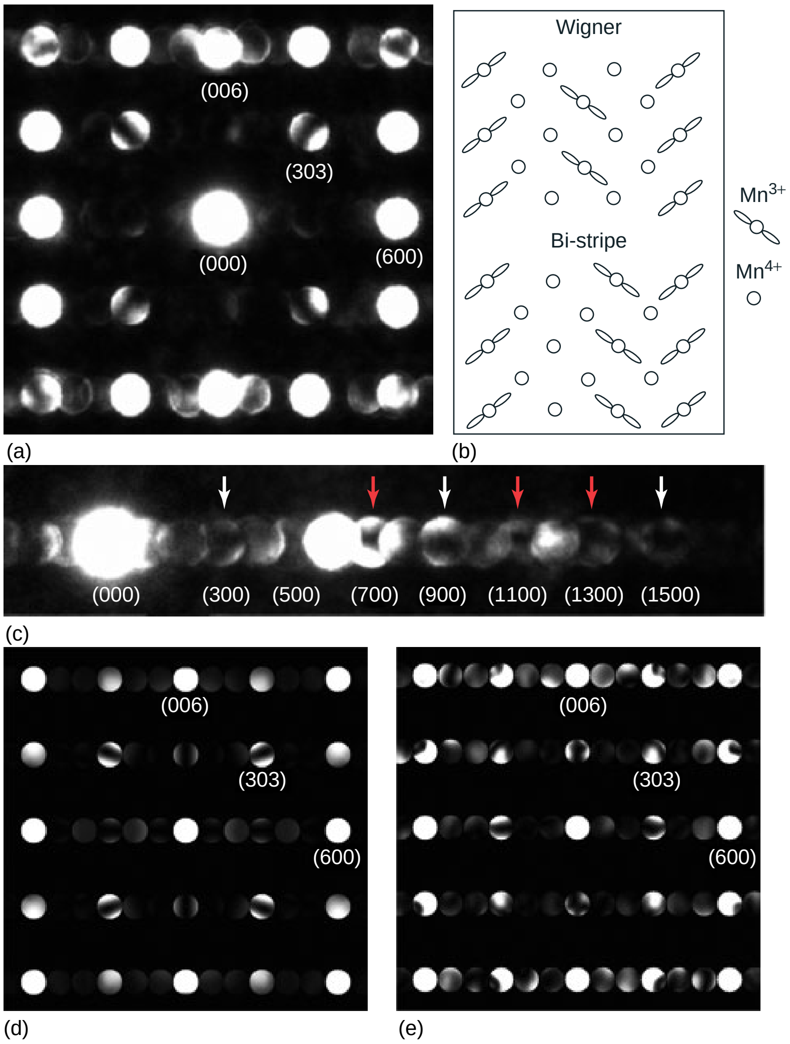

Figure 15 Symmetry identification of low-temperature charge-ordered $La_{0.33}Ca_{0.66}MnO_3$. (a) the experimental CBED pattern from a single crystal domain in $La_{0.33}Ca_{0.67}MnO_3$ recorded at ~99 K and along the [010] zone axis. (b) schematic illustration of charge ordering models. (c) the line extinction across a series of odd-indexed reflections along the reciprocal $\vec{a}^*$ direction in the experimental pattern. (d) and (e) Simulated CBED patterns from the CO structures described by the ''Wigner-crystal'' and ''Bi-stripe'' models (b) for the thickness of 300 nm

intensity of $\pm g$ disks which comes from lack of Friedel's symmetry from dynamic scattering. The difference between $\pm g$ is first calculated based on the known structural model and atomic potentials including dynamic scattering, and is then compared with experiment for polarity determination. The comparison is usually performed for the whole diffraction pattern with crystal thickness determined simultaneously. Crystal thickness can be determined accurately using this method because the intensity pattern in CBED is very sensitive to thickness and the atomic potentials available in publication are good approximations of the real crystal potential.
